An internal diagram of the North East model "O" ignition system, as used on the Dodge, is shown in Fig. 5. The primary circuit is from the battery when the generator is running slow or not running at all, or from the generator when it is running at sufficient speed to generate a voltage higher than the battery. Note that the generator is at 12 volts, and so also is the battery; therefore the ignition is a 12-volt grounded system.

The primary ignition circuit is from the (+) side of the ignition and lighting switch (IG), to the primary terminal on top of the coil, through the primary winding, to the movable contact arm on the interrupter, or breaker-box, through the points, out through the stationary contact to ground, thence to ground of battery (G2), or generator (G1), thus completing the primary circuit.

The secondary ignition circuit is from secondary terminal on the side of the coil, to the center terminal of the distributor, to the spark plugs through the revolving "rotor," through the spark-plug electrode, through the gap to the engine, through ground of the engine, to ground of the coil, to the grounded secondary terminal.

Note that a safety gap is shunted across the secondary circuit, so that if a spark-plug terminal comes loose, the spark will jump from the secondary terminal at the side of the coil to ground; thus it is shunted. This gap is slightly wider than the spark-plug gap, and thus the secondary circuit will always go to the spark plugs without jumping, unless the spark-plug gap is wider than the safety gap. The spark-plug gap should be set to .030".

The North East model "O" ignition unit (Fig. 6) consists of a shaft with a coupling yoke for driving the distributor and interrupter. The coupling yoke is connected with the pump shaft. The distributor shaft is driven at one-half the speed of the crank shaft; that is, while the crank shaft completes two revolutions the distributor shaft completes one revolution.

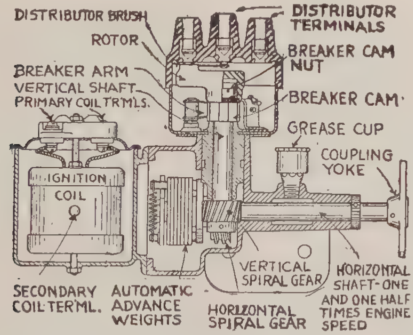

Fig. 6. North East model "O" ignition unit on the Dodge.

The distributor is advanced by an "automatic" arrangement, and by a "manual" control connected with the spark lever on the steering wheel.

The ignition coil is attached to the unit at the left, and **the condenser** is in the interrupter or contact-breaker housing. The interrupter is a "closed-circuit" type. By referring to the illustration, the names of the several parts will be found.

Adjusting the North East (Dodge) Contact Breaker

Always turn off the ignition switch when adjusting or testing any part of the ignition.

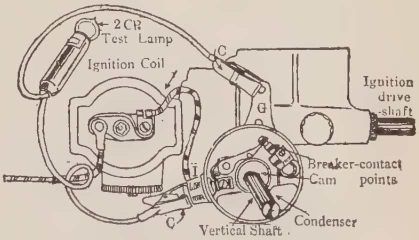

Fig. 7. Adjusting the contact-breaker points.

To adjust breaker-contact points: (1) Turn the vertical distributor shaft (Fig. 7) until one of the lobes of the breaker cam comes against the fiber block or breaker-arm so that it pushes the breaker-arm back to the limit of its normal movement. Be sure that the contact points are separated the full distance. (2) Back off the contact-breaker stud lock-nut sufficiently to release the contact stud. (3) After loosening, use a thickness gauge between the points and adjust to .020" when the points are fully separated. (4) Tighten the lock-nuts, and after the stud has been locked in the new position, check the gap once more to make sure that no alteration occurred during the locking process.

If contact points are pitted use an oil stone, as explained on page 225.

If contact points are renewed, replace both the stationary contact stud and the breaker-arm assembly. After assembling, hold a piece of white paper behind the contact points to serve as a light background and sight between them and see if they meet evenly over their entire surface. If not, bend or twist the breaker arm slightly until they are brought into correct relationship.

Timing the Ignition

If the coupling yoke (Fig. 6) attached to the shaft driving the ignition mechanism is disconnected from the pump-shaft yoke which drives it, note the position of the distributor rotor and the two halves of the coupling, and mark it carefully. If this is not done at time of removal, it will be necessary to time the ignition assembly as follows:

1. **Turn off** the ignition switch.

2. **Attach the ignition driving-shaft coupling** to the pump-shaft coupling.

3. **Crank the engine** until the position of No. 1 cylinder has reached dead center of its compression stroke and has passed 8 engine degrees beyond it.

A good way to tell this is to watch the exhaust valve on No. 4 cylinder. This valve should be just on the point of closing when No. 1 piston is approximately 8 engine degrees beyond the dead center of its compression stroke. See pages 70, 307 for methods of finding the compression stroke. The best plan is to remove the cylinder head to expose the pistons.

4. **Shift the breaker-box** to full retard position.

5. **Remove the distributor-head** or cap, and the distributor rotor arm.

6. With a broad-bladed screwdriver, **back off the breaker-cam nut** one or two turns, so that the cam can be turned free of its shaft on which it is set.

7. **Place the rotor-arm temporarily on the distributor-shaft** and turn it in a clockwise direction

---

[1] By courtesy and permission of the North East Co., Rochester, N.Y.

until the rotor is in position where it would normally make contact with No. 1 distributor terminal. The breaker-contacts should then be fully separated.

8. **Turn the cam back carefully a short distance,** until the cam lobe permits the points to come together again; then turn it back to the correct position. This action will allow for any slack in the gears. Lock the cam lock-nut.

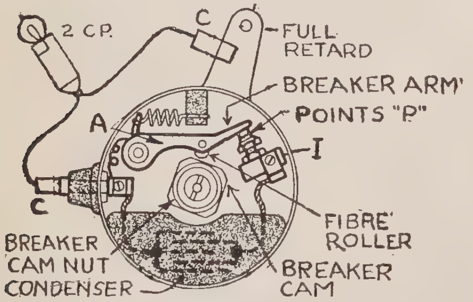

Fig. 8. To tell when the contact-breaker points open, use a 2 c.p. lamp bulb, as shown.

9. **Place a 14 to 16-volt 2-candle power test lamp across the contact-breaker circuit** (Fig. 8), by placing one clamp (C) of the test light to the binding post and the other clamp to the frame of the breaker-box, as this is a grounded system. The wires from the coil, etc., are not disconnected; the ignition switch, however, is off during this time. The purpose of the light is to enable one to tell the instant the contact points separate, because the opening of the points occurs so rapidly that it is difficult otherwise to tell, and this insures correct adjustment.

10. **Turn on the ignition switch.** Replace the distributor rotor again and verify the cam setting which has been made, by rocking the distributor shaft backward and forward as far as the slack in the gears permits. The lamp will light the moment the contacts begin to separate, and will go out the moment they come together. Note that the lamp is in series with the circuit when the contact points are opened.

Note. This is a good timing test for other ignition systems. If, however, there are two binding posts or terminals on the contact-breaker, then the test-light clamps (C) would be attached to each.

It is very important that the timing be exact, because the speed of the engine crank shaft is twice as great as the vertical distributor shaft, and inaccuracy in setting will produce a doubly magnified effect upon the operation of the engine.

The spark-plug air-gap on the Dodge is 1/32", or about the thickness of a smooth dime.

Lubrication of Ignition Mechanism

The automatic advance mechanism (Fig. 6) is lubricated by grease in this compartment. The original grease should last for several seasons. If renewed, it should have not over 3 cubic inches and grease to correspond with No. 4 Keystone grease.

The horizontal shaft is supplied with grease from the automatic compartment and also from the grease cup shown in Fig. 6. This grease cup should receive attention every few thousand miles.

Cut-Out Adjustments: N. E. Model 8100 Used on the Dodge

The air gap space at the carbon blocks of the cut-out (P), when separated (Fig. 5; see also Figs. 9 and 9A), must be .030"; the air-gap between the small copper button or the under side of the cut-out armature and the upper end of the iron core about which coils are wound, should be approximately .020".

The contact blocks (656, Fig. 9A) should be in perfect vertical alignment and the carbon blocks should be parallel. If they are not, bend with long-nosed pliers.

Inspect adjustment of the cut-out contact points by holding them up to the light, being careful to make sure that it is correct.

After aligning properly, then measure the air-gap. If it is not enough, bend the stop away from the armature slightly. If there is too much air gap, bend down.

Cut-out closes: The starter-generator should be showing 14.5 volts on test when connected with the battery through the cut-out.

The cut-out armature (A, Fig. 5, or 2168, Fig. 9A), should close at this voltage.[1] If it does not, alter the spring tension (2184, Fig. 9A).

The spring tension can be lessened by spreading apart one or two of the spring turns, or by bending down the portion of the armature spring plate that extends back beyond the iron body of the armature.

The spring tension can be increased by forcing together the separated turns, or by bending up the armature blade. Flat-nose pliers are handy for these adjustments.

Cut-out opens: As soon as the cut-out has been set to close the charging circuit when the voltage is 14.5, then check the adjustment by reducing the starter-generator speed to 500 or 600 r.p.m., and then raise it again gradually until the cut-out closes. In making this test, note the voltage carefully as registered on the voltmeter at the instant when the cut-out closes, and if found other than 14.5 volts when it closes, adjust to that voltage.

After adjusting for the closing point as just described, then adjust for the opening point as follows: Speed the generator up to 1,500 or 1,600 r.p.m.; then reduce speed gradually until the cut-out contacts open. Watch the ammeter[2] at the moment when the cut-out breaks the charging circuit, and note closely the amount of discharge current that is required to cause the cut-out to open. This discharge back through the cut-out reverse-current coil from the battery should not exceed 1 ampere. If more than 1 ampere, investigate the cause. This discharge is the reverse current flowing from the battery back to the generator in an opposite direction. It thus demagnetizes the iron core.

Too high a discharge current is due to: too great air-gap at the cut-out armature core at (A) (Fig. 5), or cut-out series coil (S) (Fig. 5) is short-circuited.

North East Cut-Out Winding Tests

To test for a cut-out ground: Hold one test lead (110 or 220-volt lamp and leads) on cover 8107 (Figs. 9 and 9A) and touch binding post No. 3, and then No 4. If the lamp lights, there is a ground. (The internal diagram of this cut is shown in Fig. 5.)

---

[1] A voltmeter is connected across the circuit leading to the cut-out, say, at the (+) terminal of the generator, or at terminal 1 of the cut-out and ground.

[2] The ammeter is shown in circuit in Fig. 5. Check it with a test ammeter to see if it indicates correctly. If not, connect in the "test ammeter" instead.

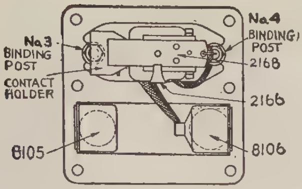

Fig. 9. Top view of cut-out.

To test for an open circuit in the shunt winding (coil **V**, Fig. 5) of the cut-out: Place one test lead on terminal No. 4 and the other on No. 1 (Figs. 9 and 9**A**). If the circuit is complete through the shunt coil, the lamp will light dimly and the cut-out armature will be drawn against the core; if an open circuit exists, the lamps will fail to light, and the cut-out armature will not respond.

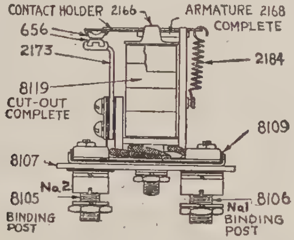

Fig. 9**A**. Side view of cut-out.

To test for an open circuit in the cut-out (see also **S**, Fig. 5) **series coil:** Place one test lead on No. 1 binding post and the other on No. 3, and close the contacts (656) by hand. If the normal circuits are complete, the test lamp will light the moment the contacts are closed.

To test for a short circuit between the cut-out shunt (V) and the series (S) coil: Place one test lead on No. 1 binding post, and the other on No. 4. If the circuits are normal, the test lamp will burn dimly; but if a short circuit exists between the coils, the lamp will burn with full brilliancy.

To test for a short circuit between the cut-out contact points on the contact bracket and cut-out frame: Place one test lead on No. 1 binding post and the other against No. 3 binding post, but do not close the cut-out contacts. If a short circuit exists, the lamps will light, even though the cut-out contacts are not closed.

To "Run In" Brushes on North East Motor-Generator

Use only North East brushes, as they are specially made and are necessary. Never transpose the third brush for a main brush.

The main brushes composed of copper graphite mixture and heavy, are copper-colored and partly copper-plated. The third brush, made of graphite only, is lighter, and is black and uncoated.

Brushes should be run-in if new ones are fitted or if old ones are resurfaced.

To "run-in" brushes: Connect the starter-generator with a battery of the proper rated voltage (a 12-volt battery is to be used with a 12-volt machine), and allow the machine to run free at a high speed for twenty or thirty minutes. The requisite high speed can be obtained by temporarily converting the machine into a plain series motor. This can be done readily by removing the fuse so as to open the shunt-field circuit. In the case of the type 3554 starter-generator, which has no fuse, the shunt-field circuit can be opened by disconnecting the pigtail from the third brush.

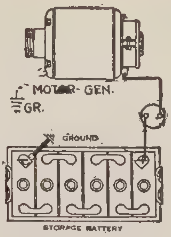

Fig. 10. Motor-generator run as a motor to "run-in" the brushes.

This applies to other makes also, except that in case of a 6-volt system a 6-volt battery should be used.

The "running in" process must be continued until the entire surface of all three brushes has become sufficiently concave to fit the commutator. Fine (No. 00) sandpaper, never emery paper, may be used, if desired, to hasten the process; but if this is done, care must be exercised to avoid rounding the edges of the brushes, or otherwise modifying their working surfaces. As soon as the brushes have become completely fitted to the commutator, the charging rate should be measured carefully, and if it is found to be at variance with the standard rate given in the table on page 375, it should be readjusted to the correct value in accordance with the directions given in the preceding section. The output variations, due to changes in the battery c.e.m.f., must always be borne in mind when the charging rate is to be measured or adjusted.

The commutator should be examined whenever new brushes have been found to be necessary, because its possibly roughened condition may have been responsible for the brush difficulty. If the commutator should be found to be in a roughened or burned state, it should be carefully resurfaced, and, if necessary, undercut. See Index under "Commutators, undercutting of."

Removing and Replacing Chain

1. Remove housing enclosing the starter-generator pinion.

2. Turn engine over until master link is exposed.

3. Break the master link and attach both ends of the new chain to the old chain.

4. Crank the engine over until the new chain is in place, when the old one may be removed and the master link of the new chain may be closed.

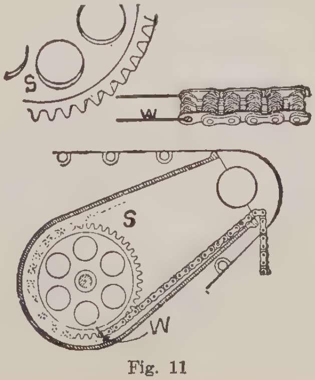

Fig. 11

Another method: (1) Pass a short piece of wire through the end of the chain and bend it into the form of a staple.

(2) start the chain on the lower side of the sprocket (S) (Fig. 11). Hook the wire (W) through the sprocket to keep the chain in mesh and turn the engine with the starting crank unit until the end of the chain appears at the top of the sprocket. Remove the wire from the sprocket, hold the end of the chain and continue to turn the engine until the chain is in position for applying the master link.

Chain-driven starting motors and generators should have the chain kept lubricated and adjusted, but the chain should never be adjusted too tightly.

Chain Adjustment

To obtain the proper adjustment for quiet running of the chain, proceed as follows:

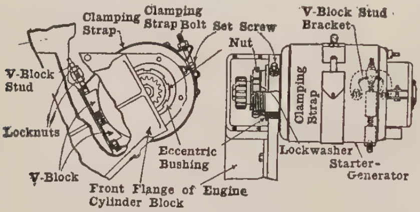

Fig. 12

Loosen the set screw and lock nut on the edge of the front flange of the cylinder block, and back off the starter binding nut, just enough to remove the pressure from the adjusting ring. Loosen the "V" blocks and strap to allow the starter-generator to move. This will allow the eccentric adjusting ring to be turned until the required play in the chain is obtained. There should be about one-half inch up-and-down movement in the chain. After the proper adjustment has been made, be sure that the set screw, lock nut, and binding nut are screwed up tightly. See that the chain tension has not been disturbed while performing this last operation.

Carefully adjust "V" blocks up snug between the engine and the starter-generator, and then tighten the holding strap. After the inspection cover has been replaced, the chain should run without perceptible noise. It is lubricated by its dipping into the oil in the bottom of the front gear compartment, thus needing no further attention after it has been properly adjusted.

Removing Armature

1. Remove the four nuts on the sprocket-end of the generator and pull the drive-end housing off with the armature.

2. Undo the pinion sprocket nut and lockwasher and pull the pinion off.

3. The armature can now be removed.

4. Remove the four screws holding the retaining plate after which the ball bearing, crimped spacer, and cork packing washer can be driven out. The front armature bearing is lubricated automatically from the chain.

Adjusting Charging Rate of North East Model "G" Motor-Generator

Adjusting the charging rate: Run the starter-generator at a speed to deliver its maximum output, which is 1,775 and 1,825 r.p.m.

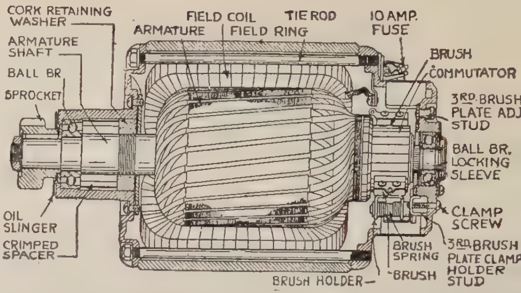

Fig. 13. Sectional view and name of parts of North East model "G" motor-generator.

The charging rate should never be set lower than 4 amperes, nor higher than 10 amperes. The adjustment is made by shifting the third brush (Fig. 15) with respect to the main brush and its maximum capacity is 12 amperes. Moving the third brush in a clockwise direction (Fig. 15 shows the commutator end-view) will **reduce** the charging rate. A counter-clockwise movement will **increase**[1] the rate. A speed of 1,800 r.p.m. of the generator on a Dodge represents about 600 r.p.m. of the engine. The average setting is for about 8 or 8½ amperes.

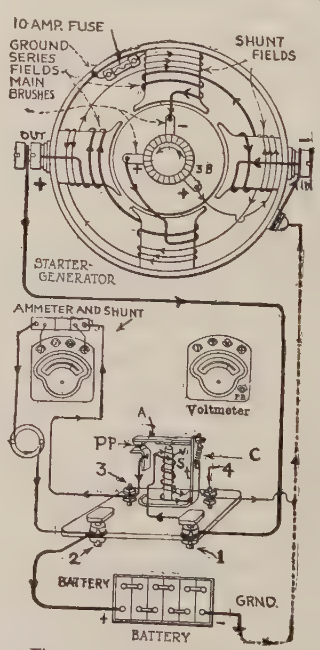

Fig. 14. Method of testing.

A test made on the car can be carried out as shown in Fig. 14 Use an ammeter reading to 30 amperes, and connect as shown, or attach between the starter-generator (+) binding post and the lead normally attached to it. If this is done, short-circuit the instrument while starting the engine, as a heavy starting current would burn it out.

---

[1] This may appear to conflict with the statement, formerly made, that to increase the charging rate, the third brush should be moved away from the main brush which is connected to the shunt field-windings. However, in the case of this 4-pole machine, another (−) main brush could be placed opposite to the one shown, that is, on the bottom of the commutator, and connected to the shunt field-windings (grounded). Therefore, by moving the third brush counter-clockwise in this instance, we should increase the charging rate because we would then be moving it away from its closest main brush. Refer to Fig. 15 and note that the commutator is turning in a counter-clockwise direction, and the third brush is shifted with the direction of rotation of the commutator to increase the output.

Connect a voltmeter (reading to 20 volts) across the starter-generator binding posts.

Compare the current and voltage readings obtained at a constant speed of 1,800 r.p.m. in accordance with the table below.

There are **certain slight variations in the output due to changes in the battery counter-electromotive force** (c.e.m.f.), which must be taken into consideration whenever the charging rate is being investigated. The variations have been tabulated below for battery voltage variations from 12 to 16 volts, the speed of the generator having been considered constant at 1,800 r.p.m. throughout.

An illustration as to how the charging rate is influenced by changes in the battery c.e.m.f. is as follows: Let us assume that a 6-cell, 12-volt battery, which has become entirely exhausted, is placed on charge by connecting it in the usual manner to a model "G" starter-generator driven at a constant speed of 1,800 r.p.m. At the beginning, while the battery is in a discharged condition, it will have a relatively low c.e.m.f., which, in this instance, we will assume to be 12 volts. The charging rate of a normal starter-generator supplying current at this voltage will accordingly be 5.5 amperes.

Variations in Charging Rate Due to Changes in Battery C. E. M. F.

Charging Rate	Battery C. E. M. F. *(Starter-generator Terminal E. M. F.)	Starter-generator
AMPERES	VOLTS	R. P. M.
5.5	12	1800
6	13	1800
Normal 6.5	14	1800
Setting 7	15	1800
7.5	16	1800

*The battery c.e.m.f. (counter-electro-motive force) and the starter-generator terminal e.m.f. (electro-motive-force) are virtually equivalent under normal operating conditions, and may accordingly be considered as identical in ordinary tests. The voltage readings should always be taken across the positive (+) and the negative (−) generator binding posts.

If, however, the battery is allowed to remain on charge 7 or 8 hours, its c.e.m.f. will rise gradually until a final high value of 15 or 16 volts is reached.

This rise in the battery c.e.m.f. will naturally result in a corresponding increase in the generator charging rate. Assuming that the battery c.e.m.f. has now risen to its highest value, 16 volts, the charging rate, as indicated by the table, will have become 7.5 amperes. At intermediate points, between charged and discharged conditions, similar variations in the charging rate will occur, in accordance with the value of the particular battery c.e.m.f. which exists at the points considered.

From this it is obvious that both voltage and speed readings, as well as current readings, must be taken whenever the charging rate of a model "G" starter-generator under test is to be compared with the established standard. Current readings alone cannot be depended upon as an accurate indication of the charging rate, because of this modifying effect of the battery c.e.m.f.

Do not increase the charging rate above a maximum of 10 amperes at a battery c.e.m.f. of 15 volts.

Do not reduce the rate below a maximum of 4 amperes at a battery c.e.m.f. of 15 volts.

To Increase or Decrease Charging Rate on Model "G" North East Motor-Generator

To increase the charging rate: Turn the adjusting pinion stud (8035, Fig. 15) slowly in a clockwise[1] direction until the ammeter indicates that the desired value of the charging rate has been obtained.

If it is ever impossible to raise the charging rate to the desired value in this way, the special measures listed below are recommended.

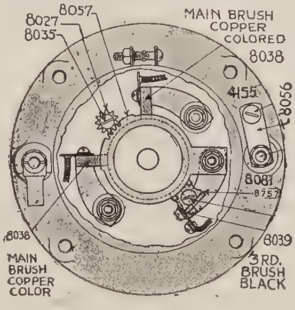

Fig. 15. End view of the N.E. motor generator, showing the commutator end. The commutator revolves counter-clockwise.

1. Increase the range of adjustment by filing an extra notch in the third brush-holder plate, taking care not to increase the range to such an extent that the third and main brush-holders are allowed to come in contact with each other.

2. Where the extra notch is impracticable or inadequate, the original third brush-holder (No. 8060-A) should be replaced by the later style brush-holder (No. 9599).

3. Should (1) and (2) ever prove inadequate, it is advisable to remove the armature and replace it by another. If the new armature gives the desired results, it may be assumed that some irregularity is in the original armature and it should be sent to the nearest North East branch for adjustment.

Do not increase the rate above a maximum value of 10 amperes at a battery c.e.m.f. of 15 volts.

To reduce the charging rate: Turn the adjusting pinion stud (8035) slowly in a counter-clockwise direction until the charging rate has been cut down as far as desired.

Do not reduce the rate below a maximum of 4 amperes at a battery c.e.m.f. of 15 volts.

Always bear in mind, when adjusting the charging rate, that the output variation due to changing battery c.e.m.f. forms an important factor in the accurate setting of the rate. By overlooking this point an error may be introduced into the setting, which can easily be serious enough to bring about the development of future battery trouble.

As soon as the proper brush position has been found, lock the third brush-plate by tightening the clamp screw. Then note once more the ammeter and voltmeter readings, to make certain that the adjustment has not been disturbed by the locking operation.

Before considering the work finished, run the starter-generator for fifteen or twenty minutes at varying speeds to make sure that the new setting for the third brush is permanent and accurate. Also make a general examination of the machine to see that no other parts have been disturbed while the charging rate adjustment was being made.

In every instance where the charging rate has been altered from its normal value for the purpose of meeting special service requirements, a close watch should be kept on the condition of the battery, and any tendency toward undercharge or overcharge should be corrected at once by further readjustment of the charging rate. Moreover, if cars with specially adjusted starter-generators are transferred back again into normal service at any time, the charging rate should be changed accordingly to the regular setting. If this readjustment is not made, possible injury may be caused to the battery.

---

[1] The starter-generator is here considered as viewed from the commutator-end. Turning the pinion in a clockwise direction will cause the third brush-plate to move in a counter-clockwise direction, and, vice versa, turning the pinion in a counter-clockwise direction will cause the plate to move in a clockwise direction.

North East Instructions for Disconnecting Battery from Model "G" Motor-Generator

If the battery is disconnected without proper precaution, or if there is an open circuit in the charging circuit of the generator and battery, and the generator is driven at a speed which will permit the generator voltage to rise, it will reach an abnormal value which will injure the commutator and the brushes, and even the field coils, if allowed to continue for any considerable period of time.

To serve as a protection in such an emergency, a "fuse," designed to "blow" as soon as the generated voltage reaches an injurious value, is included in the shunt-field circuit and is mounted on the outside of the commutator end housing. With a "blown" or removed fuse the motor-generator is incapable of producing electricity, because of the shunt-field circuit being open. Thus the motor-generator can be run without injury.

If the battery should be disconnected and the motor-generator is to be operated, remove the fuse. If the machine is of the type not equipped with a fuse, then connect the positive binding post to the negative binding post, by means of a piece of clean copper wire, not smaller than No. 18 B. & S. gauge.

As soon as the battery is replaced, be sure and install the fuse again, and the short-circuiting wire must be removed. As long as the fuse is left out, the generator cannot charge the battery, and if the short-circuiting wire is left in place, the generator will be completely short-circuited.

If the charging circuit is broken elsewhere than at the battery, the motor-generator will be subjected to the same detrimental conditions as described. Thus an open circuit in the charging indicator, or at the terminals of the motor-generator, or in the car wiring, will under ordinary circumstances cause serious trouble. Likewise, if the reverse-current cut-out is prevented from functioning properly by an open circuit in its voltage shunt coil, or in the ground, or in the ground wire from that coil to the car frame, the effect will be equivalent to a break in the charging circuit proper.

The same results, moreover, in the case of the type 3554 machine only, can be produced by an open circuit at the ground strap. In all other model "G" motor-generators, however, an open circuit at this point will cause no actual damage, but will simply prevent the machine from generating, because of the fact that the shunt-field circuit will be open as well as the charging circuit.

The ground strap, which forms not only a section of the charging circuit, but also of the starting circuit, must always be kept in good electrical contact with the motor-generator frame.

In case it is necessary to operate the equipment with the charging indicator (current type) removed from the circuit, the wires normally attached to its two binding posts should all be connected together until the indicator is again placed in circuit.

Shunt Field Fuse

The fuse (Fig. 5), located on the outside of the commutator-end housing of the starter-generator, is inserted in the shunt-field circuit, and is designed to blow if the battery circuit is opened, thus protecting the system by rendering the starter-generat inoperative.

Therefore, if the machine fails to charge the ba tery at any time, inspect the fuse first of all; anc in case it is found blown, replace it with a new one If the new fuse in turn blows as soon as the machin is started up, make a careful search for the cause c the trouble before running the generator again.

Adjustments and Tests of North East Model "G" Starter-Generator

To test for a ground: Remove the ground-stra screw and bend the ground strap away from th housing and remove the fuse (see Fig. 5; also Fig 16). Then, using the ordinary 110-volt test lead (see Index for "Test leads" or "Test light"), hol one lead against the starter-generator field ring anc touch either the positive (+) or the negative (– binding posts with the other. If a ground is present the test lamp will light.

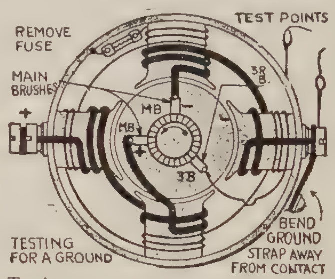

Fig. 16. Testing motor-generator windings for grounds and open circuits, test points, and light.

To localize a ground in the armature: Insert slips of paper between all three brushes (**MB**, **3B**) and the commutator to insulate the commutator and the armature from the rest of the machine. Hold one test lead against the armature shaft and touch the commutator with the other. If there is a ground, the test lamp will light.

To localize a ground in the brushes or field coils: With the brushes insulated from the commutator and the fuse removed, hold one test lead against the positive (+) binding post and touch the field ring with the other. If the test lamp does not light, the two-series field coils between the positive (+) binding post and the positive main brush (**MB**+) may be considered free from grounds.

Next, hold one test lead against the negative (–) binding post and touch the field ring with the other. If the test lamp does not light, it may be assumed that the two-series field coils in the negative half of the machine (top and right-field poles, Fig. 16) are free from grounds.

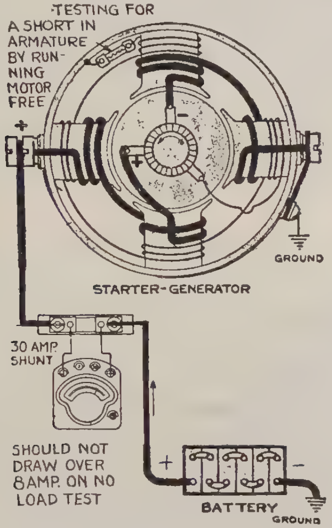
Finally, hold one test lead against the third brush (3B) and touch the field ring with the other. If the test lamp does not light, the shunt-field coils may also be considered free from grounds.

To test for an open circuit in the armature, the brushes or the series field coils: Disconnect the ground strap and remove the fuse. Hold one test lead against the positive (+) binding post, the other against the negative (–) binding post. The test lamp will light only if the circuit is complete.

To test for an open circuit in the shunt field coils: Leave the ground strap disconnected, but replace the fuse, and insulate the third brush (3B) from the commutator. Hold one test lead against one of the fuse clips and touch the third brush (3B) with the other. An open circuit in the shunt-field coils will be indicated if the test lamps fail to light.

To make sure that the open circuit is not in the fuse rather than in the coils, remove the fuse and test it by holding one test lead against each end.

To test for a short circuit, between the shunt and series field coils: Insulate the third brush (3B) from the commutator, remove the fuse, and test between the third brush (3B) and either binding post. A short circuit between these coils will cause the test lamp to light.



TESTING FOR A SHORT IN ARMATURE BY RUNNING MOTOR FREE
+
GROUND
STARTER-GENERATOR
30 AMP. SHUNT
SHOULD NOT DRAW OVER 8AMP. ON NO LOAD TEST
+
−
BATTERY
GROUND

Fig. 17. Testing N.E. motor-generator armature for short circuits.

To test for a short circuit in the armature: Connect an ammeter (20 or 30-ampere range) in the starting circuit (Fig. 17), and allow the machine to run free as a motor with no load. Note carefully the amount of current required to drive the machine as a motor. A normal 12-volt starter-generator will not draw over 8 amperes from a 12-volt battery when tested in this way. As a matter of fact the current drawn by the average machine when tested in this way is generally about 5 amperes. An ammeter reading of more than 8 amperes should be considered as evidence of a short-circuited armature, provided the machine is free from mechanical difficulties.

Note. The ammeter shown connected is the Weston model 280, used in connection with a 30-ampere shunt, explained under "Ammeters" (see Index).

Directions for Assembling the Sprocket-End Housing-Models "G," North East Motor-Generators

The construction of the housing, No. 8003, used on all model "G" machines is shown in Fig. 18. This shows how the oil is kept from the interior of the generator.

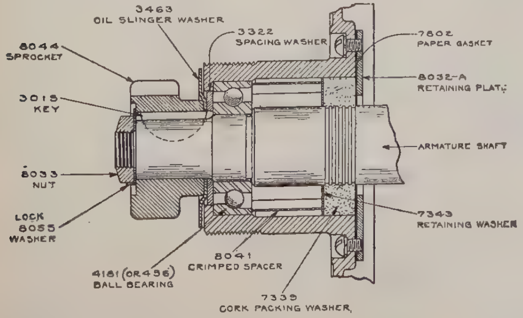


Fig. 18. Showing how oil is kept from the interior of the N.E. motor-generator.

It is ordinarily assembled as follows:

1. Insert the ball bearing (4181 separable type, or 456 annular type) in the housing.

2. Put in the crimped spacer (8041) and its retaining washer (7343).

3. Press the cork packing-washer (7339) into position, and lubricate its inner surface, where it will come into contact with the armature shaft, with a small amount of graphite grease. Whenever a cork washer has been damaged by removing it from the housing or is found to have become worn so that it no longer fits the shaft tightly, it must always be replaced by a new one. A cork packing-washer that is not in practically perfect condition cannot be relied upon to prevent the entrance of oil into the interior of the machine, and should, therefore, never be used.

Early Model North East Motor-Generators and Electric Systems Used on the Dodge

The North East system described on pages 367, 369 is the standard model "G" used on the Dodge since the fall of 1916, with slight internal modifications. For ignition, the Dodge has used the high-tension magneto and also the Delco ignition system, and since March, 1918, the North East model "O" system has been used, as shown in Fig. 5, page 369.

On the 1915 and early 1916 cars, the model "D" electric system (Figs. 19 and 21) were used. With this system a cut-out and regulator were contained in the starter-generator unit (this can be determined when there are four terminals on the starter-generator; see Fig. 23).

The model "G" system (page 369), differs from all previous models in that it has a third-brush regulation instead of an electromagnetic type regulator, shown in Fig. 23, which formed a part of all preceding North East models. The cut-out, however, is retained, but it is now enclosed in the housing with starting switch (pages 368, 369), instead of in the generator itself. There is, therefore, only one connection to the starter-generator and one grounded terminal.

—*Continued from page 377.*

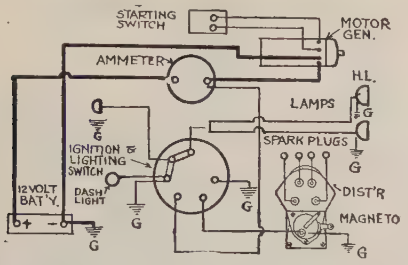

Fig. 22. Early 1916 Dodge-North East electric system with magneto ignition. Note the four terminals on the motor-generator.

This system differs from the one in Fig. 19, in that two wires are used from the motor-generator to the battery instead of a single wire. The internal connections of the model "D" four-pole North East motor-generator are shown in Fig. 23.

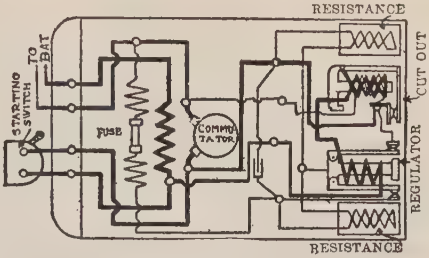

Fig. 23. The four-terminal North East model "D" motor-generator, used on the 1915 and early 1916 Dodge. The diagram shows the internal circuit of the motor-generator. A regulator of the electro-magnetic type with resistance which was cut into the shunt-field circuit at high speeds was used for regulating the output of the generator instead of a third brush. The regulator and cut-out are inside of the motor-generator.

SIMMS-HUFF SIX-POLE MOTOR-GENERATORS

Simms-Huff Type "HM" Motor-Generator

The Simms-Huff motor-generators are of the six-pole type. They are all designed essentially on the same principle, but differ in construction, as will be explained.

An example of a six-pole motor-generator compound-wound, with an electromagnetic shunt-field regulation, is shown in Fig. 1 as used on the 1918 Maxwell with a 12-volt battery, generator, and motor.

Field poles: There are six field poles with "shunt" winding on all. Three of the field poles have "series" windings, connected in "series-parallel."

Motor Circuit

Motor circuit (see arrow points on the outside of the wires): From (+) of the battery, to starting switch (**SC**), through switch to (**A+**) of the motor-generator, which is connected with the (+) ring bar, to the (+) brushes, through the armature, out the (−) brushes to the three series-field coils on poles 5, 1, and 3, to grounds on field poles (G5), (G1), and (G3), to the (−) ground of the battery.

Shunt-field circuit during motor operation is from (**A+**), through wire (**W1**), through the shunt-field fuse, to (**C1**), through regulator blade (**F**), through closed regulator points, to (**R2**), through wire (**W2**), to (**T**), through shunt-field windings 4, 5, 6, 1, 2, 3, to ground (**G1**), to the (−) ground of the battery.

Note that the current flow from the battery during the motor operation is in the same direction around the "shunt" and "series" field windings (see arrow points on the outside of the wires—not on the wires; the arrow points on the wires are the generator path). Thus it would be termed "cumulative action," where they assist each other to build up a strong magnetic field from N to S poles.

Switch-lock circuit: Before the starting switch was closed to operate as a motor, the lock button was pressed, which caused pin (**P**) to raise so that switch rod (**R**) could be moved. The circuit was then from (+) of the battery, through the button, through the electro-magnet or solenoid coil (**C**), to (**X**), through the motor-generator, to (−) ground of the battery. Note that switch circuit (**SC**) is open when this operation takes place, and the purpose of this switch lock is to prevent the starting

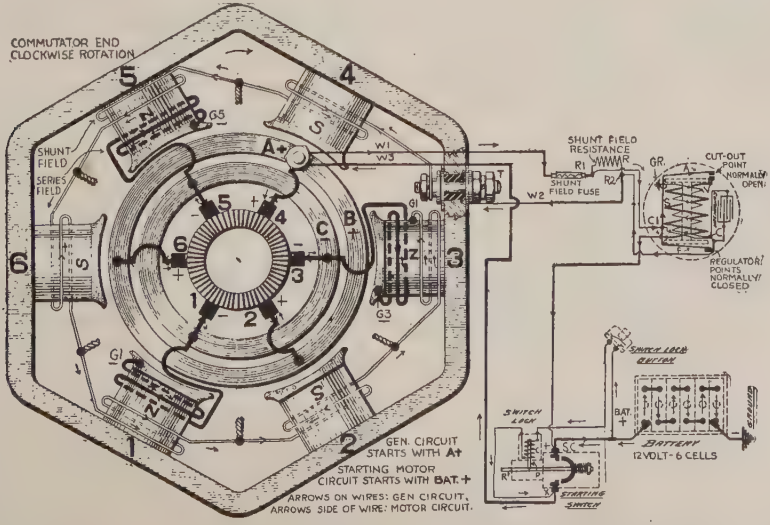

Fig. 1. Simms-Huff type "HM" motor-generator, with six field-poles. A 12-volt system with shunt field-resistance regulation.

switch from being depressed until the pin (P) is raised by the electro-magnet coil (C).

Generator Circuit

The shunt-field circuit is from (A+), to (R1), to (C1), through regulator points, to (R2), to (T), to the other end of the shunt-field winding which is grounded on pole 3 at (G1), through ground of the series coil at (G3), to (−) brush (3), through the armature, to the (A+) ring.

Cut-out voltage circuit: From (A+), to (R1), to (C1), to (C), through voltage winding (V), to ground (GR), to the (−) ground of battery. When the generator voltage is higher than that of the battery, this winding has sufficient voltage to exert sufficient magnetic influence to cause the cut-out core to draw blade (A) and close cut-out points (P).

Charging circuit: From generator (A+), to (R1), to (C1), up side of cut-out, to points (P), through cut-out armature blade (A) (supposed now to be closed), through cut-out current windings (S), to (SC) on the starter switch, to (+) of the battery, to (−) ground of the battery, to grounded series field coils (G1, G3, G5), to (−) brushes (1, 3, 5).

Note that the current flow around the "shunt" and "series" field is in opposite directions when used as a generator (see arrow points on the wires). Thus a "differential action" or "bucking" effect, where they oppose each other, is produced. The shunt field governs the polarity of the poles.

Shunt-Field Regulation; Electromagnetic Principle

Regulation is by means of an electromagnetic principle. Note the regulator points at the bottom of the cut-out core. The heavy winding (S) controls the opening of the regulator points, and is therefore a "constant current" regulator. Note that one set of windings serves for a cut-out and regulator.

At high speeds when the voltage and amperage rise rapidly, the maximum amperage is kept from rising above 7.5 amperes by the regulator.

Regulator action at high speeds: When the charging current passes through the series winding (S) of the cut-out and regulator, the regulator points are closed unless the current passing through this coil (S) is more than 7.5 amperes (1,700 r.p.m.). If so, it exerts sufficient magnetic strength to pull regulator blade (F) to the core, thus opening the points.

This action cuts in "resistance" (R) into the shunt-field circuit, and the circuit would be from (A+), to (R1), through resistance (R), to (R2) (because the points of the regulator are now open), to (T), to the shunt-field winding, thus cutting down the lines-of-force or strength of the shunt field, and consequently keeping the current below 8 amperes. During variations of speeds the regulator vibrator vibrates rapidly, opening and closing the shunt-field circuit.

Simms-Huff Model "SMS2" Motor-Generator—a 12-Volt System

Simms-Huff six-pole motor-generator, compound wound, model "SMS2," used on the 1919 Maxwell, using a "third brush for regulation" instead of an external electromagnetic regulator as in Fig. 1, is shown in Fig. 2. This is a straight 12-volt system.

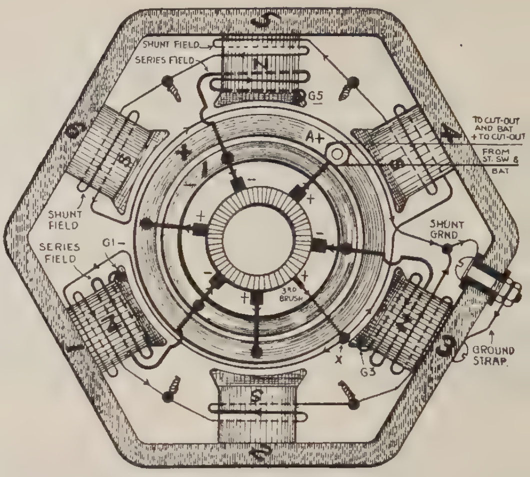

Fig. 2. Simms-Huff six-pole type "SMS2" motor-generator with third-brush regulation (1919 model). A 12-volt system.

The motor principle is similar to that shown in Fig. 1.

The generator principle: The shunt-field circuit starts with the third brush and divides at (X), going (to the left) through field windings 1, 2, and 3, and from (X) (to the right), through field windings 4, 5, and 6, to shunt (GRND), through the frame to the series field grounds (G1), (G5), (G3), to the (−) main brushes.

The charging circuit is from the generator (A+), to the cut-out, to the battery, to the (−) battery ground, to the (−) ground (G1), (G5), (G3), through the "series field coils" to the (−) brush ring, to the (−) brushes.

Simms-Huff Models "HB," "HK" Motor-Generator—12-Volt Starting Motor, 6-Volt Generator

A Simms-Huff six-pole motor-generator, models "HB," "HK," compound wound, used on the 1915, 1916, and 1917 Maxwell is shown in Fig. 3. The generator is 6-volt, and the motor is 12-volt. Regulation is by means of an electromagnetic regulator, similar to that shown in Fig. 1, except that instead of the generator being 12 volts, it is 6 volts and the starting motor is 12 volts.

Motor circuit: From battery (+12), to (12) on switch, to (13), to (13) of battery, connecting (+) of cell 12 to (−) of cell 13, making a 12-volt battery; from (+10), to switch (10), to (11) (when switch is closed), to (A+) of the motor-generator, through (+) brushes, through the armature, to (−) brushes, to (−) brush ring (B), to field coils, to ground of frame, to (−) of battery (19).

Generator field circuit: From (A+), through wire 2, to (2) on the regulator and cut-out, through the cut-out frame, through the regulator points to (3) to terminal (3) on the motor-generator, through the shunt-field windings, to ground, through series coil on pole 3, to (−) brush (4).

Cut-out voltage circuit: From generator (A+), wire 2, to cut-out (2), through the cut-out frame, to voltage winding (V), to ground of the motor-generator, through series fields, to (−) brushes. This winding causes the cut-out points to close when the generator voltage is higher than the battery voltage.

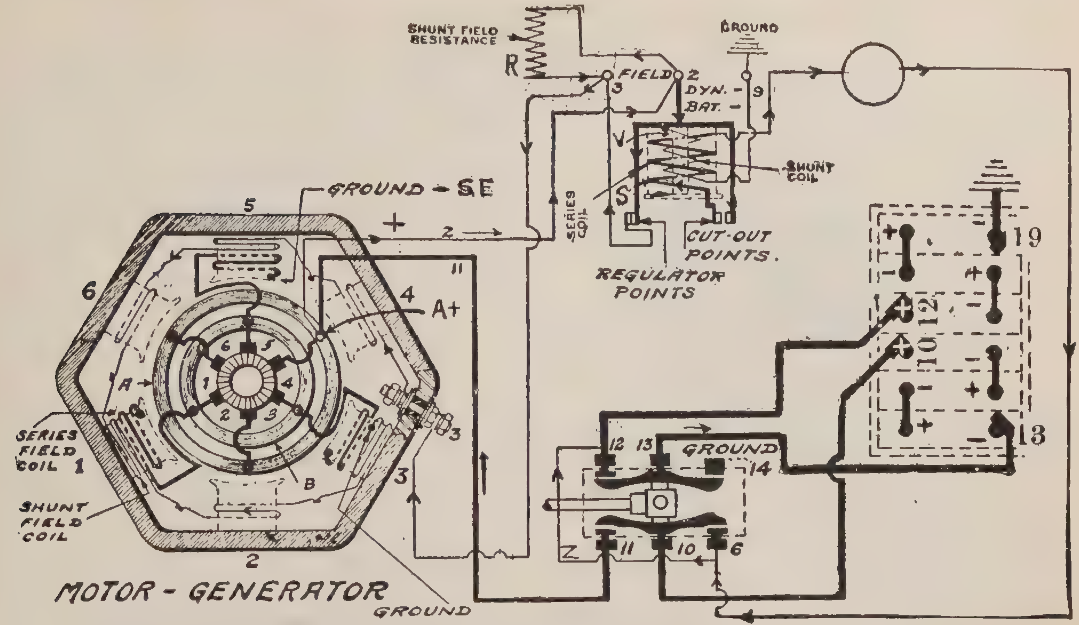

Fig. 3. Simms-Huff models "HB" and "HK" motor-generator. It operates as a 12-volt motor and a 6-volt generator.

Charging circuit: From generator (**A**+), wire 2, to cut-out (2), to the closed points of cut-out, through cut-out winding (S), to ammeter (round circle at right of cut-out), to (6) on starting switch.

After the engine is started, and on releasing the starting pedal, the starting switch plunger comes all the way back and makes connection between (13) and (14), and (10) and (6) on the starting switch.

From (6) on the starting switch the current divides, in order to join (10) and (12) (+) on the battery in multiple as follows:

From (6) through the switch terminal (shown open—should be closed) to (10) on the switch, to (10) on the battery, through the three cells to (13), to (13) on the switch, through contact (14) which is grounded. This grounds (13) (−).

Now follow from (6) through the permanent wire connection (Z) to (12) on the switch, to (12) (+) on the storage battery, through three cells to (19) (−) which is grounded.

We now have batteries 12 (+) and 10 (+) connected together, and batteries 13 (−) and 19 (−) grounded.

Thus (+) current, coming in at (6) on the starting switch, divides and passes through (12) to (+12), out (−19), to (−) ground of series coils, to (−) brushes on the generator. Current also passes from (6) to (+10) to (13), out (−13) to the (−) ground of series field coils, to (−) brushes on the generator.

In other words, the 12-volt battery is connected in multiple as two 6-volt batteries.

In regulation at high speeds, or where more than 15 amperes of current is passing in the charging circuit (which flows through the winding (S) of the cut-out and regulator) the regulator points are drawn to the core, and resistance (**R**) is inserted into the shunt-field circuit.

The shunt-field circuit would then be from (**A**+), wire 2, to cut-out (2), to and through resistance (**R**) (because the regulator points are open), to (3), to (3) terminal of the generator. Thus the magnetic strength of the shunt field is weakened by this resistance (**R**). The regulator blade vibrates at varying speeds, cutting in and out this resistance, thus holding the output normal. The generator delivers 15 amperes at 1,300 r.p.m.

The method of regulation would be termed "constant current," by an "electromagnetic action."

If the generator does not appear to charge at a high enough rate, see if the belt is tight and does not slip, that the regulator is adjusted properly, that the commutator is clean, that the brushes are clean and not sticking, and that all terminals and connections are tight and clean.

To test as a generator, remove all wires. Connect a wire from the field terminal on the side to the main terminal post on the front; then connect another wire from the main terminal post through an ammeter or test lamp to ground. Run the motor-generator at about 1,200 r.p.m. The generator should show a charge of about 12 amperes on the ammeter.

Oil and dirt cause the most trouble, as they will cut down the current output, short-circuit the brush holder, etc. Inspect and clean the motor-generator occasionally.

Electric Systems on Maxwell—1915 to 1921

1915-16-17 Maxwell cars used a Simms-Huff motor-generator combined in one unit. As a starting motor it operated at 12 volts from the 12-volt battery (as in Fig. 3). As a generator, it delivered current at 6 volts to the battery in two halves, or in parallel. A Simms magneto was used for ignition.

The 1918 car used the same system, except that the Atwater-Kent 6-volt ignition was used instead of a magneto. In August, 1918, the system was changed to a straight 12-volt battery and 12-volt ignition (Fig. 1).

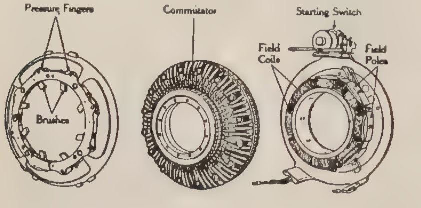
The 1919 cars used the system shown in Fig. 2.

The 1920 cars used an Auto-Lite 6-volt generator, third-brush regulation; 6-volt Atwater-Kent ignition, and a separate starting motor with a Bendix drive and 6-volt battery.

The 1921 and part of the 1920 cars use a Simms-Huff type "G," 4-pole third-brush regulated generator and a separate 6-pole type B starting motor with Atwater-Kent type "CC" closed-circuit ignition.

U.S.L. MOTOR-GENERATOR (EARLY MODEL)—24-VOLT MOTOR AND 12-VOLT GENERATOR

The U.S.L. motor-generator consists of a motor and generator combined. The motor-generator takes the place of the flywheel.



Brush Rig **Armature** **Field and Starting Switch**

Fig. 1. Armature and field-poles.

The field has two windings: a shunt and a series. When the machine operates as a motor the two windings have a "cumulative" action.

When operating as a generator, the two windings oppose each other, resulting in a "differential" action.

The voltage of the motor is 24 volts and of the generator, 12 volts.

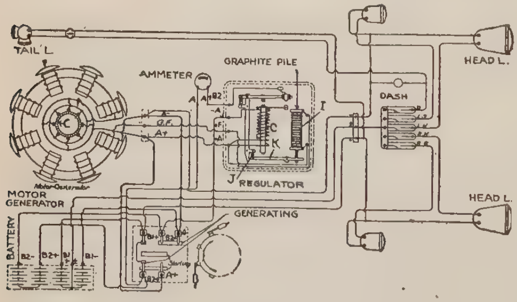


Fig. 2. Wiring circuit of the U.S.L. motor-generator.

Motor action: When the foot pedal is depressed, the battery is connected to the motor which turns over the engine at the rate of 200 to 300 r.p.m. The battery is connected in series by the starting switch when used as a motor; thus 24 volts are used.

Generator action: As soon as the engine picks up to a speed going 8 m.p.h., the motor-generator becomes a shunt-wound generator and starts to charge the battery, restoring the current used at a 3-ampere rate. The generator charges the battery at 12 volts; thus the battery is connected in multiple by the starting switch being released.

Regulation of output: A carbon-graphite pile regulator is used. It is similar in action to an electromagnetic principle of regulation.

Instead of resistance in the form of resistance wire being cut into the field circuit at high speeds, a **carbon pile resistance** is used which offers resistance to the flow of current, thus weakening the strength of the field circuit at high speeds.

The series coil (C) keeps the output constant from 600 to 1,200 r.p.m. Thus it is termed a "constant-current" electromagnetic regulation.

The electromagnetic principle of regulation is shown in Fig. 3. The current for the **voltage winding circuit** of the coil is from (+) brush, through fine wire winding (V), to the series winding on the motor-generator, to the (−) brush.

When sufficient voltage is generated the points (**P**) close. The **charging circuit** is then from the (+) brush, through the regulator series coil (**C**), to points (**P**), to the battery connected in multiple, and thus charges at 12 volts.

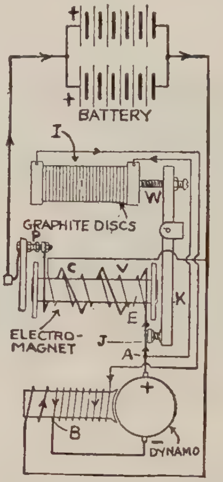

Fig. 3. Explaining the regulation method.

The shunt-field circuit is from the (+) wire above the (+) brush at (**A**), through the graphite pile, to the shunt-field winding of the motor-generator, to (**B**), to the (−) main brush of the generator.

The regulation is maintained by pressure upon the graphite disks (**I**), which are pressed together by lever (**K**), through the pressure of the coil spring (**J**).

The less the pressure, the greater the resistance thrown into the field winding, for if the disks are not close and tight, resistance is offered to the flow of current.

When the generator speed is low, the tension of spring (**J**) is great enough to cause screw (**W**) to press tightly against the graphite disks; thus the resistance is less and the generator shunt field builds up.

When the generator speed is high, the current flowing through coil (**C**) increases the magnetic pull of core (**E**), thus drawing blade (**K**) to it, thus relieving the pressure of screw (**W**). As the disks are not so tightly pressed together, the resistance is greater, thus the field strength is cut down.

On a later U.S.L. system, the carbon pile was eliminated, as also the "series parallel switch."

No regulator is used, as the windings of the generator are so proportioned that the output of the generator cannot exceed the current demand of the storage battery and lamps.

A portion of the multi-polar field of the motor-generator is wound with a series coil for starting purposes. The other portion of the fields is wound with shunt and compensating coils for generating and regulating purposes. The brushes are so connected that the entire number is used for starting, whereas but three are used for generating.

The storage battery is provided in some cases with two and in some cases three terminal posts. When two terminals are provided, a 14-volt lamp must be used. When three posts are provided, 7-volt lamps are used.

The number of cells of the battery are cut down from 12 to 6, giving 12 volts instead of 24.

This system was formerly used on the early models of Jeffery, Sheffield, Simplex, Willys-Knight, S.G.V., and Mercer.

INSTRUCTION No. 35

DELCO ELECTRIC SYSTEMS[1]

In order that the reader may understand the later Delco systems, it will be necessary to begin with the 1914 models. Some of the early model Delco systems will therefore be shown before taking up the later models.

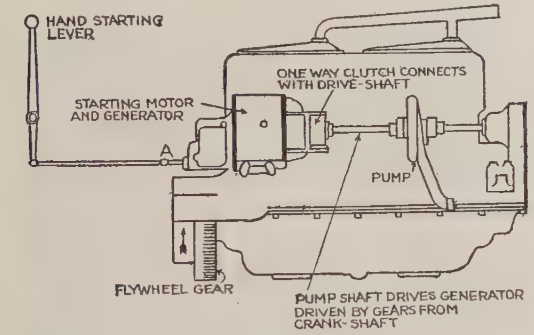
The motor-generator principle was first used by Delco—and is still used, but with a different regulating principle, and with other changes from the early models.

The Delco also make single-unit systems, where the generator and starting motor are separate, as will be explained farther on.

The early 1914 system should be carefully studied in order to understand the later systems.

DELCO 1913-14 MOTOR-GENERATOR; ELECTROMAGNETIC REGULATION; CONSTANT VOLTAGE

The 1914 Delco motor-generator and electric system, as used on the 1914 Cadillac and Hudson 1914, "6-54," Oakland 43, Olds 55, Packard 1-38, 3-48, Cole series 9, model cars is explained as follows: The motor-generator is located alongside of the engine driven by a pump shaft (Fig. 1).

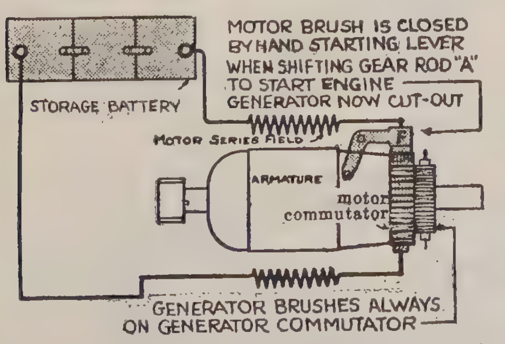


HAND STARTING LEVER
ONE WAY CLUTCH CONNECTS WITH DRIVE-SHAFT
STARTING MOTOR AND GENERATOR
A
PUMP
FLYWHEEL GEAR
PUMP SHAFT DRIVES GENERATOR DRIVEN BY GEARS FROM CRANK-SHAFT

Fig. 1. The mounting of the 1914 Delco motor-generator is similar to that of the later models.

The armature is used for both the starting motor and the generator with two windings; one a "series" winding for the motor (Fig. 2), and a "shunt" winding for the generator (Fig. 3).

When the motor is in operation, the current flows from the battery to the series-field winding through the motor brush (**F**) and commutator.



MOTOR BRUSH IS CLOSED BY HAND STARTING LEVER WHEN SHIFTING GEAR ROD "A" TO START ENGINE
GENERATOR NOW CUT-OUT
STORAGE BATTERY
MOTOR SERIES FIELD
F
ARMATURE
motor commutator
GENERATOR BRUSHES ALWAYS ON GENERATOR COMMUTATOR

Fig. 2. The motor brush is now down and the starting motor is working. The generator is cut out.

The starting switch is eliminated, as the action of the motor brushes is lowered to the motor commutator, and thus when starting, the lever meshes the gears with the flywheel and so takes the place of a starting switch.

The starting motor drives the flywheel gear through the gears (**C**), (**D**), and (**B**) (Fig. 4). A roller-type clutch is provided on the front part of the armature shaft, so that the armature is free from the pump shaft which drives the generator.

When the generator is in operation, the motor brush (**F**) is raised (Fig. 3). The generator brushes remain on the commutator at all times. The current then flows through the shunt-field winding.

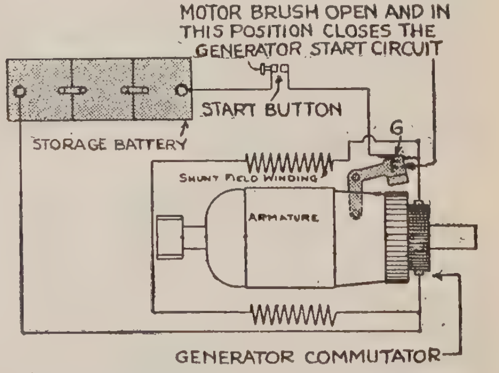


Fig. 3. To start, the "start button" is pressed. This sends current from the battery to the generator (not the motor) armature, through the field winding and the armature revolves slowly. Note that the motor brush is up and makes contact at (G) for the generator.

The armature is driven by connection with the pump shaft by the engine (Fig. 1), after the engine is started and after the starting gears are out of mesh. A one-way clutch connects the pump shaft with the armature shaft to drive the generator. This clutch will permit the pump shaft to drive the generator, but the generator armature, when running as a motor, cannot drive the shaft.

Starting Operation

First: Place the ignition switch on the battery side. Next: depress starting button on the dash (see Fig. 3). This sends current from the storage battery to the generator (not the motor), and in passing through the generator field shunt winding, and the armature winding, the armature slowly revolves. This is termed **"motoring the generator."**

---

[1] **The Delco Service Manual** can be secured of A. L. Dyke, St. Louis, Mo., price $3, which contains descriptions of all Delco systems, tests, and diagrams from 1913. Manuals on Remy, Autolite, and other systems can also be furnished.

The purpose of using the generator as a motor is to revolve the armature slowly, so that the gears will mesh with the flywheel gears when the starting lever throws them in mesh. It must be remembered that the brush on the starting motor commutator is not in contact, but, being in the position as shown in Fig. 3, the generator circuit is closed at (G), but not the motor circuit.

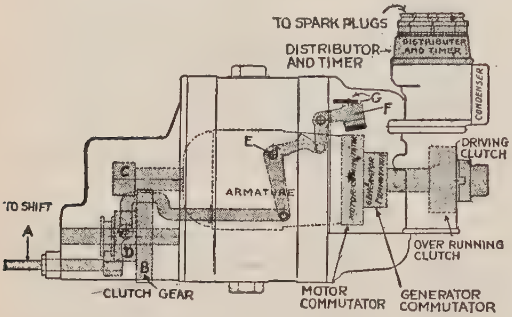

Fig. 4. Phantom view of motor-generator.

After the generator armature is revolving slowly pull back on the starting lever (see Figs. 1 and 4).

This causes rod (A) (Fig. 4) to be pushed forward, causing gear (B) of the starting clutch to mesh with motor pinion (C).

Immediately after gears (B) and (C) are meshed, the gear (D), which is integral with (B), meshes with the gear teeth on the flywheel. At the same time, the extension of the rod (A) to the bell crank (E) allows the motor brush (F) to travel toward the motor commutator, opening the generator circuit and shunt field at (G), and closing the motor circuit.

The generator would then be cut out and the starting motor is causing the engine to revolve, through the flywheel (Fig. 2).

Generating Current

When the starting lever is released, the spring throws the gears out of mesh, and at the same time raises the motor brush (F) from the motor commutator and closes the generator circuit again at (G). The "start" button having been released in the first operation, the generator is now generating current, as the engine is running and driving the armature as a generator through the pump shaft.

The starting motor has served its purpose and is now cut out of operation, as the brush (F) is away from the motor commutator (Fig. 3).

Regulation of the Generator (Shunt-Field; Electromagnetic)

A mercury type of voltage regulator was used, which is an electromagnetic principle of cutting resistance into the shunt-field circuit, explained as follows: The generator, as stated previously, is driven from the pump shaft which is driven by gears in front of the engine from the crank shaft.

After the engine is started, and the hand-starting lever disengages the gears out of the flywheel, and motor brush (F) is lifted off the motor commutator, the motor is cut out and the generator is now in action. It must run when the engine runs, as the pump shaft is connected with the armature through a one-way clutch (Fig. 4), which permits the engine to drive the armature. But the armature, when revolving as a motor, cannot drive the engine except through the gears to the flywheel. This clutch permits the armature to run ahead of the driving shaft during the cranking operation.

The generator now begins to generate current; but until the engine is running at a speed which will turn the generator armature fast enough to generate a pressure of 6 volts, or the required amount to overcome the pressure or voltage of the storage battery, the current will pass from generator commutator 1, to 2, around the fine wire voltage winding (V) of cut-out core (D) (Fig. 5), thence back to the other commutator brush 15. This current will continue to travel in this path until it has sufficient pressure, which is slightly over 6 volts, to magnetize the core (D) so that it will draw the magnet armature of cut-out (C) down, closing cut-out points (P) at which time the circuit is closed to the battery. The battery will then be charged from the generator, or the generator will also supply current for light. (At other times, the storage battery supplies current for lights.)

If the engine is speeded up, the pressure increases and the lights would be burned out. Therefore, the "mercury regulator" is brought into action.

Voltage regulator: As the voltage increases with speed, the intensity of the magnetic pull exerted by the magnet voltage coil (A) upon plunger (C) causes the plunger (C) to move up out of the mercury (see Figs. 5 and 6).

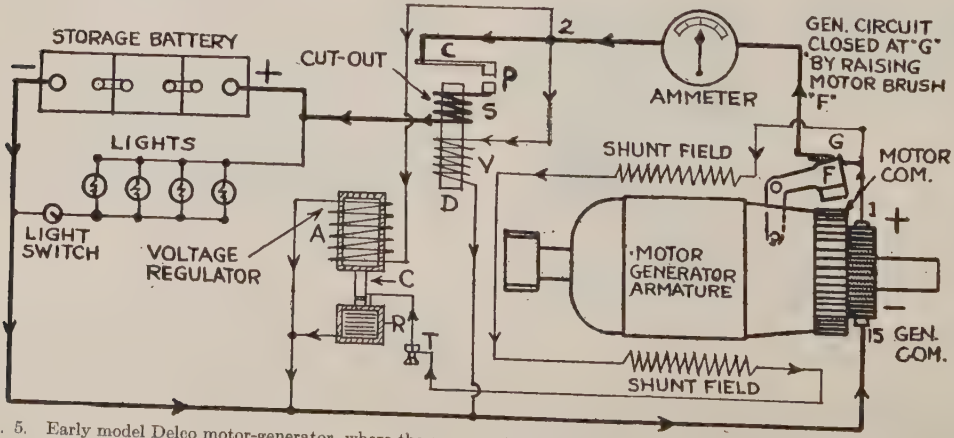

Fig. 5. Early model Delco motor-generator, where the mercury type of voltage regulator was used to regulate the generator output.

The regulator voltage coil (A) circuit is from (+) brush (1) to (2), through (A) to (−) brush(15).

The current to the shunt field of the generator starts at the (+) brush of the generator, through the two field windings, to (T) on the regulator, and must follow a path leading into the outer well of mercury, through the resistance coil (R) wound on the plunger tube, to the needle (D) carried at the center of the plunger, into the center well of mercury and out of the regulator, back to the (−) brush (15).

It will be seen that as the plunger is withdrawn from the mercury, more resistance is thrown into this field circuit, owing to the fact that the current must pass through a greater length of resistance wire. This greater resistance in the field of the generator causes the amount of current flowing to the battery to be gradually reduced as the battery nears a state of complete charge, until finally the plunger is almost completely withdrawn from the mercury, throwing the entire length of resistance coil into the shunt-field circuit, thus causing a condition of practical electric balance between the battery and generator, and obviating any possibility of over-charging the battery. As the speed decreases, the magnetic pull of the core (A) of the regulator voltage coil is weaker and plunger (C) assumes a lower position.

Note that **there are two voltage windings:** one (V), on the cut-out core to close the cut-out points, and one (A), on the regulator to operate the needle which cuts in and out the resistance to the field circuit. Both voltage coils are placed across the generator circuit.

The charging circuit is from the (+) brush (1) of the generator, through generator switch (G), to cut-out (2), through cut-out series winding (S), through points (P), to (+) terminal of the battery, to (−) brush of the generator (15).

FIG. 6

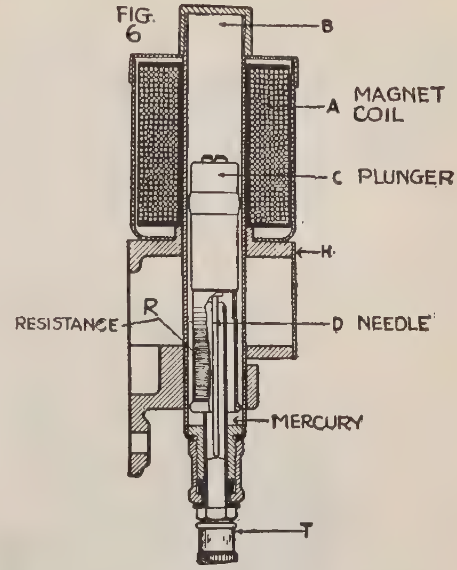

Fig. 6. **The Delco mercury-type voltage regulator** is located alongside of the cut-out, both being in the battery box or on the inside of the dash under the hood.

Purpose: to control the amount of current flowing from the generator to the storage battery.

Description: A magnet coil (A) surrounds the upper half of the mercury tube (B). Within this mercury tube is a plunger (C) comprising an iron tube with a coil of resistance wire (R), wrapped around the lower portion on top of mica insulation. One end of this coil is attached to the lower end of the tube, the other end being connected to a needle (D) carried in the center of the plunger.

The lower portion of the mercury tube is divided by an insulation tube into two concentric wells, the plunger tube being partly immersed in the outer well, and the needle in the inner well. The space in the mercury tube above the body of the mercury is filled with an especially treated oil, which serves to protect the mercury from oxidization, and to lubricate the plunger. A bracket (H) serves to support the parts described.

MOTOR GENERATOR
IGNITION COIL

Fig. 7. External connections of the Delco electric starting, generating, and ignition system, with an automatic advance of ignition. A single-wire grounded-return wiring system.

On the Hudson "Six-40" (1915–16), Buick models "C–54, C–55, C–36–37" (1915), Cole "6–50," Oakland 49 (1915), Olds 42 (1915), the Delco motor-generator was used, but with a "variable resistance" cut in and out of the shunt-field circuit by means of a mechanical governor instead of the electromagnetic principle, as previously described.

The armature winding: There are two regular "drum"-type windings on the armature, one for the generator and one for the motor. But only one armature is used. There are two commutators on this system, one at each end; one for the generator circuit and one for the motor circuit (see Fig. 8).

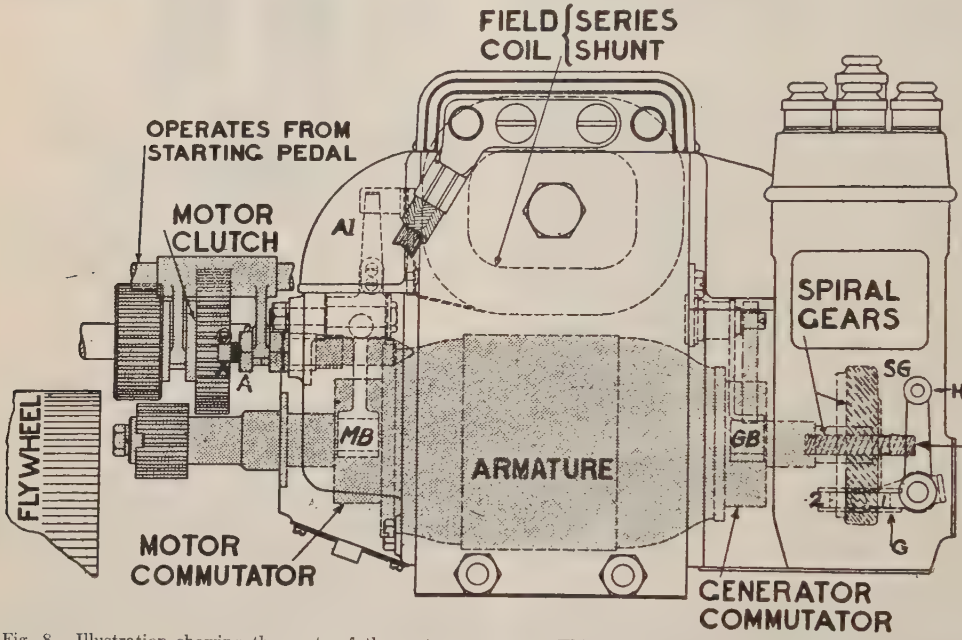

Fig. 8. Illustration showing the parts of the motor-generator. This is a "single-unit" system, the motor-generator and ignition unit being in one unit. (HC) is the manual control of the spark and connects with the spark lever on the steering wheel.

The cut-out is also eliminated. A circuit-breaker of the vibrating type is used to take the place of fuses. See Fig. 15, page 392, for an explanation.

Field windings: There are two windings, a series-field winding for the motor and a shunt-field winding for the generator.

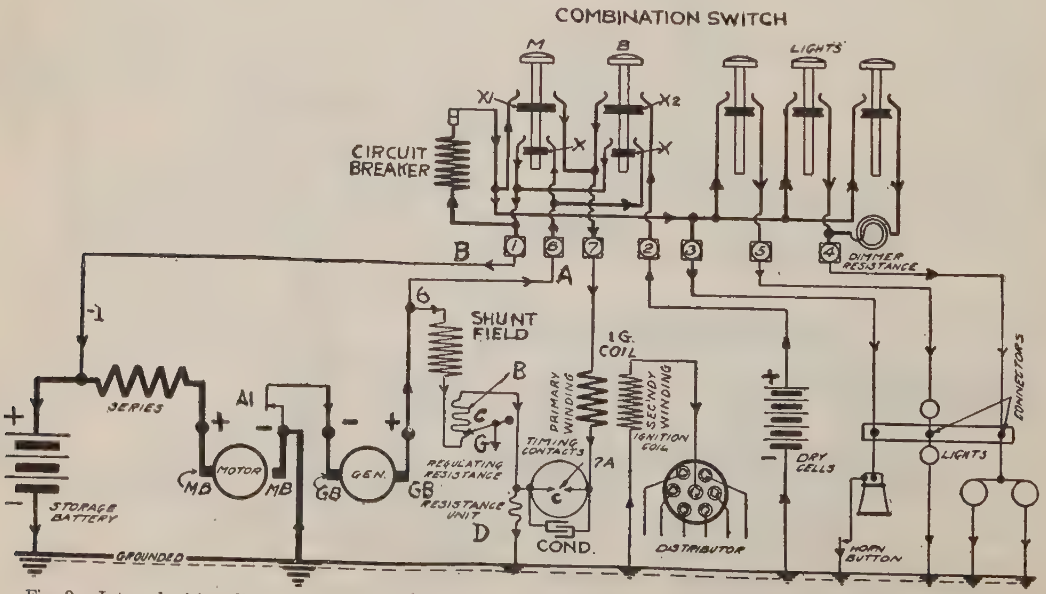

Fig. 9. Internal wiring diagram of the system shown in Figs. 7 and 8. Note the variable resistance (B), which is cut into the shunt field-circuit.

Motoring Generator

When first starting, the (**M**) ignition button (see diagram, Fig. 9) is pulled out and the starting pedal depressed. This causes rod (**A**) to shift gears into mesh with the flywheel gear, and at the same time connection is made from the battery (+) terminal to (1), through (**X**), to (6), to the shunt-field winding of the generator, to ground, also to the (+) generator brush, through the armature, to the (−) generator brush, to (**A**1), to ground, to (−) ground of the battery. This circuit causes about 5 amperes of current to pass through the generator, which permits the generator to revolve as a motor in order to make it easy for the gears to mesh. This is termed "motoring the generator."

The purpose of using the generator as a motor is to cause the armature to revolve slowly, so that the gears will mesh with the flywheel gears when starting. If the current was immediately applied to the starting motor, it would revolve at full speed immediately. By "motoring the generator," however, the armature revolves slowly until gears are meshed, and then the full current is applied to the starting motor.

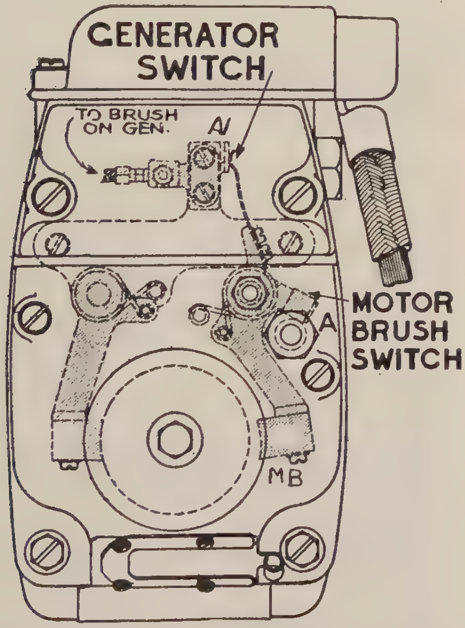

Fig. 10. View of motor-generator showing the motor brushes, also the generator switch (**A**1). The large wire on right of Fig. 10 connects with the battery. The generator circuit is opened and closed by action of switch (**A**1). When the motor brush (**MB**) is raised by rod (**A**), the generator circuit is closed at (**A**1). When the motor brush is lowered on to the commutator by rod (**A**), for starting purposes, the generator circuit is opened at (**A**1).

Starting Motor or Cranking Operation

As the starting pedal is depressed still farther, the motor brush (**MB**) makes contact with the commutator and the generator is opened at generator switch (**A**1). The full force of the current from the battery then passes (+) through the motor series-field winding and the armature, through closed brush (**MB**) on the right, to ground, to the (−) battery grounded terminal.

When the starting pedal is released and the engine starts, the motor brush (**MB**) is raised from the commutator, and the generator circuit is again closed at generator switch (**A**1).

Generator Operation

When the engine is not running, or when it is running below 300 r.p.m., and the circuit between the generator and the storage battery is closed either by the (**M**) or the (**B**) button on the combination switch, the direction or flow of the current is from the battery to the generator. If the speed is very low indeed, as when throttled down to three miles per hour, the generator will "over-run" and the clutch will be heard in operation.

A warning is given when the ignition button is pulled out or left pulled out (and the engine stopped) by the clicking of the ratchet type of driving clutch (Fig. 11), with which all these generators are equipped.

Cut-Out Not Used

On the Delco system described on page 384, the cut-out served the purpose of disconnecting the battery, when the generator was running at a slow speed, or not at all, or if generating less than 6 volts.

On the system now being explained and present-day systems, the "cut-out" is eliminated. The ignition buttons (**M**) and (**B**) in a way take the place of this cut-out. The operation of either button controls the circuit between the generator and the storage battery. Should the engine stop and the ignition button (**M**) or (**B**) remain pulled out, the amount of current that comes from the storage battery is that which is required to operate the generator as a motor when first starting, and is about 5 amperes.

When the engine is running below 300 revolutions, then this clicking of the ratchet will take place again, because the current from the battery is running back into the generator which is slowly revolving it. This indicates that the generator is not running fast enough to overcome the pressure of the battery. The amount of current that flows from the battery back to the generator at this slow engine speed is so small that it is negligible. Therefore the automatic "cut-out" is eliminated.

Generator Charging Circuit

At over 300 revolutions, the generator is running fast enough to overcome the battery pressure and the **generator charging circuit** would be as follows (see Fig. 9, wiring diagram): Start with the (+) generator brush, to (6), to (**X**), to (1), to (+) terminal of the battery, to (−) ground of the battery, to (−) grounded generator brush through the closed generator switch (**A**1). (Note that the motor brush (**MB**) is raised from the commutator.)

Generator Shunt-Field Regulation

The regulation of the shunt-field generator circuit is by means of a "variable resistance" (**B**), which is cut into the shunt-field circuit at high speeds automatically and mechanically, by a centrifugal governor arrangement (Fig. 11). This arrangement controls a lever (**C**), which is raised and lowered by the action of the governor and which cuts the resistance (**B**) into the shunt-field circuit at high speeds. This results in weakening the strength of the shunt fields, and consequently the output of the generator. This is termed a "variable resistance" method of regulation and is "mechanically" controlled.

When the generator is running at low or medium speeds, the lever (**C**) is at the lowest point, as shown in the wiring diagram (Fig. 9). Therefore, the resistance (**B**) is cut out and the circuit of the shunt field is from the (+) brush of the generator, to (6), to lever (**C**), to ground (**G**), to (−) ground of the generator brush (through the generator switch **A**1).

When the generator is running at high speeds, the lever (C) raises. As a consequence, the resistance (B) is cut into the shunt-field circuit. The amount of resistance cut into the shunt-field circuit depends upon the speed. The higher the speed, the higher the lever (C) is raised, with a consequent higher resistance being cut into the field circuit.

Control of the "Variable" Regulating Resistance—by Governor Action

Note the action of the governor which controls the cutting in and out of this resistance. (See Fig. 11, and diagram, Fig. 9.) The spiral gear (SG) is attached to the timer shaft (TS). This is operated by the pump shaft independently of the armature shaft, this gear being a part of the clutch which connects with the pump shaft.

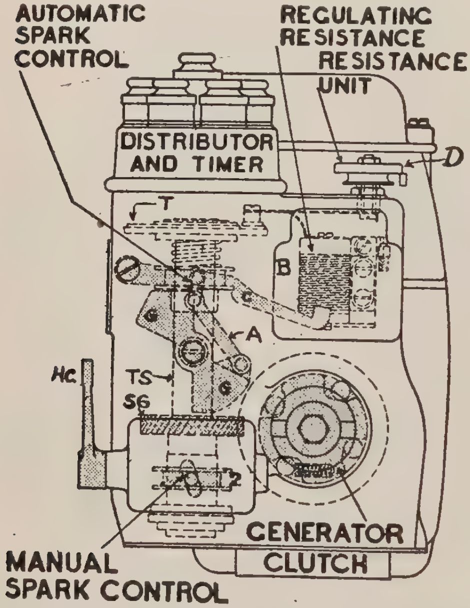

Fig. 11. View of the "variable resistance" mechanism, automatic advance of the spark and the generator clutch. The spiral gear on the generator clutch drives gear (SG), which drives the timer shaft (TS). The governor (G) tends to assume a horizontal position as the speed increases, and thus it operates arm (A) controlling lever (C), which cuts in the bare wire resistance (B) on the spool. This same action actuates the automatic advance of the spark as explained under the "ignition" section of this subject.

If the distributor was driven from the armature shaft the timing would be effected during the starting operation, at which time the armature operates at a different speed from that of the pump shaft.

The pump shaft runs at one and one-fifth times the crank-shaft speed, but the six-lobe cam and the shaft operate at half engine crank-shaft speed.

As the timer shaft revolves, the governor weights (G) assume a rising position which raises the arm (A), thereby raising the lever (C), which makes contact with the bare resistance wire (B), wound on an insulated spool. The principle is that as the speed of the engine increases, the speed of the timer shaft increases, and the governor arms (G) rise higher as the speed increases, thereby raising the arm (C) higher.

The higher arm (C) is raised, the more of this resistance wire is thrown into the field circuit, thereby weakening the output and keeping the current from gaining as the charging rate increases at the higher speeds.

Ignition

The ignition system consists of an open-circuit timer, ignition coil, mounted as shown in Fig. 7, and a distributor which distributes the high-tension current to the spark plugs.

The primary circuit (if the battery supplies the current, Fig. 9) is from (1), through the circuit breaker, to (X1), to (7), to the primary winding of the coil, to (7A), through the timer points, through ignition resistance (D), to ground, to the (—) ground of the battery.

The primary circuit (if the generator supplies current) is from 6, to (X), to and through the circuit-breaker, to (X1), to (7), and from there the same circuit as given in the preceding paragraph.

The dry cell batteries are used as an emergency set for ignition. The current is supplied in exactly the same manner as though it was coming from the storage battery; the (B) button on the combination switch closes the circuit between terminals No. 1 and No. 6 at (X), in order that the generator may be connected to storage battery for charging purposes.

The dry-cell primary ignition circuit would then be from (+) of the dry cells, to (2), to (X2), to (7), through the primary winding of the coil, to the timer, to resistance unit (D), to ground, to (—) ground of the dry cells.

The secondary ignition circuit is from the secondary winding, to the distributor, to the spark plugs, to ground, to ground of the secondary winding.

Automatic Advance of Ignition Controlled by Governor Action

At the same time the timer cam on the end of the timer shaft is automatically "advanced." As the speed is increased the action of the governor turns the timer cam in the direction of rotation, thereby causing earlier contact.

The ignition system consists of a non-vibrating coil mounted as shown in Fig. 7. The timer is an open-circuit system in this system, but the closed-circuit type is used on later systems. See Index for "Delco ignition systems."

The ignition resistance unit shown at (D) (Figs. 9 and 11) is a coil of resistance wire, the purpose of which was explained on page 198 in the instruction on ignition.

This ignition resistance unit has connected in parallel with it, the shunt-field regulating resistance (B) (Fig. 9).

When the arm (C) is in the lower position, the resistance of this path greatly exceeds that through the resistance unit, and practically all the ignition current passes through the ignition resistance unit.

But as the arm rises, as at high speed, this resistance is decreased, and when the arm is at the top position the full voltage is applied to the ignition coil.

In the event of the ignition resistance unit (D) being disconnected or burned out, it is impossible to get sufficient current through the regulating resistance, unless the arm (C) is held near the top.

Generator Clutch

A clicking sound will be heard during the "motoring of the generator." This is caused by the "overrunning of the clutch" in the forward end of the generator which is shown in Fig. 11.

The purpose of the generator clutch is to allow the armature to revolve at a higher speed than the pump shaft during the cranking operation and to permit the pump shaft to drive the armature when the engine is running on its own power. Spiral teeth are cut on the outer face of this clutch for driving the distributor. This portion of the clutch is connected by an Oldham coupling to the pump shaft. Therefore its relation to the pump shaft is always the same, and does not throw the ignition out of time during the cranking operation.

How to Remove Generator Clutch

Two views of the generator clutch are shown in Figs. 12 and 12**A**. This clutch is removed from the armature and end-frame assembly by loosening the screw in the end of the armature shaft and removing the lock washer and key washer. Cut a hole in the work bench about ¼″ larger in diameter than the armature. Insert the armature through this hole. Allow the armature and end frame to drop about two inches, being careful to have the end frame come squarely in contact with the bench. Hold the armature from below, so that it will not be injured by striking the floor.

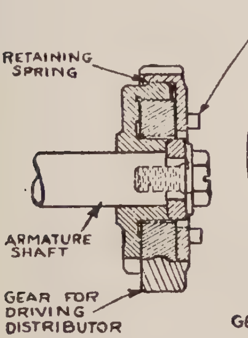

Fig. 12

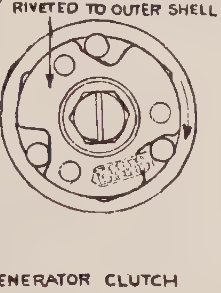

Fig. 12A

The clutch is held together by a retaining spring wire which, when removed, allows the clutch to be disassembled for inspection.

Motor Clutch

The "motor" clutch operates between the fly wheel and the armature pinion (Fig. 8), and is for the purpose of getting a suitable gear reduction between the motor generator and the fly wheel. It also prevents the armature from being driven at an excessively high speed during the short time the gears are meshed after the engine is running on its own power.

Single-Wire or Grounded System

The Delco wiring of the different parts is shown in Fig. 9. Note that the single-wire system is used in the illustration—the frame of the car being used to carry the return circuit.

The motor-generator, storage battery, lamps, horn, and ignition apparatus each have a connection "grounded" to some part of the frame of the car or engine. The other connections are made with copper wires or cables.

Circuit-Breaker

The circuit-breaker does not take the place of a cut-out. It is provided so as to open the circuit in case of a short circuit, and it thus takes the place of fuses. See Fig. 14, page 390.

DELCO MOTOR-GENERATOR THIRD-BRUSH REGULATION—CONSTANT CURRENT

As an example of a third-brush-regulated Delco motor-generator we will use the Delco electric system on one of the first models of the Hudson "Super-Six" cars, models "H" (1916–17) and model "J" (1918). The Hudson "Super-Six" was produced after the Hudson "6-40," which used a variable resistance regulation which was cut into the field winding automatically by a governor. The late Hudson "Super-Six" model uses a similar system, except that a "third-brush" regulation is used instead of "variable resistance," the combination switch is arranged differently, and there are differences in a few other minor details. See Index under "Wiring diagram of the 1921 Hudson."

The Delco motor-generator used on the Hudson consists of a motor and a generator contained in the same housing, thus forming a single unit. Electrically, however, they are just as separate as if they were built in separate housings.

There are two armature windings and two commutators entirely independent of each other. The commutator and brushes at the rear end belong to the motor part of the machine; those at the front belong to the generator part.

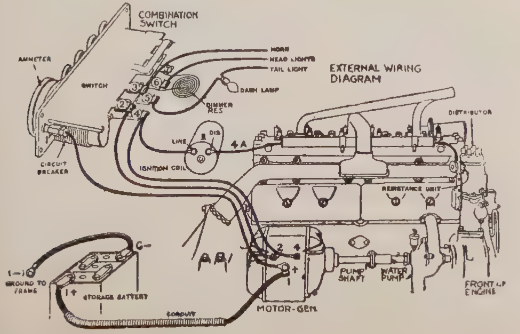

Fig. 13. External circuits of the Delco electric system on the Hudson "Super-Six," models "H" and "J."

There are two sets of field windings or coils: a set of "shunt-field coils" used for the generator action, and a set of "series-field coils" used for the motor to crank the engine.

"Motoring-Generator" Circuit

When first starting, the ignition button is pulled out (Fig. 14), which closes three circuits as follows:

1. **The ignition primary circuit,** from battery (+) to (1) on the ammeter, to a point on the switch above (3), to (**X**), to (**X1**), to (4), to the primary coil winding, through (4**A**), to the ignition resistance unit, to the timing contact points (closed-circuit type), to ground, to (—) ground of the battery. **The ignition secondary circuit** is from the lower ignition coil winding to the distributor, to the spark plugs, to ground, to (—) ground of the battery, to (1), to (**X**), to (**X1**), to (4), to the primary winding, to where the secondary joins the primary winding.

2. **The generator-field circuit** (for motoring generator) is from (+) of the battery, to (1), through the ammeter, to (**X**), to (**X1**), to (4), through the shunt-field windings, to the third brush, through the armature coils, to the (—) grounded generator brush, to (—) ground of the battery.

3. **The generator motoring circuit** is from (+) of the battery, to the ammeter, to (**X**), to (2), to the generator switch (which is closed), to the (+) generator brush, through the armature, to the (—) generator brush, to (—) ground of the battery.

These circuits from the battery give an ignition circuit for the spark plugs and also turn the generator armature over slowly (termed "motoring the generator"), so that the gears can easily be meshed with the flywheel gear.

Starting Motor Circuit

During the "motoring of the generator" operation, as explained, both motor brushes are raised from the commutator. They remain in this position at all times, and the generator switch is closed at all times, unless the starting pedal is depressed for starting the engine.

When motoring the generator, the first operation in starting, is to depress the starting pedal which meshes the drive gear with the flywheel driven gear on the rim of the flywheel. At the same time that the gears are meshed, the rod operating in contact with the lower brush arm of the motor moves, allowing both motor brushes to come in contact with the motor commutator, and at the same time the generator switch is opened, opening the circuit to generator and closing the circuit from battery to motor.

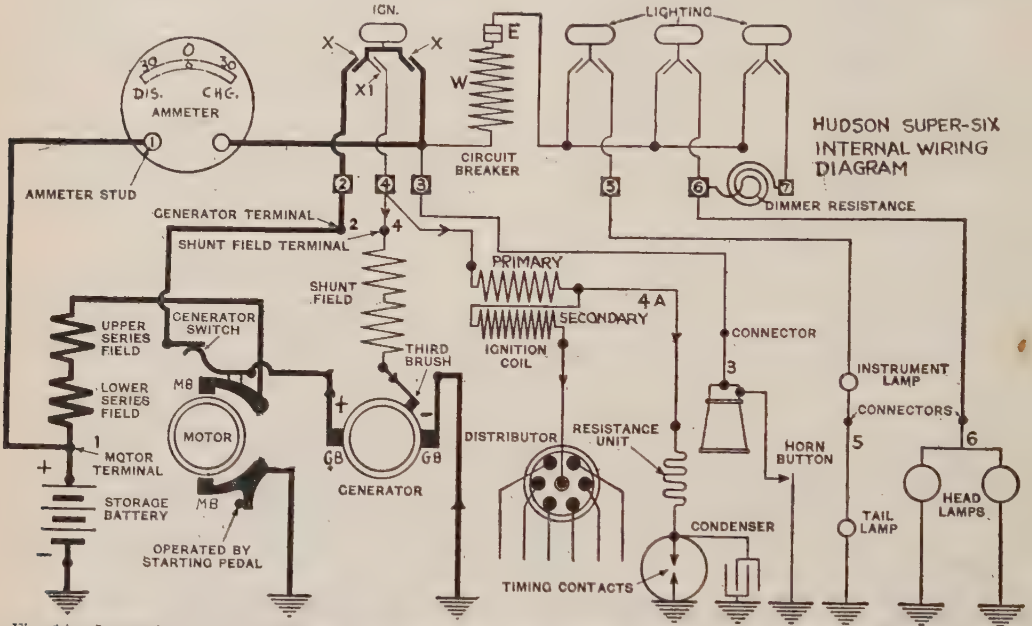

Fig. 14. Internal circuits of the Delco Electric system on the Hudson "Super-Six," models "H" and "J." The wiring is a single-wire, or grounded-return system.

The raising and lowering of the motor brushes, therefore, functions like a switch, i.e., when the brushes are in contact with the commutator, the circuit is closed; when they are raised away from the commutator the circuit is opened. Thus a starting switch is not used.

The motor circuit will then be from (+) of the battery, to motor terminal (1), through the series field winding of the motor, to the upper (+) brush, through the armature winding, to the lower motor brush, to ground, to (−) ground of the battery.

Generator Action

Now, let us assume that the engine starts. The starting pedal is released and the gears run out of mesh again. The plunger travels into place and lifts the motor brushes off the commutator, at the same time closing the contact at the generator switch. The generator circuits are complete again, and if the engine is driving the generator fast enough, current is being generated.

If, however, the generator is being driven by the engine at less than 300 r.p.m., the generator will "motor," as the pressure (voltage) from the batter is greater than from the generator at this slow speed Thus the battery current flows to the generato through the generator windings, as it did in th "motoring of the generator" operation, and th ammeter will show on the "discharge" side. A automatic cut-out could be used to prevent th battery from discharging in this manner through th generator windings at speeds lower than 300 r.p.m. but inasmuch as the current used is very slight (abou 3 or 4 amperes), and as the engine seldom runs a this low speed, the automatic cutout is eliminated

Generator clutch: When the engine is running a less than 300 r.p.m., the generator armature, a stated, turns as a "motor" and turns faster than it is being driven by the engine. Therefore a roller clutch, similar in action to the one described on page 324, and which is also similar in action to the free-wheel clutch on a bicycle, is used to allow the generator to over-run at speeds lower than 300 r.p.m., as explained above. This clutch also permits the armature to revolve when the ignition switch is first pulled out, as explained above under "Motoring the generator."

If the engine should be stalled or stopped without switching off the ignition button, a steady discharge from the storage battery of about 3 or 4 amperes would take place, causing the armature to revolve. Therefore the ignition button should be pushed in whenever the engine is not running.

Generator Charging Circuit

When the engine is revolving more than 300 r.p.m., the generator begins to generate current, and at higher speeds, sufficient voltage is generated to overcome the battery voltage and the generator sends current to the battery, as well as supplying current for ignition and lights.

The shunt-field circuit during the charging action is from (+) brush of the generator, to generator switch, to (2), to (**X**), to (**X1**), to (4), to third brush.

The main generator charging circuit is from (+) brush, to the generator switch, to (2), to (**X**), to a point above (3), to the ammeter, to (+) of the battery, to (−) of the battery, to ground, to the grounded (−) generator brush. The ammeter will now indicate on the "charge" side.

Generator Regulation

The regulation of the current (generator output) is obtained simply by varying the strength of the magnetic field, but this is brought about in a different manner to, and is an improvement over, the methods formerly used. By referring to Fig. 14, it will be seen that the lower end of the shunt field is connected to a "third brush" which is in contact with the generator commutator.

The strength of the magnetic field depends upon the amount of current flowing through the field windings, and this in turn depends upon the voltage (pressure) applied to the third brush.

This voltage depends upon two things: (1) the position of the brush on the commutator with relation to the other brushes, and (2) upon the speed of the armature.

The position of the brush on the commutator is set before leaving the factory, to give the best average charging rate, and must not be moved or interfered with as long as the charging rate is satisfactory.

If it becomes necessary to increase the charging rate, loosen the two screws by which the arm supporting the third brush is attached and move to the right (looking at the front end of the generator). A small movement makes a considerable difference in the charging rate. Then tighten the screws.

It is highly important after moving the third brush to sand it carefully down, so as to fit the commutator accurately, otherwise the generator will not deliver the full amount of current.[1]

If it becomes necessary at any time to decrease the charging rate, proceed exactly as outlined above, but move the brush to the left.

Third-Brush Effect of Generator Output

The third brush affects the generator output at varying speeds in the following way: **At low speeds** the voltage or pressure applied to the third brush is comparatively high; therefore a considerable amount of current will flow through the shunt field windings. This gives a strong magnetic field at low speeds, and the generator output will be good, considering the low speed. Increasing the speed under these conditions would increase the generator output too rapidly, and at high speeds there would be too much current produced. **With the increase in speed,** however, the voltage applied at the third brush decreases; consequently the magnetic field becomes weaker and the generator output is kept from becoming too great (see, also, pages 361, 408). In this way the generator output increases until a speed of about 20 to 24 miles per hour is reached. The current is then at a maximum which is arranged to take place at this speed, because experience has proved that this gives the best all-around results. **At still higher speeds,** the magnetic field becomes so weak that the output begins to diminish, thus preventing the storage battery from being charged at too high a rate.

The following table represents on an average the manner in which the charging rate should vary at different speeds.

Miles per Hour	Amperes
9	5
12	10
18	16
24	17
30	15
36	13
42	11

The Ignition System

The ignition system consists of a distributor, an ignition coil, a contact-breaker of the closed-circuit type, a condenser, and ignition resistance units—all fully explained under "Delco ignition systems."

The distributor-timer is driven by a vertical shaft and is located directly above the oil pump at the front end of the engine. On it is mounted the condenser and the resistance unit.

Timing the Ignition[1]

The cam which makes and breaks the contact points is adjustable. To move the cam it is necessary to loosen the screw in the center of the shaft. Before attempting to time the engine or ignition, see that the contact points are clean and set at a clearance of .018″, or the thickness of the gauge on the distributor wrench (in the tool kit) when on the highest point of the cam or at their widest opening.

Turn the engine over slowly with the hand crank until No. 1 cylinder is on compression stroke. To determine this, remove the other spark plugs and turn until you feel the resistance of compression. Turn the engine over very slowly until the pointer on the observation hole on the flywheel case is directly over the mark "A" which is stamped on the flywheel. See that the button on the rotor is directly under the contact in the distributor cap which leads to No. 1 cylinder spark plug. Loosen the set screw at the center of the cam and turn the cam until the contact points just start to separate. When checking the result, the cam should be held on tension in the opposite direction to rotation, and the back lash in the gears should then allow the points to start to separate when the cam is rocked back and forth. Then tighten the screw. Rub a very small quantity of vaseline on the track in the distributor cap, around which the contacts are spaced, and then rub off the free vaseline. Replace the rotor and distributor cap.

It is important to keep contact points clean and set at a clearance of .018″, or to the distributor wrench gauge. Use fine sandpaper for cleaning points. The small sandpaper disks used by dentists are excellent for this purpose.

Keep the distributor-cap track polished with vaseline. (Use sparingly.) Do not allow oil or dirt to accumulate on the contact points.

The distributor cap and high-tension wires should always be clean and dry. The resistance unit should be kept clean and all connections tightened.

Ignition Circuits

The ignition circuits, as explained on page 389, give the circuit when battery supplies current.

When the generator supplies current for ignition, the circuit is from (2), to (**X**), to (**X1**), to (4), and it then follows same path as described on page 389.

Purpose of the Circuit-Breaker

This is a protective device to prevent excessive current from flowing through the lighting circuit in the event of a ground or short circuit developing in the line. In other words, it takes the place of fuses.

There are two types of Delco circuit-breakers: the "vibrating type" and the "locking type." The vibrating type is used on the Hudson, as shown in Fig. 14, the details of which are shown in Fig. 15.

Construction of the Delco "Vibrating-Type" Circuit-Breaker

The Delco vibrating circuit-breaker is shown in Figs. 14 and 15. The coil (W) is connected in series

---

[1] The third brush must make good contact with the commutator at all times. To realize the importance of this, raise the third brush with the finger while the engine is running, and watch the hand on the ammeter go back to zero. The same thing applies to the two main brushes.

[1] Also applies to Hudson "Super-Six," model "O."

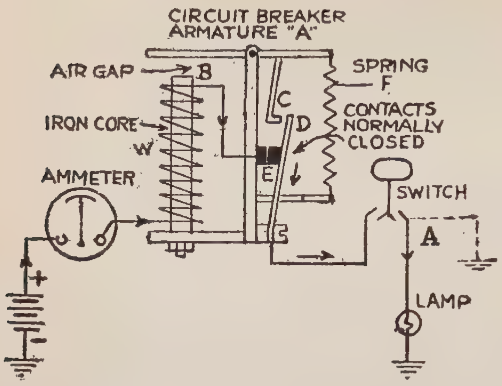

Fig. 15. Internal view of Delco vibrating type of circuit-breaker.

with the lighting circuit or other electric appliances. It consists of a single winding on a soft iron core.

It is set by adjustment of the air-gap, by spring (F) to carry a predetermined load of say 12 amperes, and the current passes through the winding (W), through points (E) which are normally closed, to the switch, to the lights, to ground, to battery ground. By the use of the circuit-breaker, fuses are eliminated from the circuits.

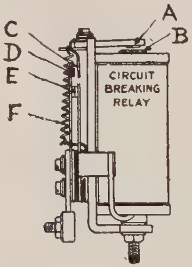

Fig. 15A. External view of Delco vibrating type of circuit-breaker.

If a short circuit occurs in the wiring, this would draw a greatly increased amount of current, and at from 27 to 30 amperes, the wire coil (W) becomes so strongly magnetized that the armature (A) is drawn to the core, thus causing arm (C) to push blade (D), separating points (E). The moment this occurs the circuit is broken; therefore contact will be made again, and again separated. Thus an action similar to a vibrating coil takes place, and the armature vibrates back and forth, but consuming only about 5 to 7 amperes. The vibrating action is kept up until the ground or short circuit is removed.

Note the point (A) (Fig. 15) in the circuit between the switch and the lamp. Should a ground occur at this point, the heavy flow of current would cause the circuit-breaker to operate.

When the vibrating type of circuit-breaker is used, it is mounted on the back of the combination switch.

Delco "Lock-Out Type" of Circuit-Breaker

Another type of Delco circuit-breaker is called the "lock-out" circuit-breaker. It is of similar construction, except that it has an additional fine wire voltage winding around the same core, the ends of which are connected across the contacts. When an overload occurs, as from a short-circuit or ground, the armature (A) (Fig. 15) is pulled down against the core, thus opening the circuit as in the vibrating type. The magnetism flowing through the fine wire winding will hold the armature (A) against the core and prevent it from vibrating. This limits the flow of current through the lock-out circuit-breaker to a small fraction of an ampere. The internal circuit of the lock-out type of circuit-breaker is shown in the wiring diagrams of Lafayette, Marmon, and Cadillac. See Index under "Wiring diagrams."

A double circuit-breaker is used on several cars, such as the Cadillac, Lincoln, and Lafayette, and is mounted in a single housing. One of these is the **vibrating** type and the other the **locking** type.

The vibrating type of circuit-breaker is used with the main lights, which are more frequently used. The locking, or lock-out type of circuit-breaker is used in connection with the tonneau lights, dome lights, and horn, as grounds are more likely to occur.

The ignition current in some cases is also taken through the vibrating type of circuit-breaker.

Delco Circuit-Breaker Pointers

If any part of the lighting circuit becomes grounded without first of all passing through the lamps, a heavy flow of current far in excess of the normal amount will take place. This heavy current magnetizes the iron core of the circuit-breaker so strongly that it attracts the small piece of iron called the armature, thus separating the contact points. This momentarily cuts off the flow of current, which in turn allows the contacts (E) to close again, and the operation is repeated, causing the circuit-breaker to give out a clicking sound.

The circuit-breaker thus not only gives warning of a ground in the lighting circuit, but also prevents injury to the wiring by permitting only from about 5 to 7 amperes to flow through it when vibrating.

When the circuit-breaker vibrates, push in the three lighting buttons. If the breaker continues to vibrate, the trouble should be looked for in the switch. If the breaker stops vibrating when the three lighting buttons are pushed in, pull them out one at a time and observe which one causes it to commence vibrating. The ground or short circuit must be in this line. The trouble may be located more accurately by disconnecting the wires at the junction block at the lower left-hand side of the dash. If the circuit-breaker continues to vibrate when these wires are removed, the ground must be in the wiring between the switch and the junction block; but if it stops vibrating, the trouble must be in the wiring between the junction block and the lights.

By testing each wire individually, the exact circuit wherein the trouble exists may be located.

In case the circuit-breaker vibrates repeatedly, do not attempt to increase the tension of the springs, as the vibration is an indication of a ground in the system. Remove the ground, and the vibration will stop.

Lights

Let us return to the point above switch terminal No. 3 (Fig. 14), where the line divides. The line going to the right leads to the circuit-breaker. After passing through the circuit-breaker winding, represented by the zig-zag lines and contact points, connection is made from this point to each of the three lighting contacts. The operation of each of the three lighting buttons will now be described.

Dash and Tail-Light Circuit

When the lighting button nearest to the ignition button is pulled out, the dash and tail-light circuit is completed, and the current passes out through terminal No. 5, then to the dash lamp socket, and through the lamp filament.

A wire leads from this lamp to terminal No. 5 of the junction block on the dash, and from there a wire leads to the tail lamp. After the current passes through the tail lamp, it goes to ground, i.e., the frame of car. Thus the lamps are "in series," and the current has to pass through both bulbs before it reaches ground. It follows, therefore, that if the filament of either lamp burns out or the line is broken or ground disconnected, both lamps will go out. The wiring is arranged thus to warn the driver when the tail light is out.

Headlights (Bright) Circuit

When the center one of the three lighting buttons is pulled out, the headlight circuit is completed and current passes out through terminal No. 6 to terminal No. 6 of the junction block on the dash, and from there a wire leads to the front cross member of the frame, where it branches out immediately back of the radiator. One branch wire feeds the right-hand headlight, the other the left. After the current passes through the lamp bulb, it goes to ground. Since both lamps are fed from branches of the same wire, they are "in parallel."

Therefore if one bulb burns out, the other circuit is still intact, and the lamp on that side will continue to burn.

Headlights (Dim) Circuit

When the end lighting button is pulled out, the headlight circuit is completed, but instead of the current passing directly out through terminal (6), it first of all passes to (7), through the dimmer resistance. This is a coil of wire that has the effect of choking the current supplied to the headlights, and they do not burn so brightly, nor do they consume so much current.

If the headlights are operating "dim," it is unnecessary to depress the "dim" button in order to get them to operate at full candle power. Simply pull out the second button. This operation cuts out the resistance, because the current takes the easier path. If the second button is again depressed, the lights will operate "dim," as the current then passes through the resistance.

The Junction Block

The junction block is located on the engine side of the dash, near the left-hand side frame. It provides a handy means of disconnecting the lighting connections in case of trouble on any particular line, or when removing the body. For instance, if the circuit-breaker commences to vibrate or click when any of the lighting switches are pulled out (indicating a ground), it is obvious that any of the junction-block connections can be reached quickly and the wires can be disconnected one at a time till the faulty line is discovered.

Storage Battery

The storage battery is a three-cell, six-volt battery. The (−) battery terminal, as well as the (−) generator brush is grounded.

Never run the generator with the storage battery disconnected from the car. This is a "constant-current" system, as explained on page 346.

Ammeter Readings

Ammeter readings during cranking operation: During the cranking operation the ammeter will show a "discharge." This is the current that is used both in the shunt-field winding and the ignition current. The ignition current being an intermittent current of comparatively low frequency, it will cause the ammeter to vibrate during the cranking operation. If the lights are on, the meter will show a heavier discharge.

The main cranking current is not conducted through the ammeter, as this is a very heavy current and it would be impossible to conduct this heavy current through the ammeter and still have an ammeter that is sensitive enough to indicate accurately the charging current and the current for lights and ignition.

When the generator is charging the battery, the ammeter needle will be on the "charge" side of the scale.

DELCO MOTOR-GENERATORS (1921) THIRD-BRUSH REGULATED

Delco motor-generators and electric systems installed on the 1921 Buick and McLaughlin are shown in Fig. 1; on the Cadillac, in Fig. 3; on the Hudson, in Fig. 5; on the Lafayette, in Fig. 7; on the Lincoln, in Fig. 9. Wiring diagrams and the various circuits of each are also shown.

Each of the cars mentioned use a Delco motor and generator as a single unit, termed a "motor-generator."

There are two windings in the field and armature, one set for operation as a generator and one set when used as a motor to crank the engine. The generator armature winding and its commutator, together with the generator winding in the field coil, are connected in the circuit at all times when the ignition switch is "on," except when the starting pedal is depressed. There is no electrical connection between the motor and the generator windings on the armature. Third-brush regulation is used on all.

When the motor-generator is used to crank the engine, the motor windings are brought into use, and it operates as a series-wound motor. These windings are not in circuit with the battery until the motor brush, or brushes, make contact with the commutator by the action of the starting pedal.

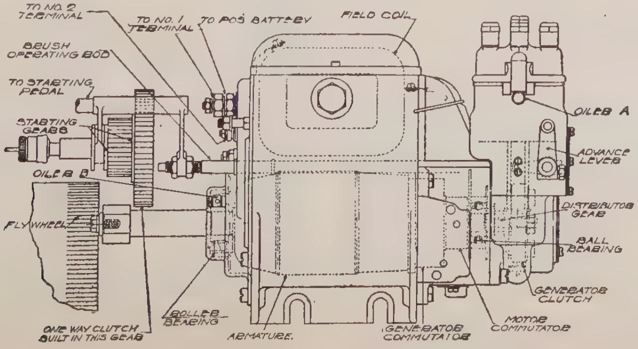

Fig. 1. Delco motor-generator used on the Buick and McLaughlin (1921).

When cranking the engine, the motor-generator drives the flywheel through a pair of sliding gears which are at the rear of the motor-generator and controlled by the starting pedal. An over-running clutch is built in the hub of these gears, so that the flywheel will not drive the generator through the starter gears after the engine starts running under its own power, and before the starter pedal is released.

The driver should make a practice of releasing the starter pedal as soon as possible after the engine has started running so as to insure long life and usefulness of the lubricant within the clutch.

When the engine is operating at slow speeds, the generator voltage is not sufficient to provide current for lighting or ignition. At such times the battery is the source of current. At low engine speeds also, current may flow from the battery through the generator windings and cause the armature to revolve faster than the engine drives it. Under this condition the over-running generator clutch at the forward end of the motor-generator permits the armature to revolve faster than the driving shaft, and makes a clicking noise.

During the time that the engine is driving the armature, the circuit between the generator winding and the storage battery is completed, allowing current from the generator to charge the storage battery and supply current directly for lights and ignition.

During the cranking operation, the generator circuit is interrupted by having one of the generator brushes raised off the commutator in the Buick model. The upper generator brush on the Buick type of motor-generator is raised.

A very great reduction in engine cranking speed will be the result if the generator circuit is not opened during cranking by the above method.

It may happen, through accident or otherwise, that the brush-lifting mechanism is bent in such a way that it fails to operate the generator brush as just described. Care should be exercised, in renewing the upper generator brush, to obtain one of the proper length. If too long, the brush-lifting mechanism may not function properly.

In the motor-generator applied on Cadillac and Hudson cars, this feature of opening the generator circuit during cranking is taken care of by a set of contacts in the rear end of the motor-generator housing, known as the generator switch and operated through the action of one of the motor brushes.

During the cranking operation the electrical current flows from the storage battery through the motor windings, causing the armature to rotate. The closing of this circuit is effected by the upper motor brush in the Buick model, and by both upper and lower motor brushes in the Cadillac and Hudson models. These are operated by the starting pedal.

The motor-generator performs three different operations, which are as follows:

1. **Motoring the generator:** This operation is necessary in order that the starting gears may be brought into mesh with the small gear on the armature shaft, and with the teeth on the fly-wheel. This takes place whenever the "ignition" switch lever is turned to position marked "on." This completes the circuit from the storage battery to the generator windings, and permits current to flow from the storage battery through the shunt-field coil and the generator windings on the armature, thus causing the armature to revolve slowly.

In meshing these gears, if difficulty is encountered, do not try to force them, but simply allow the starting pedal to come back, giving the gears time to change their relative positions.

The clicking sound heard during the motoring of the generator is caused by the over-running of the generator clutch in the forward end of the motor-generator. The "M.G. 82" used on 1918 Hudson cars was equipped with a smooth clutch. The motoring of the generator is one of the most important operations for the mechanic to familiarize himself with, as the same wiring and parts of the generator are used during this operation as when generating. Therefore, if this operation is performed properly, it is sure to generate when driven by the engine.

2. **Cranking operation:** The cranking operation is performed when the starting gears are brought fully in mesh and when the motor brush or brushes make contact with the commutator. It is arranged that the starting gears are properly meshed before the motor brush, or brushes, make contact on the commutator. The cranking operation requires a heavy discharge from the storage battery. There must be no loose connections in this circuit. All the battery connections, together with the ground-strap connections, the motor connections, and motor brushes must make good electrical contact.

3. **Generating electrical energy:** After the cranking operation is completed, the starting pedal is returned by a spring. This disconnects the starting gears, breaks the motor circuit, by raising the motor brush or brushes, and completes the generating circuit either through the generator switch, or, in the Buick model, by lowering the upper generator brush.

At car speeds of from five to seven miles per hour, the generator is generating a voltage sufficient to prevent current discharging from the battery through the generator windings. At higher speeds a part of the current generated is used directly for ignition and lighting purposes, while the remainder of the current is used to charge the storage battery.

The ignition distributor is located on the forward end of the motor-generator on the Buick models, and is for the purpose of properly timing and distributing the ignition current. Separate distributor units are installed on Cadillac and Hudson models, and are driven from the timing gears. See the instruction on "Ignition."

The operation of the distributor on the Buick car in no way affects the motor-generator, it being located in this manner simply as a convenient method of mounting and driving.

DELCO ELECTRIC SYSTEM ON THE BUICK (1921)

Generator field circuit: From (+) main brush, to (2) (Fig. 2), to (3), to (F), to the generator shunt-field winding, to third (−) brush (3B).

Generator charging circuit: From (+) main brush, to (2), to (1), to the ammeter, to (+) battery, to (−) ground of the battery (GB), to (−) ground of the generator (GG), to the (−) generator, main brush.

Ignition primary circuit: From (1) on the combination switch, if the current is from the battery as when starting, or from (2), if the current is from the generator after the engine is running, thence to (3), to the ignition resistance unit on the coil, to primary winding (PRY), to contact-breaker points (P), to ground, to (−) of battery or (−) of generator.

Starting motor circuit: From (+) of the battery, through the motor-series field coil, to the (+) motor brush, through the armature, to the (−) grounded brush, to (GM), to the (−) grounded battery terminal (GB).

Motoring generator field circuit: When first depressing the starting pedal, the generator is "motored," and current flows from (+) of the battery, through the ammeter, to (1), to (3), to (F), to (3B) for the shunt-field circuit. For this about 5 amperes are required. This makes it easy for the gears to mesh, as the generator armature turns over slowly.

The armature circuit, during the motoring operation of generator, is from (+) of the battery, through the ammeter to (1), to (2), to (A), to (+) brush, to the armature, to the (−) grounded brush, to (GG), to (GB).

As the starting pedal is depressed still more, the (+) motor brush is lowered to the commutator and the generator brush (A) is lifted; the series field of the motor and the armature winding of the motor receive the full current from the battery, and the engine is started through the starting motor circuit as first explained.

When the engine starts, and the starting pedal is released, the gears to the flywheel are thrown out of mesh, the (+) motor brush is raised, the generator brush (A) is lowered, and the generator begins to generate current at over 300 r.p.m. Thereupon the circuit is as explained under "generator circuit."

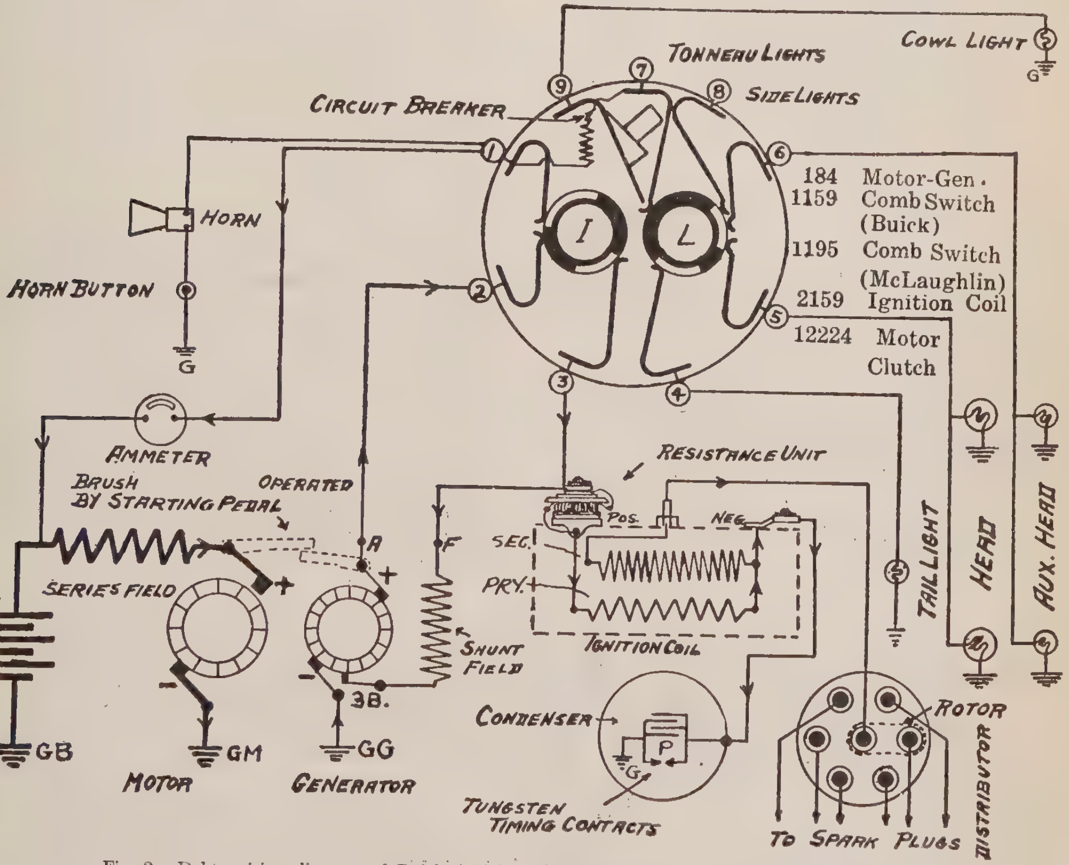

Fig. 2. Delco wiring diagram of Buick (1921), series 21; models 44 and 50, and also McLaughlin.

DELCO ELECTRIC SYSTEM ON THE CADILLAC TYPE 59 (1921)

The Delco motor-generator (Fig. 3) is used on the Cadillac. The regulation is by means of a third brush. It is therefore a constant-current-regulated generator of a 6-volt system.

A thermostatically controlled protective device operates in case of excessive charging current, to protect the generator from over-heating and the battery from over-charging. Provision is made for mounting the device on the third-brush arm in such a position that it may readily be influenced by radiated generator heat.

The thermostat consists essentially of a coil of resistance wire and a set of contacts. The blade holding one of the contact points is made from a piece of bi-metal—a strip of brass welded to a strip of nickel steel—a combination which warps at its free end when heated, owing to the greater expansion of the brass side. The contacts, normally closed, are caused to separate at a temperature of 195°-200° F. within the generator. Thus the field current which passed through the contacts is shunted through a resistance. The direct-field circuit is restored as soon as the temperature has again become normal.

No attention need be given to the thermostat, and its operation, which is accomplished by a sudden drop of 50 per cent in the ammeter reading, should cause no concern.

Motor-generators used on the Cadillac, Lafayette, Lincoln, and Wills cars, each have four field coils, two of them being shunt coils and two series coils. Each pair of coils is mounted opposite in the frame. Thus it operates as a four-pole shunt generator, although field windings are used on two poles only, the other two acting as consequent poles.

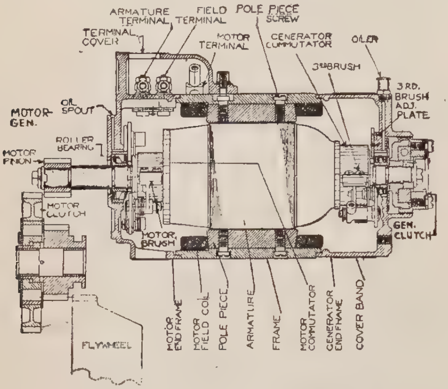

Fig. 3. Side sectional view of the Delco-Cadillac motor-generator.

Cranking operation: When the starting gears are meshed, the motor brush or brushes make contact with the commutator. Note that the motor brushes **take the place of a starting switch.**

Generating current: After the cranking operation is completed, the starting pedal is returned by the spring. This disconnects the gears, breaks the motor circuit by raising motor brushes, and completes the generating circuit through the generator switch.

These operations can be clearly understood by referring to the diagram (Fig. 4) and the illustration (Fig. 3).

Cadillac-Delco Circuits

Generator field circuit: From the (+) third brush (Fig. 4), through the thermostat points, to the shunt-field windings, to (8), to (6), to the (—) generator brush. When the thermostat points are open, resistance (**R**) is automatically cut into the shunt-field circuit.

Generator charging circuit: From the (+) grounded main brush (**G1**), to the (+) grounded battery, to the ammeter, to (5), to (6), to the generator switch (**A**), to minus (—) of the main brush.

Ignition primary circuit: From (+) ground of the battery, or the generator after it is running fast enough to charge the battery, to ground (**G**) of the contact-breaker points (note the two points in multiple), through the ignition resistance unit, through the coil primary winding (**P**), to (7) on the combination switch to (6) if the generator is supplying current, to the generator switch (**A**), to the (—) generator brush. If the battery is supplying the current, then to (5), to the ammeter, to the (—) terminal of the battery.

Starting motor circuit: From (+) ground of the battery, to the (+) grounded brushes (**G2**), which are lowered to the commutator by movement of the starting pedal which shifts the gear in mesh with the flywheel gear and at the same time opens the generator circuit at generator switch (**A**), then through the armature, to (—) brushes, through the series-multiple field windings, to the (—) terminal of the battery. Thus the action of the motor brushes serves as a starting switch. After the engine is started and the starting pedal is released, the motor brushes are again raised and consequently generator switch (**A**) is closed by this action.

The vibrating and locking circuit-breaker is made use of in the manner described and explained on page 392.

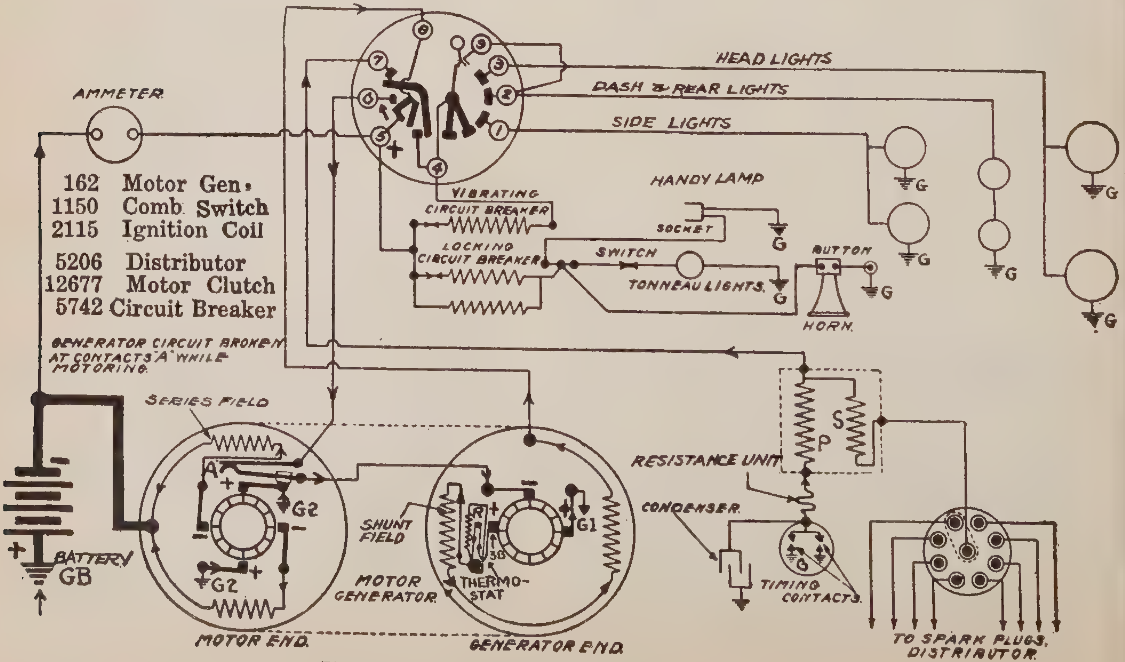

Fig. 4. Delco wiring diagram of Cadillac type 59 (1921).

DELCO ELECTRIC SYSTEM ON THE HUDSON MODEL "O" (1921)

The Delco motor-generator used on the Hudson "Super-Six," model "O," is shown in Fig. 5, and the explanation given on page 393 will serve in this case also.

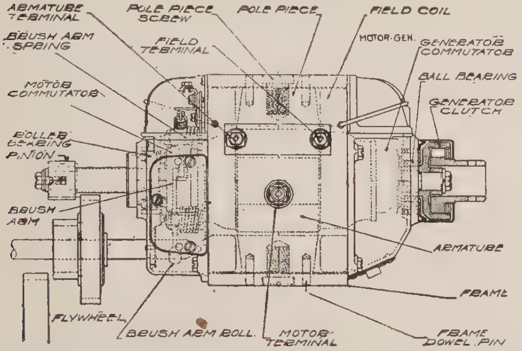

Fig. 5. Side sectional view of the Delco-Hudson model "O" motor-generator.

This is a two-pole machine with a single armature having a separate generator and motor windings connected to separate commutators. Above the armature is a motor series coil and a generator shunt-field coil. Below the armature is a series-field motor coil and a shunt-field generator coil.

Hudson-Delco Circuits

Starting motor: From (+) of the battery (Fig. 6), to the motor-series field coils, to the motor (+) brush, through the armature, to the (–) brush, to ground, to (GB) ground of the battery. The motor brushes are lowered by starting the pedal when the gears are shifted to mesh with the flywheel. At the same time, generator switch (A) is opened. Thus the action of the brushes serves as a starting switch. When the engine starts, and the starting pedal is released, the motor brushes are raised and generator switch (**A**) is closed.

Generator shunt-field circuit: From the (+) brush of the generator, to (2) on switch, to (3), to the generator shunt-field winding, to the third brush.

Generator charging circuit: From the (+) brush, to the generator switch (**A**), to (2), to (1), to the ammeter, to (+) of the battery, to the (–) battery ground (**GB**), to the (–) ground of the generator (**GG**).

Primary ignition circuit: From (1) on the combination switch, if from the battery, or from (2) if from the generator, to (3), to the coil primary winding (**P**), to the ignition resistance unit (**R**), to the contact-breaker points (**P**), to ground, to the (–) ground of the battery or to the minus ground of the generator.

Secondary ignition circuit: From secondary winding (**S**) of the coil, to the distributor, to the spark plugs, to ground, to ground of the battery or generator, to the other end of (**S**).

The circuit-breaker used in this model is of the vibrating type.

The following will assist in tracing the different circuits. To trace, **start** with the part mentioned in brackets: starting-motor circuit [+ of battery]; generator shunt field circuit [+ main brush of generator]; generator charging circuit [+ main brush of generator]; primary ignition circuit [start with 1 on switch if from battery, or 2 if from generator]; secondary ignition circuit [secondary winding S of ignition coil].

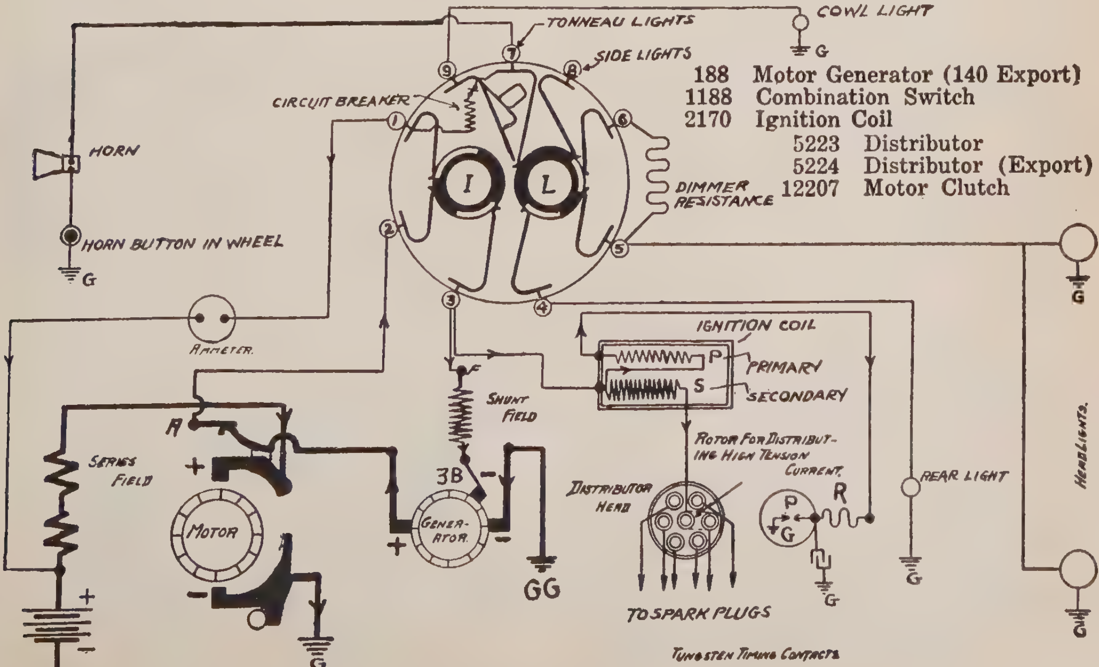

Fig. 6. Delco-Hudson model "O" wiring diagram (1921).

DELCO ELECTRIC SYSTEM ON THE LAFAYETTE (1921)

The **Delco motor-generator** used on this car is explained on pages 393 and 394. An illustration of this is shown in Fig. 7.

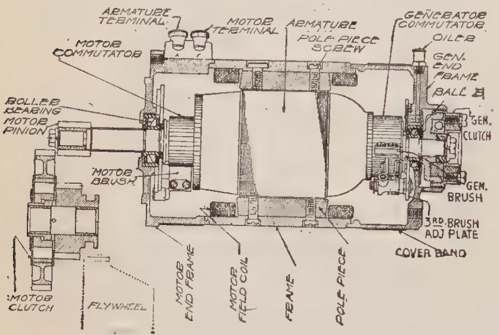

Fig. 7. Side sectional view of the Delco-Lafayette (1921) motor-generator.

Lafayette-Delco Circuits

Starting motor: From the (+) grounded battery terminal (Fig. 8), to the (+) grounded brushes of the motor, through the armature, to the (—) brushes, to the series-parallel field windings, to the (—) terminal of the battery. The motor brushes are lowered to the commutator by the action of the starting pedal, which thus serves as a starting switch.

Generator field-circuit: From the (+) third brush, through thermostat (T), to shunt-field coils, to (8) on switch, to (6), to (—) generator brush.

Generator charging circuit: From (+) grounded generator brushes, to (+) grounded battery terminal, to ammeter, to (5) on combination switch, to (6), to generator switch (A), to (—) main brush.

Primary ignition circuit: From the (+) ground of the battery, or generator, to ground (G) of the contact-breaker, through the resistance unit, to primary coil winding (P), to (7), to (6), if the current is from the generator, back to the (—) brush of the generator, or to (5), if from the battery, to the (—) battery terminal.

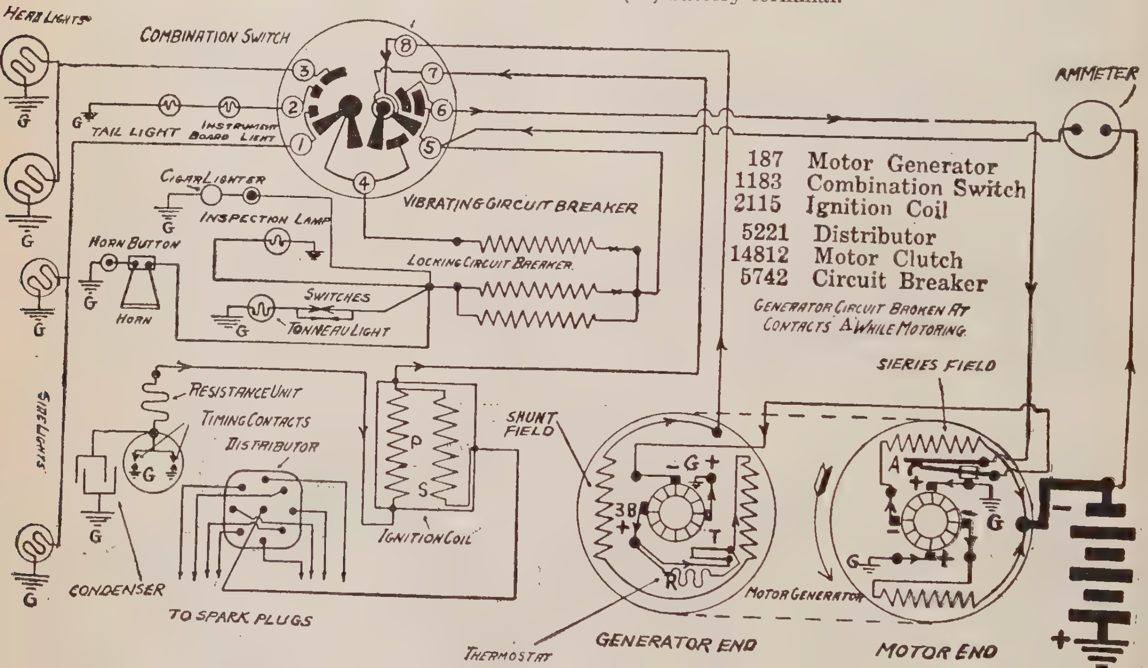

Fig. 8. Delco-Lafayette (1921) wiring diagram.

DELCO ELECTRIC SYSTEM ON THE LINCOLN (1921)

The **Delco motor-generator** used on the Lincoln is shown in Fig. 9; its principle is explained on pages 393 and 394.

Lincoln-Delco Circuits

Starting motor: From the (+) battery terminal (Fig. 10), to the series parallel fields, to the (+) brushes which are lowered to the commutator when the starting pedal shifts the gears into mesh with the flywheel through the armature, to (—) brushes (G) which are lowered by the same action, to (—) ground of the battery. Thus the action of the motor brushes serves as a switch. The generator switch (A) is opened when the brushes are lowered and closed when the starting pedal is released and the motor brushes are raised.

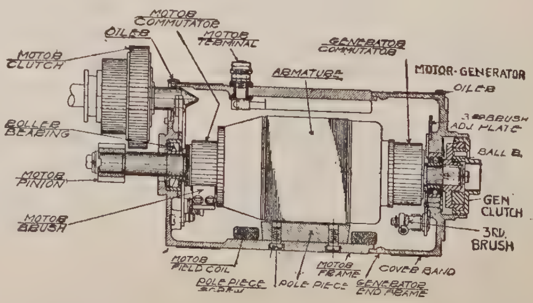

Fig. 9. Side sectional view of the Delco-Lincoln (1921) motor-generator.

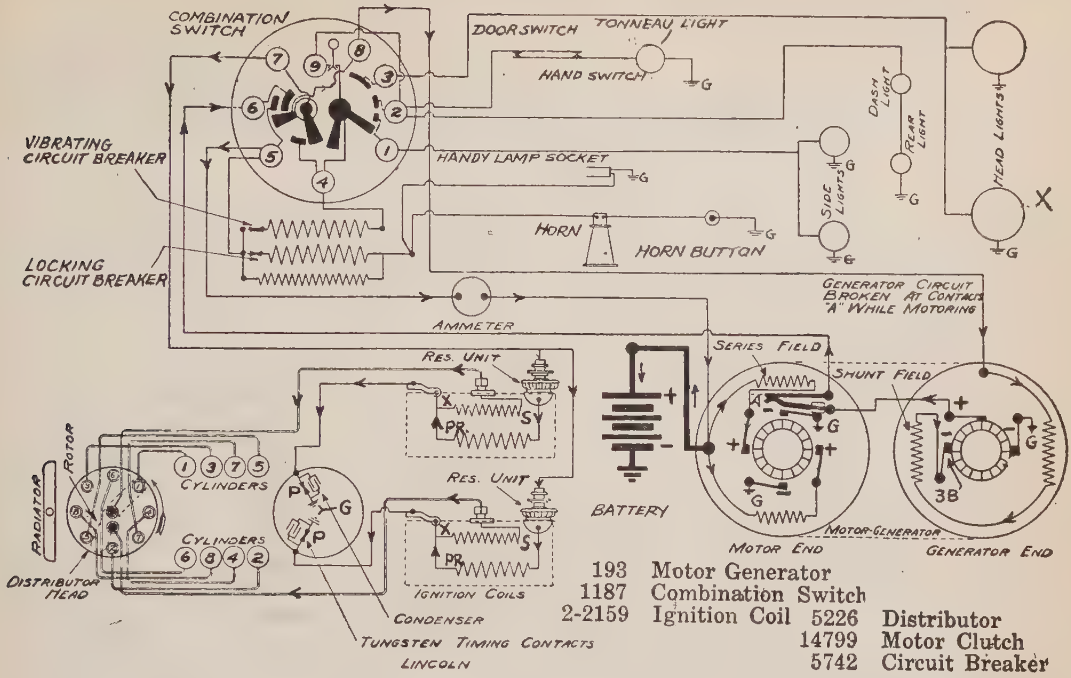

Fig. 10. Delco-Lincoln (1921) wiring diagram.

Generator shunt-field circuit: From (+) brush, to and through switch (**A**), to (6) on combination switch, to (8), to generator shunt-field windings, to (−) third-brush.

Generator charging circuit: From (+) brush, to generator switch (**A**), to (6), to (5), to ammeter, to (+) battery terminal, to (−) battery terminal, to (−) grounded main generator brush.

Primary ignition circuit: From (5) on the combination switch if the battery is supplying current, or from (6), if current is from the generator, then to (7), to the ignition resistance unit on the ignition coils, connected in multiple, to primary windings (**PR**), to contact-breaker points (**P**), to ground (**G**), to the (−) ground of the battery or generator. For details see Index under "Lincoln distributor and contact-breaker."

Secondary ignition circuit: From secondary windings (**S**), to the distributor, to the spark plugs on the right and left cylinder blocks, to ground, to the ground of the battery or generator, back to the primary windings of the coils, to (**X**), where the secondary joins the primary.

A vibrating and locking type of circuit-breaker is used.

DELCO SEPARATE GENERATORS AND MOTORS (1921)—THIRD-BRUSH REGULATED GENERATORS USING CUT-OUTS

Examples of Delco separate generators and motors with third-brush regulated generators using cut-outs are given in the pages following, the Marmon 1921, model 34B, H.C.S. 1921, Moon 1921, Westcott 1921, and Pierce-Arrow series 32, being selected for the purpose. The last-mentioned uses an electromagnetic principle of regulation in addition to the third brush.

MARMON 1921 MODEL, "34B"

The Delco electric system is used, consisting of a separate four-pole starting motor with a Bendix drive and field windings connected in multiple-series.

The generator is a four-pole generator, third-brush regulated, constant-current type, with the ignition unit attached to the generator, and it is thus a "two-unit" system.

A cut-out is used as shown in Fig. 12, mounted on the drive end of the generator.

Starting circuit: When the starting switch is depressed, the starting circuit is from (+) ground of terminal (**GB**) of the battery (Fig. 11), through the (+) grounded brushes (**G**), through the armature, through the (−) brushes, through fields, through starting switch to (−) terminal of battery.

The generator (Fig. 12) consists of a four-pole shunt-wound, third-brush-regulated constant-current generator which is separate and distinct from the motor. See also the wiring diagram.

The generator shunt-field circuit is from the third brush (+) through the four field windings, to the (−) main brush, through the armature coils, back to the third brush.

The cut-out[1] is placed on the top of the generator (Fig. 12), at the commutator end of the generator.

Cut-out voltage winding: After starting the engine, current from the generator (+) main brush passes from the (+) grounded main brush (**G1**),

---

[1] Adjustment of this cut-out is shown elsewhere. See Index under "Adjusting Delco cut-out."

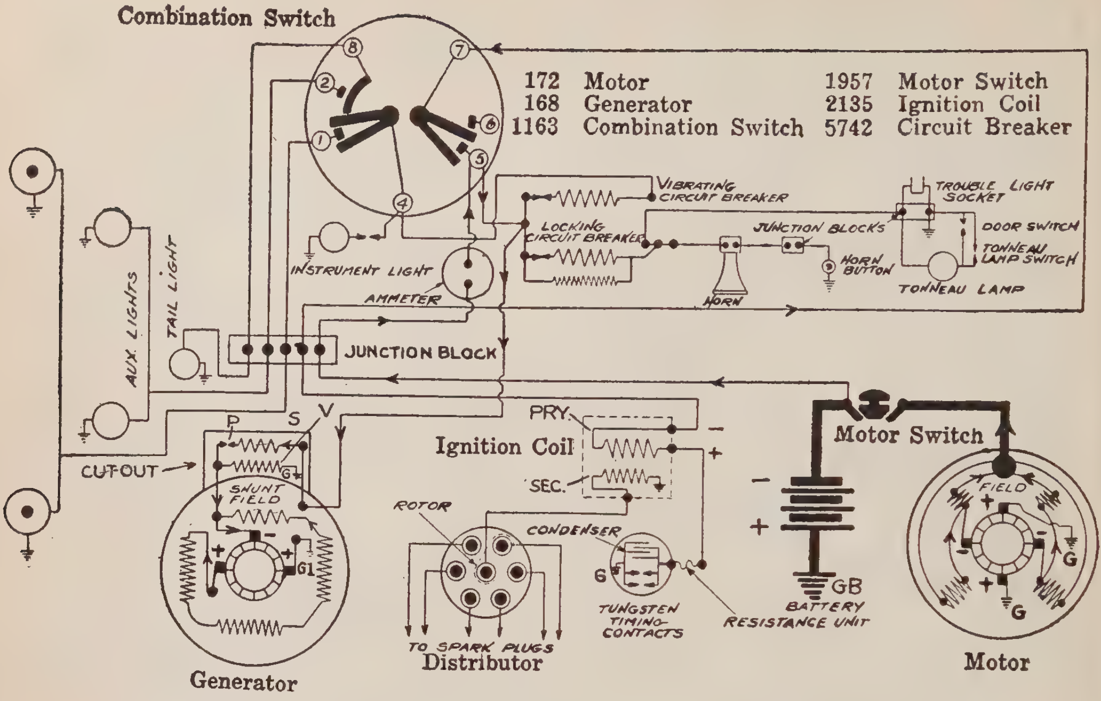

Fig. 11. Delco-Marmon model "34-B" wiring diagram. Note that the generator and motor are separate.

through the grounded end of voltage (V) fine wire winding (G) of the cut-out, to the (−) main brush of the generator. When the speed of the generator increases to where the generator voltage reaches 7 to 8 volts, the silver cut-out points (P) close.

Charging circuit: When cut-out points (P) close, the charging circuit is then from the grounded end of the (+) main brush (G1) of the generator, to the (+) grounded terminal of the battery (GB), through the battery, through the ammeter, to the switch terminal (5), to the cut-out current winding (S), through the cut-out points (P), to the (−) main brush of the generator.

When the generator speed decreases to where the generator voltage is less than the battery voltage, then cut-out points (P) should open. Just before doing so, however, the battery discharges back through the current coil (S) of the cut-out in a reverse direction, in order to demagnetize the iron core on which this winding is wrapped. This amount of current which passes in reverse direction from the battery should not be over 2 amperes.

Ignition: The interrupter and distributor and ignition coil are mounted on rear end of generator (Fig. 12). The distributor shaft is driven at half engine speed by spiral gears from the armature shaft.

An automatic governor spark-advance mechanism is incorporated in the vertical shaft.

Interrupter: Two sets of contact-breaker points are connected in parallel (see wiring diagram), and are separated at the same time by one cam with lobes opposite each other (see also page 214). The adjustment screw in center of cam is for timing.

The condenser, connected across both points, and is mounted on outside of distributor-timer housing.

For timing the ignition and adjusting the contact-breaker points see page 220.

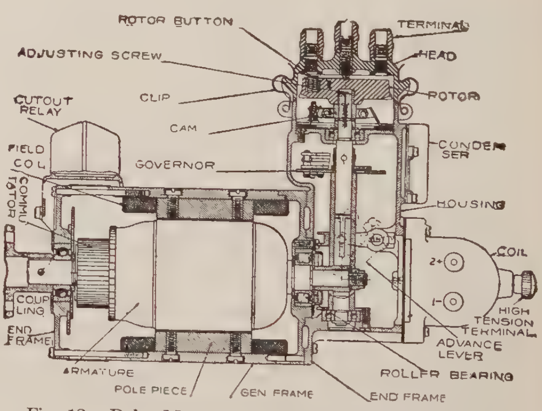

Fig. 12. Delco-Marmon (model "34-B") generator with ignition unit and cut-out mounted on the generator.

The ignition circuit (see wiring diagram) is from the grounded (+) terminal of the battery, through the grounded contact points on the left side of the contact-breaker at (G), through the resistance unit, through the primary winding (**PRY**) of the ignition coil, through the junction block, through the switch terminal (7), through the switch blade, through the ammeter, back to the battery (−) terminal.

If the generator is supplying the current, the circuit is from (5) to and through the cut-out series coil, to the (−) main generator brush.

The ignition resistance unit is connected in series with the primary winding and prevents excessive discharge from the storage battery when the engine is not operating and the ignition switch is turned "on." It also causes the spark to be more nearly uniform at all speeds of the engine (see explanation, page 198).

DELCO ELECTRIC SYSTEM ON THE H.C.S. (1921-22) AND MOON "6-68" (1921)

"H.C.S." stands for Harry C. Stutz. The generator and motor are each separate units on this car.

The generator is of the round type with a cut-out mounted on the generator similar to that of the Marmon. The third-brush regulation is used.

H.C.S.-Delco Circuits

Starting motor: From (+) of the battery to the starting switch, to the series-parallel field windings of the starting motor, to the (+) brushes, to the (−) brushes, to ground, to the (−) ground of the battery. The Bendix drive is used.

Generator shunt-field circuit: From the (+) main brush, to the shunt-field windings, to the third brush.

Cut-out voltage circuit:[1] From the (+) main brush, to cut-out voltage coil winding (V), to ground (G), to the grounded (−) main brush of the generator (G).

Generator charging circuit: From the (+) brush, to the cut-out points (P closed), to the cut-out series winding (S), to (5) on the switch, to the ammeter, to the (+) terminal of the battery on combination, to (−) ground of the battery, to the (−) grounded main brush of the generator.

Primary ignition circuit: When starting, and the generator is operating at low speed, current for ignition is from the battery, as follows: From the (+) battery terminal, to the ammeter which shows slightly on the "discharge" side, to (5) on the switch, to (7), to primary winding (PRY), to the resistance unit on the contact-breaker (interrupter), through points (P), to ground (G), to (−) ground of the battery.

When the generator supplies current: From (5), to (7), and thence along the same path. The ammeter will then indicate the amount of current passing to the battery (on the "charge" side of the ammeter).

Secondary ignition circuit: From the secondary winding, to the distributor rotor, to the spark plugs, to ground, to ground of the generator, if it is supplying current, or to the battery ground if it is supplying current, to (5) on the switch, to (7), to the primary winding, to point (X) in the coil where the secondary joins the primary winding.

The circuit-breaker is placed between the source of electric supply at (5) on the switch and the lighting circuits, to (4), to 3, 2, 1, 8, and 9.

Timing Delco-Moon Ignition

1. Place the spark lever on the steering-wheel sector in fully retarded position.

2. Turn the engine over with the crank until No. 1 piston is just past top dead center on the flywheel at the end of the compression stroke.

3. Loosen the timing adjustment screw in the center of the distributor shaft and turn the breaker cam so that the rotor button will be in position under No. 1 terminal, with the distributor head properly located. Locate the breaker cam carefully in this position, so that when the slack in the distributor driving gears is rocked forward, the contacts will be just opened by the breaker cam, and so that when the slack in the gears is taken up by rocking backward the contacts will just close.

4. Tighten the adjustment screw securely, and replace the rotor and distributor head.

Note. **The Moon ignition resistance unit** is mounted on the coil instead of on the contact-breaker.

---

[1] See page 409 for cut-out adjustments.

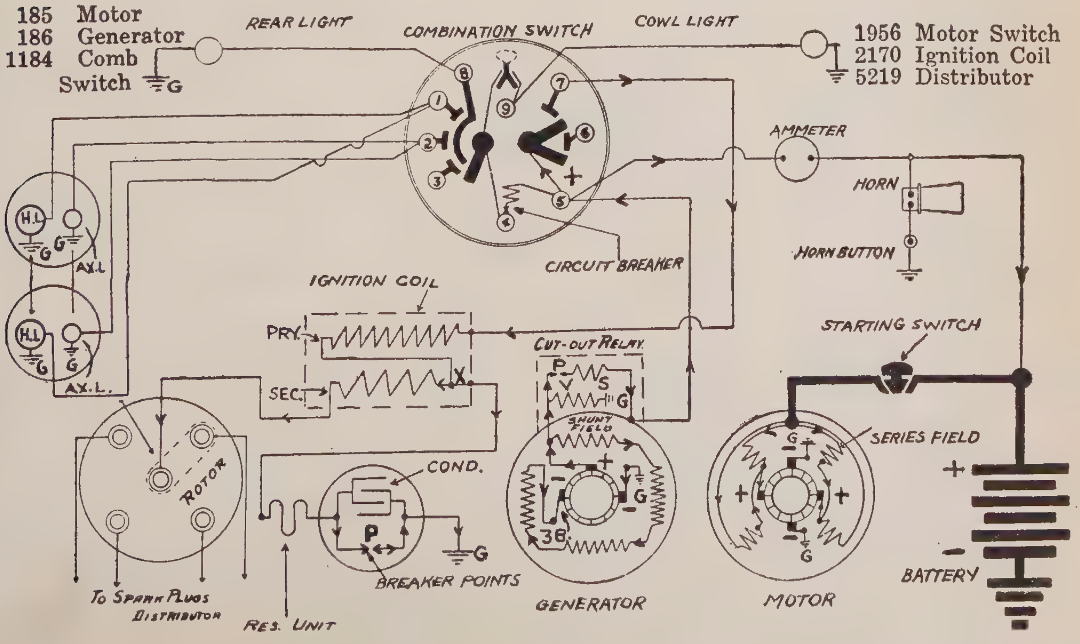

Fig. 13. Wiring diagram of Delco-H.C.S. (1921–22) electric system, using the Weidely "MB" engine. Note that the generator and motor are separate. On the first five-hundred cars the "headlights" were connected to No. 3 terminal on the switch.

DELCO-WESTCOTT ELECTRIC SYSTEM (1921)

The generator on Type "C-48" is mounted on the right-hand side of the engine, and on the Type "C-38" it is mounted on the left-hand side. It is so designed that it starts to generate at approximately seven miles per hour in high gear or at correspondingly lower speeds in low gear. The generator output is increased to speeds of 18 to 25 miles per hour. At higher speeds the charging rate decreases.

To adjust the charging rate, see directions given on pages 407 and 409.

Cut-out adjustments are effected as shown on pages 409 and 410.

The ignition distributor on the "C-48" is mounted on the right-hand side of the engine and is driven by the pump shaft, while on the "C-38" the distributor is mounted on the left-hand side. The distributor is equipped with both a manual and an automatic control.

Timing the Ignition (Types "C-48," "C-38")

1. Place the spark lever on the steering-wheel sector in fully retarded position.

2. Turn the engine over with the crank until No. 1 piston is 1⅜" past top dead center on the flywheel at the end of the compression stroke.

3. Loosen the timing adjusting screw in the center of the distributor shaft and turn the breaker cam so that the rotor button will be in the position under No. 1 high-tension terminal with the distributor head properly located. Locate the breaker cam carefully in this position, so that when the slack in the distributor driving gears is rocked forward the contacts will be just opened by the breaker cam; and when the slack in the gears is taken up by rocking backwards the contacts will just close.

4. Tighten the adjustment screw securely and replace the rotor and distributor head.

Westcott-Delco Circuits

Starting motor: From (+) of the battery to the switch, to the series-parallel windings, to the (+) brushes, to the (−) brushes, to ground, to (−) ground of the battery. Bendix drive is used.

Generator field circuit: From the (+) main brush, to the shunt field windings, to the (−) third brush.

Cut-out voltage winding: From the (+) main brush, to (V), to (G), to the (−) grounded main generator brush.

Generator charging circuit: From the (+) brush, to cut-out closed points (**P**), to cut-out series coil (**S**), to (1) on the combination switch, to the ammeter, to (+) of the battery, to (−) of the battery, to the (−) brush of the generator.

Primary ignition circuit (battery): From (+) of the battery, to the ammeter, to (1), to (3), through the ignition resistance unit, to the primary winding of coil (**P**), to contact-breaker points (**P**), to ground, to (−) ground of the battery.

Primary ignition circuit (generator): From (1) on the combination switch, to (3), through the same path as just described.

Secondary ignition circuit: From (**S**) on the ignition coil, to the distributor rotor, to the spark plugs, to the ground of the battery or generator, to (1), to (3), to the resistance unit on the coil, to (**X**), where the secondary circuit joins the primary.

The circuit-breaker is shown at (**C**) on the combination switch.

The ammeter should always indicate the charge when the car is being driven at speeds faster than eight miles per hour with the lights off. With the lights on a slight discharge will be indicated at slow speeds. The lamp load will also reduce the charging rate at high speeds, as there will be a corresponding reduction in the amount of current passing through the storage battery.

The ammeter indicates the amount of current passing to or from the storage battery, but does not indicate the actual generator output. Should the ammeter indicate discharge at normal driving speeds, it should be taken as an indication of trouble and the electrical equipment should be checked over.

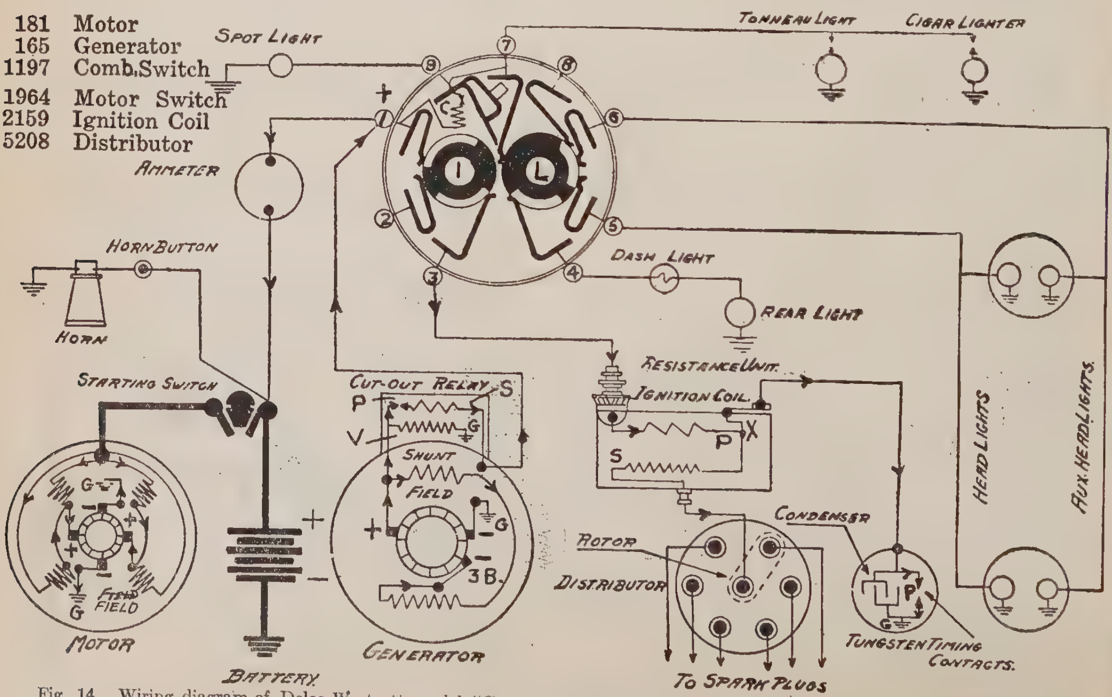

Fig. 14. Wiring diagram of Delco-Westcott model "C-38," using "7-R" Continental engine. Note that the generator and motor are separate.

PIERCE-ARROW (1921) MODEL SERIES 32—A DELCO THREE-UNIT SYSTEM

The generator is an example of a Delco shunt-wound, "constant-current," third-brush regulated generator and also of a "constant voltage" regulation (by means of an electromagnetic voltage regulator). The generator and starting motor are separate units.

Generator Circuits

Circuit from generator through voltage coil of cut-out: Start with the (+) grounded main brush (G) of the generator, to ground (G1) on the "apparatus box," through the cut-out voltage coil to (A), then to terminal (A) of the generator, to the (−) brush.

Charging current from generator to battery: When the generator voltage is more than the battery voltage, then the voltage through the cut-out voltage coil is strong enough to magnetize its core and the cut-out points (P) close (they close at 6¼ to 6½ volts) and the charging-current path is as follows: Start with the grounded (+) main brush (G) on the generator, to the grounded (+) terminal of the battery (GB), through the battery, through the ammeter to junction box terminal (2), through the 30-ampere fuse, through the bus-bar to (4), thence back to terminal (B) on the apparatus box, up through the current coil of the cut-out, through cut-out points (P), through ground (X) (dotted lines) to (A), thence to the (−) terminal (A) of the generator main brush.

Battery discharge circuit: When the generator is slowed down and the voltage drops to less than the battery voltage (less than 6¼ volts), then the battery will discharge back through the current coil of the cut-out in a reverse direction. While doing so, the cut-out contact points (P) should open with the discharge from the battery through the current coil of the cut-out of less than 3 amperes. The circuit is as follows: Start with the (+) grounded terminal of the battery, through the (+) grounded main brush of the generator, through the armature, to (A), to (A) on the apparatus box, up through the dotted lines and cut-out points (P), through the cut-out current coil (note that the current from the battery is now flowing in a reverse direction, thus demagnetizing the cut-out core), to (B), to (4) on the junction box, to (2), then back to (−) terminal of the battery.

Generator shunt-field circuit: Start with the (+) third brush at left, then through the four shunt-field coils (this is a four-pole generator) to the (F) terminal of the generator, thence to the (F) terminal on the "apparatus box," through the regulator closed points (RP), down dotted lines to (A), thence to terminal (A) of the generator, to the (−) brush of the generator. Note that in this instance the generator field current is flowing around the regulator coils, and is, therefore, not generating too high an output.

Purpose of the Voltage Regulator

With a discharged battery, insufficient current is forced through the voltage coil of the regulator to cause the regulator vibrating points (RP) to operate. Hence these points remain closed, thus causing the generator to operate as a third-brush machine.

As the battery approaches a condition of full charge (approximately 1.250 specific gravity or more), sufficient current is forced through the voltage coil of the regulator to cause contact points (RP) to open and to begin to vibrate. This action cuts down the field current of the generator, which in turn reduces the generator's charging rate. This is a desirable condition when the battery approaches full charge.

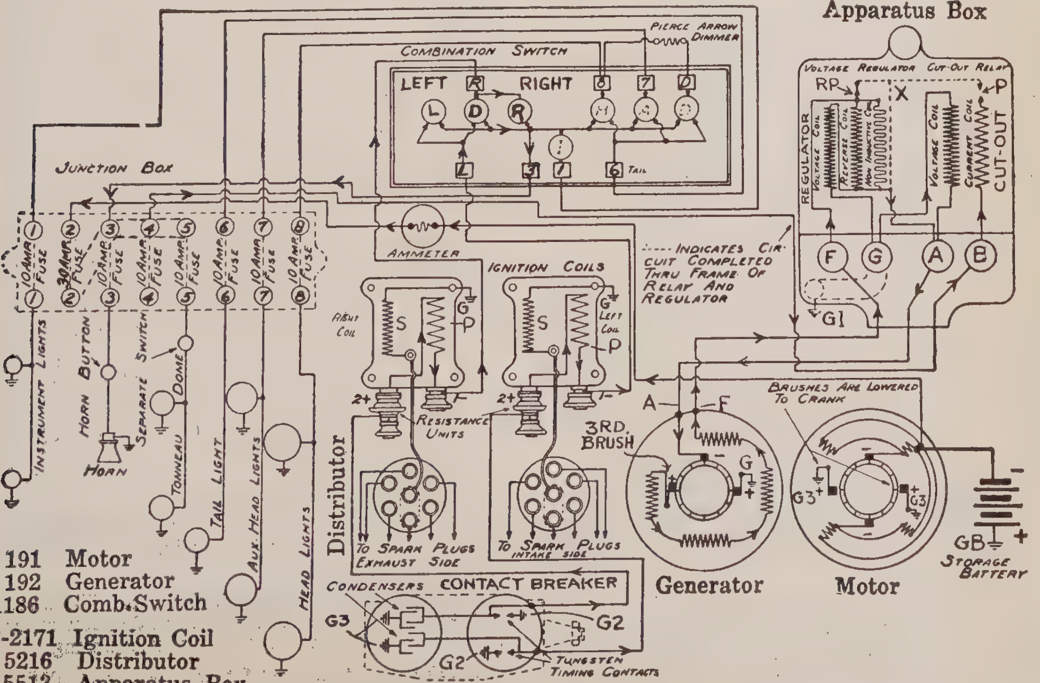

Fig. 15. Wiring diagram of Delco-Pierce-Arrow (1921, series 32). Note that the generator and motor are separate.

The vibrating voltage regulator consists chiefly of an electro-magnet having three windings and a set of contact points (RP) normally closed, which can be opened by the magnetic influence of the current through the regulator voltage winding.

The winding of the voltage coil consists of a large number of turns of fine copper wire around the core. This winding is connected directly across the main generator circuit.

The two other coils consist of: first, a reverse winding consisting of a large number of turns of fine wire wound around the core in the opposite direction to the voltage winding; and, second, the non-inductive winding having half its turns wound in each direction around the core. The reverse and non-inductive windings are in parallel with the contacts and add resistance to the field circuit when the contacts (RP) are open. This prevents the generator output from becoming excessive at high car speeds by weakening the strength of the generator field. Arcing at the contacts is prevented by the non-inductive winding.

The **reverse coil of the regulator** is balanced in ampere turns to counteract the action of the voltage coil and to allow the spring to close the contacts. This action is sluggish, owing to the high resistance of the reverse coil, so the non-inductive coil is connected in parallel with the reverse coil to cut down the resistance in the field-circuit. It has no magnetic effect on the regulator core, but gives a high-speed action to the regulator armature, as the generator will build up more rapidly.

To Test Opening of Regulator Points

A reliable voltmeter must be used to check the voltage of the generator. Connect the voltmeter leads: one to the main generator terminal (**A**), and the other to ground. With the storage battery in a fully charged condition, or removed entirely from the circuit, a maximum voltage with the generator in operation should be 7¾ volts. Above this voltage the regulator points (**RP**) will open and thus cause the resistance of the regulator reverse coil and the non-inductive coil to be cut into the field circuit. This reading should be checked at different engine speeds. Increasing the tension in the spring by means of the adjustment nut on the regulator will raise the voltage when points (**RP**) open, and decreasing the spring tension will lower the voltage.

Cut-in voltage limits of the cut-out in the "apparatus box," which is a part of the Pierce-Arrow equipment, are from 6¼ to 6½ volts.

Cut-out points open when the generator voltage is less than the battery voltage, and the battery should discharge back through cut-out current coil with less than 3 amperes. The correct amount shown on the dash ammeter (all lights off) should be approximately 4 amperes, as ignition is included.

For cut-out adjustment, see page 409.

Pierce-Arrow-Delco Ignition

Refer to the wiring diagram, and note that there are **two sets of tungsten contact-points** on the circuit-breaker, as well as two distributors and two ignition coils. Each set of contact-points is connected to separate coils.

There are **two sets of spark plugs:** one set in the "exhaust side," and the other set on the "intake side" of the "T-head" type of engine with dual valves. Thus "double ignition" is provided, or either the "single" or "double" system may be operated by the ignition switch control.

The double ignition is recommended, where two spark plugs are fired in each cylinder simultaneously. The result is an increase in power and greater mileage per gallon of gas than if the single system is used. The reasons for this are explained on pages 263 and 216.

The single ignition system would probably only be used for testing out one system independently, or under special conditions where the storage battery might be badly discharged. It is therefore desirable to use no more battery current for ignition purposes than necessary, until the battery has been recharged.

Automatic advance: The double distributor is equipped with a device which automatically advances the spark in proportion to the speed of the engine.

Ignition switch: The ignition system is controlled by the three buttons (see wiring diagram) to the left of the key opening in the panel. The first, or the one marked "L," when pulled out operates that ignition set terminating in the spark plugs on the left or inlet side of the engine. The button (**R**) controls the ignition set terminating in the spark plugs on the right or exhaust side of the engine. Each button operates the respective single systems. These buttons should only be used when the necessity arises to test out one system.

The button marked (**D**) "double" operates both systems, and should be used at all times for starting and running purposes.

The panel or switch key cannot be withdrawn unless all ignition switches are in the "off" position.

To lock the ignition, push in all ignition buttons, turn the key to the right, and withdraw.

Note that the switch panel can be locked with the "Aux" and instrument panel light (1) on.

Ignition coil primary circuit (right coil): Start with the (+) terminal of the battery (**GB**), to ground (G2) of the upper contact-points of the contact-breaker, to the (+2) terminal of the right coil, through primary winding (**P**), to terminal (−1) of the coil, to the switch at (**R**), to (3), to (3) on the fuse block, thence to (2), to the ammeter, to the (+) terminal of the battery (if the battery supplies current for ignition), or to (4) on the fuse block, to (**B**) below the cut-out, through the cut-out series winding, to (**X**), to (**A**), to (**A**) on the generator, to the (−) brush of the generator (if the generator supplies current when charging the battery).

Ignition coil primary circuit (left coil): The circuit is practically the same as for the right coil, except that the path is through the lower contact-points of the circuit-breaker, to the primary winding of the coil, to (**L**) on the switch, to (3), and thence as above.

Note. If the systems (right or left coils) are used separately, the (**L**) switch button or the (**R**) switch button is used. If both coils are used, then the double switch button (**D**) is used.

Note that **there are two condensers,** one for each set of contact points, which are connected across the primary circuit.

The secondary circuit is from the secondary coil (**S**) to the distributor, through the spark plugs to ground of the engine, to grounded end (**G**) of the secondary winding.

See **Figs. 8 and 9, page 216,** for an illustration of the Pierce-Arrow double ignition distributor, and **pages 217, 220, and 221,** for "Ignition timing."

Breaker points are set for an opening of .018″ to .027″; **spark-plug gaps,** .030″, or about 1/32″; size of spark plug, ⅞″ A.L.A.M.

Pierce-Arrow Starting Motor

The starting motor is a separate unit on the Pierce-Arrow, as well as in the Marmon, and many other Delco systems.

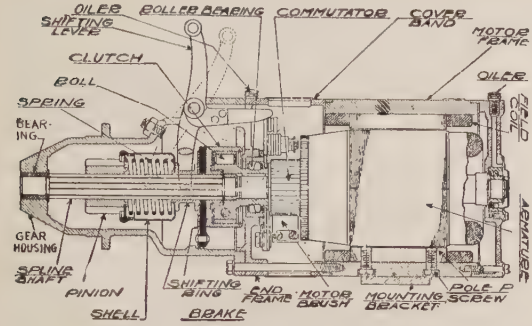

Fig. 16. Delco-Pierce-Arrow starting motor. The word "brake" refers to the black section shown above the words "shifting ring."

Some unusual features of construction are incorporated in the starting motors used on Pierce-Arrow passenger cars and trucks. Both starting motors are identical, except for the starting pinion housings, which are designed with the flywheel openings on opposite sides, the passenger car motor being mounted on the right side of the engine, and the truck motor on the left side.

This motor, shown in Fig. 16, employs a mechanically operated pinion shaft, shifting the starter pinion in and out of mesh with the flywheel. The same shift lever operating the starter pinion also raises and lowers the grounded set of brushes, thus taking the place of a starting switch. The shift lever in turn is operated by the starting pedal located on the floor boards in front of the driver.

When the starting pedal is pressed down, the lever moves the starter pinion along the splined shaft into mesh with the flywheel, and at the same time lowers the two grounded motor brushes on to the commutator, closing the circuit and causing the motor to revolve. The design is such that the pinion teeth engage with the flywheel teeth before the brushes touch the commutator.

To provide for the few occasions **when the starter pinion teeth butt squarely against the flywheel teeth** to prevent immediate meshing, a compression spring within a cup housing is attached to the pinion and mounted on the splined shaft.

When the pinion does not mesh, the control lever moves on, compressing the spring until the brushes are lowered to the commutator. Then with the slightest motion of the shaft the pinion moves enough to clear the flywheel teeth, and the compressed spring instantly forces it into mesh before the motor can turn fast enough to cause clashing, or damage to the gear teeth.

There is **an over-running clutch** of special design between the pinion shaft and the armature shaft. When the engine starts running, the pinion shaft over-runs and prevents the motor armature from being driven by the engine at a dangerously high rate of speed.

The brake shown at the inner end of the splined shaft in Fig. 16 causes the armature to come to rest almost instantly when the starter pedal is released, permitting the operator to make a second application of the starting motor without delay, if necessary.

There is only one motor terminal, and to this, connection is made direct from the negative terminal of the battery, using very heavy starting motor cable.

The very small spring and plunger located on the inner face of the flange of the small gear on many of the Bendix drives should not bear excessively against the spiral shaft lest the proper movement of the gear be prevented. Should the small spring around the plunger become weakened, the gear will occasionally jingle against the flywheel teeth while the engine is operating.

The driver should operate the starting motor in cranking the engine only when the ignition spark has been retarded. If the engine for some reason only runs for a second or two after the first application of the starting motor, be sure to wait until the engine flywheel has ceased rocking backward and forward and has come completely to rest before applying the starting motor the second time. Observance of these two rules will very largely eliminate breakage of starting motor gear housings.

DELCO ELECTRIC SYSTEM ON THE ESSEX MODEL "A"

Separate starting motors and generators are used on the Essex and Cole, but cut-outs are not used. The motor brushes serve as a starting switch.

Electric system: This is the Delco three-unit single wire system. The starting motor drives through the flywheel and a mechanically shifted pinion is used. In place of a starting switch, the motor brushes are used instead (explained below).

The generator is driven from the right side of the engine, and has the third-brush regulation. To change the output of the generator, shift the third brush; 16 amperes is maximum.

Ignition: Delco closed-circuit timer and distributor driven at one-half crank-shaft speed with automatic advance. The condenser and ignition resistance unit is mounted on the side of the timer.

The adjustment of the timer gap is .018″; of the spark-plug gap, .030″; the firing order is 1, 3, 4, 2.

The ignition timing: Place the spark lever full advanced. Turn the engine until No. 1 piston starts to come up on compression stroke and stop when the D.C. 1-4 mark on the flywheel is in line with the pointer on the flywheel of the engine. Then loosen the timer adjustment screw in the center of the distributor shaft and turn the breaker cam so that the rotor button will be in position under No. 1 high-tension terminal, or that which leads to No. 1 cylinder, when the distributor head is down in place. Locate the breaker cam carefully in this position, so that when the slack in the distributor driving gears is rocked forward, the contacts will be opened by the breaker cam, and when the slack in the gears is rocked backwards, the contact will just close.

For the valve timing, see the Index.

Owing to the wearing to a seat of the fiber rubbing block of the contact-breaker arm against the cam, the contacts will require one or two adjustments during the first season's driving, after which no attention is necessary. The timing contacts are of tungsten metal, and are very hard. They should require no attention other than to maintain the proper adjustment.

Essex-Delco Circuits

Starting motor: From the (+) terminal of the battery (Fig. 17), to the series parallel field windings of the starting motor, to the (+) brushes, through the armature, to the (−) brushes, to (−) ground of the battery.

Instead of a starting switch, the motor brushes are lowered to the commutator when starting, and are raised after starting by the action of the starting pedal.

When the starting pedal is depressed it performs two distinct operations. The first of these takes place when the button is part way down, at which time the starter gear mounted to the rear of the starting motor is caused to mesh with the flywheel. The second action occurs when the pedal is all the way down, bringing the motor brushes in contact with the motor commutator, thereby closing the circuit and energizing the motor, which results in the revolving of the armature and the consequent cranking of the motor through the over-running clutch and thence through the flywheel. Release the starting button as soon as the engine starts.

The brushes on this motor are of a special composition, and must not be replaced with brushes of any other material, as this is almost sure to lower its efficiency very materially. Neither the brushes nor commutator should be lubricated, as lubrication of the commutator with a compound of any kind is almost sure to cause the brushes to fail to make contact at all, or at least to make insufficient contact to permit the cranking operation.

Generator shunt-field circuit: From the (+) main brush to (**A**), to (2), to (3), to (**F**), through the shunt field windings, to the (−) third brush.

A cut-out is not used on the Essex. See page 387, explaining the reason why it can be eliminated. The explanation on page 387 is for a Delco motor-generator, whereas the Essex generator is separate from the motor; however, the principle is the same.

Generator charging circuit: From the (+) brush, to (**A**), to (2), to (1), to the ammeter, to the (+) battery, to the (−) battery ground (**GB**), to the (−) main brush of the generator (**G**).

Ignition primary circuit (from the battery when starting): From (+) of the battery, to the ammeter, to (1), to (3), to the ignition coil primary winding, to ignition resistance unit (**R**), to contact-breaker points, to ground (**G**), to (−) ground of the battery.

Ignition primary circuit (from the generator after the engine is running at sufficient speed for the generator to charge the battery): From (+) of the generator, to (2), to (3), and over the same path as in the preceding paragraph.

Note. The ammeter shows the ignition current on the "discharge" side (also lights, etc.) used from the battery. It shows on the "charge" side only, the current going from the generator to the battery when the generator is charging the battery.

Secondary ignition circuit: From the secondary coil winding, to the distributor, to the spark plugs, to ground, to ground of the generator or battery, to (3), to the other end of the secondary circuit.

The condenser is placed across the ignition contact-breaker points.

The lighting circuit, when from the generator, is from (2) to (1), and when from the battery, from (1). The **circuit-breaker** of the vibrating type is placed in series with the lighting circuits. The purpose is explained on page 391.

The combination switch is located in the cowl. It is for the purpose of controlling the lighting and ignition circuits, and the circuit between the generator and storage battery. The lever (**I**) on the left controls the ignition and generator circuit. The lever on the right (**L**) controls the lights and has three positions, "off," "dim lights," and "bright lights." The cowl and tail lights are lit when the headlights are either dim or bright.

By controlling the circuit between the generator and storage battery with the ignition switch lever, an automatic cut-out, which is commonly used for this purpose, is not required. The ignition button should never be left in the "on" position when the engine is not operating, as the storage battery would run down.

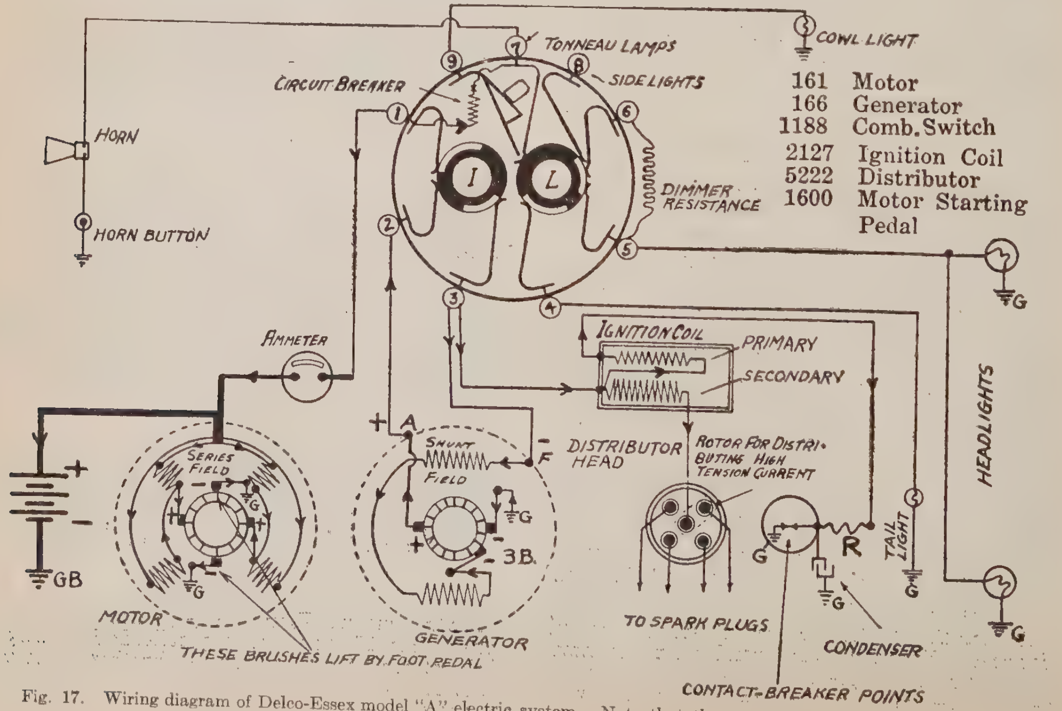

Fig. 17. Wiring diagram of Delco-Essex model "A" electric system. Note that the generator and motor are separate.

DELCO ELECTRIC SYSTEM ON COLE MODEL 870 (1921); SEPARATE STARTING MOTOR AND GENERATOR; CUT-OUT NOT USED

The generator and motor are separate units. The circuits are as follows:

Starting motor circuit: From (+) of the battery, to switch (**S**), to the two series-parallel field windings, to the (+) brushes, to the (−) brushes, through the two field coils, to ground, to (−) ground of the battery.

Generator field circuit: From the (+) main brush to the shunt field coils, to the third brush (3**B**).

Generator charging circuit: From the (+) main brush, to (6), to (5), to the ammeter, to (+) of the battery, to the battery (−) ground, to the (−) grounded brush (**GG**) of the generator.

Primary ignition circuit: From (6) if the generator is supplying current, or from (5) if current is supplied from the battery, to (7), to primary winding (**P**), to the resistance unit, through the two contact-breaker points connected in multiple, to ground (**G**), to ground (**GG**) of the generator, or to ground of the battery.

Secondary ignition circuit: From the secondary winding of coil (**S**), to the distributor, to the spark plugs, to ground, to ground of the generator, or of the battery, to (**X**) on the coil, where the primary and secondary circuits connect.

The circuit-breaker is of the vibrating type.

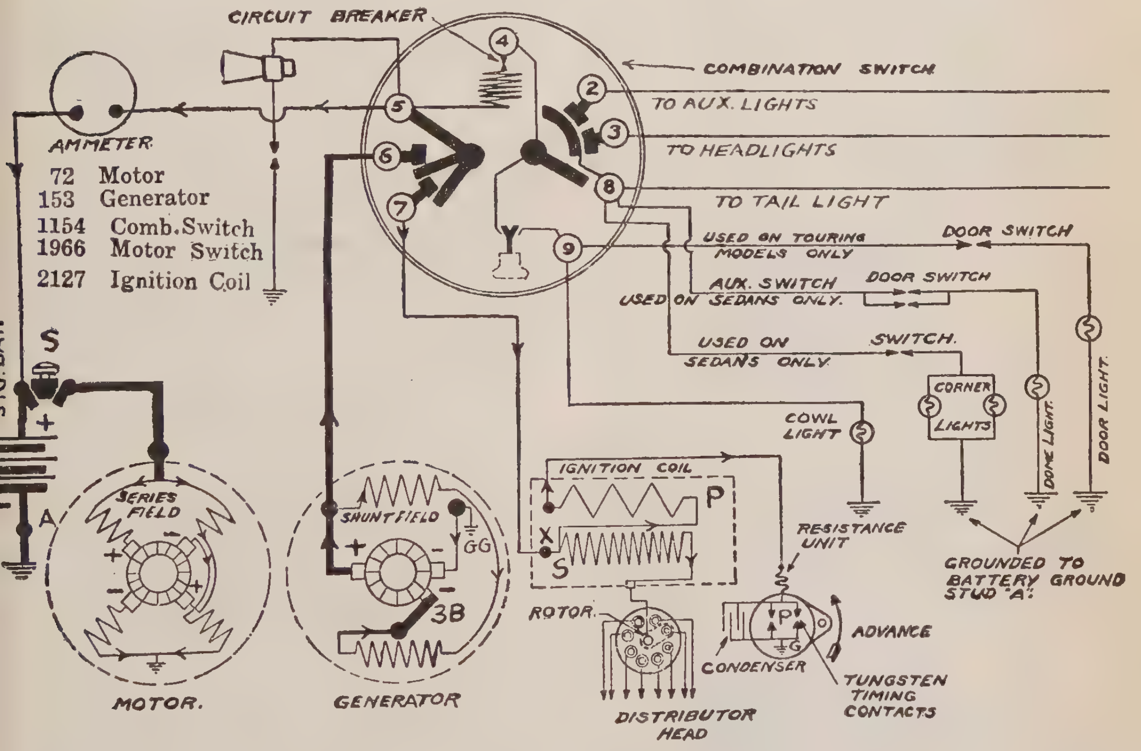

Fig. 18. Wiring diagram of the Cole (1921) model "870" using the Northway "M-309" engine.

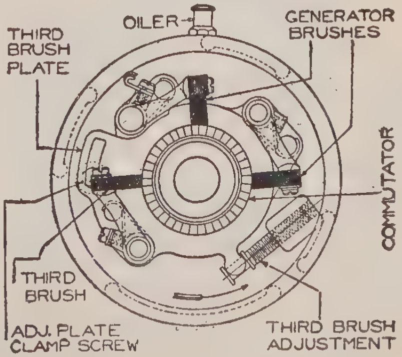
ADJUSTING GENERATOR CHARGING RATE ON DELCO GENERATORS

The charging rate may be increased by moving the third brush in the same direction as the armature rotates; or in the opposite direction, to decrease the rate.

An ammeter should be connected in the charging circuit and should be carefully observed while the engine is gradually speeded up, and the maximum rate noted. With all lights off, the charging rate should not, in any case, exceed 16 amperes.

In some instances the charging rate is too high, yet the driver of the car does not complain in regard to the charging rate. His complaint is on the short **life of the lamps,** and the necessity of **frequent addition of distilled water to the storage battery.**

It is possible to adjust the charging rate to give satisfactory results, by studying the driving conditions of individual cars.



TO DECREASE CHARGING RATE MOVE ADJ. PLATE IN DIRECTION OF ARROW

Fig. 19

To adjust the position of the third brush on generators applied to Cadillac and Marmon models, first remove the cover band over the generator brushes. Loosen the clamp nut on the front end of the generator one or two turns. **To increase the charging rate,** turn adjusting screw (Fig. 19) slightly in a clockwise direction, which **shifts the third brush in the direction of the armature rotation.** The reverse operation decreases the charging rate. After adjustment is complete, tighten the clamp nut securely. Make sure that all brushes are well seated.

When the position of the third brush is changed, it is necessary to reseat the brush on the commutator to obtain the maximum true charging rate. To refit the third brush, place a strip of fine sandpaper or sand-cloth, having a width slightly greater than that of the brush, around at least half of the commutator, with the rough side next to the brush. Drawing the sandpaper back and forth a few times will properly seat the brush. Never use emery cloth (explained farther on).

The design of many of the generators is such that in adjusting the third brush, the brush arm on the inside of the generator is moved after loosening two adjusting screws as in Fig. 20. Certain of the later type generators (Fig. 21) are provided with a plate on the end of the generator which can be moved within certain limits after loosening the three adjusting screws. An arrow on this bearing retainer plate through which the screws pass indicates the direction in which the brush is to be shifted to increase the charging rate.

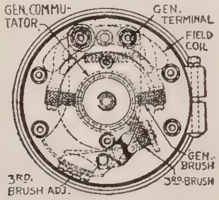


Fig. 20

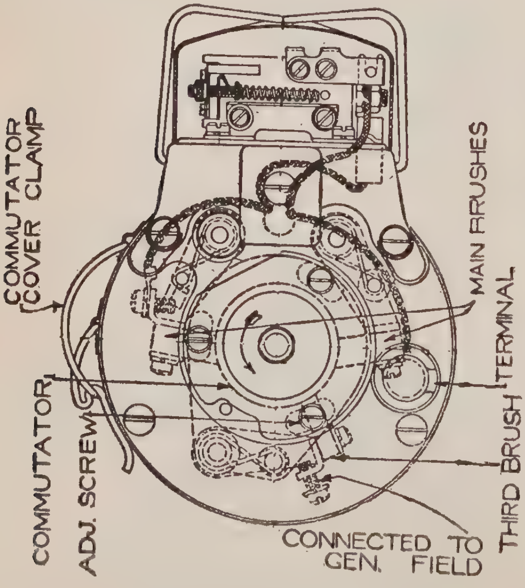

Fig. 21. Separate generator (motor not attached) as used on Marmon, Moon, Jordan, and Westcott cars.

Procedure of adjustment (Fig. 21): The charging rate can be changed by loosening the three screws holding the third-brush plate, as shown in the illustration, and by shifting the brush in the direction of rotation of the armature to increase the charging rate, and against the rotation to decrease the charging rate. In no case should the ammeter indicate a charging rate in excess of 14 amperes when the generator is hot; as this rate is beyond the capacity of the generator, serious damage will result. Whenever the third brush is moved in either direction it should be fitted to the commutator by sanding the brush with fine sandpaper between the brush and the commutator, with the sand side next to the brush. If this is not done, the brush will fit the commutator imperfectly and the charging rate will be lower than when the brush fits properly.

Explanation of Delco Third-Brush Regulation

The voltage generated by the generator varies directly with the speed of the armature. In order to maintain a nearly constant voltage with variable speed, it becomes necessary to decrease the magnetic field as the speed increases.

Since the magnetic field of the generator is produced by the current in the shunt-field winding, it is evident that should the shunt-field current decrease as the speed of the engine increases, the regulation would be affected. In order to understand this explanation fully it must be borne in mind that a current of electricity always has a magnetic effect, whether this is desirable or not. Referring to Fig. 22, the theory of this regulation is seen to be as follows: The full voltage of the generator is obtained from the large brushes (**C**) and (**D**). When the magnetic field from the pole pieces N and S is not disturbed by any other influence, each coil is generating uniformly as it passes under the pole pieces. The voltage from one commutator bar to the next one is practically uniform around the commutator.

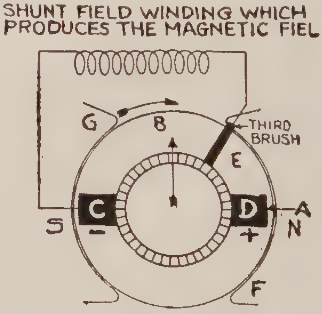

Fig. 22. Explanation of the third-brush principle (see also Index).

Therefore, the voltage from brush (**C**) to brush (**E**) is about 5 volts when the total voltage from brush (**C**) to brush (**D**) is 6½ volts, and 5 volts is applied to the shunt-field winding. This 5 volts is sufficient to cause approximately 1¼ amperes to flow in the shunt-field winding.

As the speed of the generator is increased the voltage increases, causing the current to be charged to the storage battery.

This charging current flows through the armature winding, producing a magnetic effect in the direction of the arrow (**B**). This magnetic effect acts upon the magnetic field which is in the direction of the arrow (**A**), with the result that the magnetic field is twisted out of its original position in very much the same manner as two streams of water coming together are each deflected from their original directions (termed "armature reaction," see page 361). This deflection causes the magnetic field to be strong at the pole tips, marked (**G**) and (**F**), and weak at the opposite pole tips, with the result that the coils generate a very low voltage while passing from the brush (C) to the brush (E) (the coils at this time are under the pole tips having a weak field), and generate a greater part of their voltage while passing from the brush (E) to (D). The amount of this variation depends upon the speed at which the generator is driven; with the result that the shunt-field current decreases as the speed increases, thus holding the output of the generator constant.

Regulating Charging Current (Delco)

The output of these generators can be increased or decreased by changing the position of the regulating brush. Each time the position of the brush is changed it is necessary to sandpaper the brush, so that it fits the commutator. Otherwise the charging rate will be very low because of the poor contact of the brush. The charging current should be carefully checked, and in no case should the maximum current on this generator exceed 22 amperes. Also careful watch should be kept on any machine on which the charging rate has been increased, to see that the generator is not being overloaded.

Considerable variation in the output of different generators will be obtained, as the output of the generator is affected by temperature and battery conditions.

AMMETER, DELCO COMBINATION SWITCH, AND CIRCUIT-BREAKER

Ammeter: On the later models of cars the ammeter is not incorporated with the lighting and ignition switch, but is mounted in the cowl separately, as will be noticed in the circuit-wiring diagrams of some of the 1921 Delco systems.

This instrument is for the purpose of indicating the net amount of current that the generator is supplying to the storage battery when the engine is running, and indicates the amount of current that the battery is furnishing for lights when the engine is not operating.

If the ammeter hand remains on the "discharge" side of the scale, and vibrates violently at each revolution of the armature during the motoring of the generator, and when the engine is running at low speeds, it is conclusive evidence that the armature has either a ground, open coil, or a shorted coil.

Combination switch: Although the appearance of the different combination lighting and ignition switches may vary, their internal construction and operation in controlling the charging, ignition, and lighting circuits is quite similar.

On those cars whose equipment does not include a cut-out relay the ignition switch controls both the charging and ignition circuits, through the same switch lever. In these cases, therefore, the ignition switch completes the circuit between the storage battery and the generator. It should therefore always be in the "off" position, except when starting or when the engine is running, as otherwise the storage battery would discharge through the generator windings and ignition circuit.

Cars not equipped with two large and two small headlight bulbs carry a dimmer resistance unit on the back of the switch.

The switch levers can be securely locked by Yale or Sargent locks. The majority of ignition switches carry the circuit-breaker on the back of the switch.

The ignition and lighting switch used on Pierce-Arrow cars (see page 403) carries a large round button at the top of the switch connected with a plunger which extends through the back of the switch about six inches. The plunger engages the starting switch which is not a part of the Delco equipment.

The starting switch is mounted on the back of the ignition and lighting switch.

The circuit breaker assembly on the systems used on Cadillac (page 396) and Marmon (page 400), Lincoln and Lafayette cars includes the lock-out as well as the vibrating type. Such accessories as the horn, trouble lamp, and tonneau light are as a rule placed on the circuit protected by the lock-out circuit-breaker. See page 392.

If a ground occurs, the points of the lock-out circuit-breaker remain open until the ground is removed. This action is controlled by the use of an additional small coil around the core of the circuit-breaker through which will pass a sufficient amount of current to magnetize the core sufficiently to keep the points open after they have been separated.

DELCO CUT-OUT (1921 TYPE)

As stated, a cut-out is not used with Delco motor generators for reasons stated on page 387.

On Delco generators which are separate from the motor, as two and three-unit systems, as on the Marmon and Pierce-Arrow, Westcott, Moon, Jordan and other cars using the separate generator (see Delco wiring diagrams), the cut-out is used.

The cut-out consists of a set of magnetically operated contacts that are held open by a tension spring and closed magnetically. When the engine is not running the contacts should be open. They are open also when the speed of the generator is too low to enable it to charge the battery.

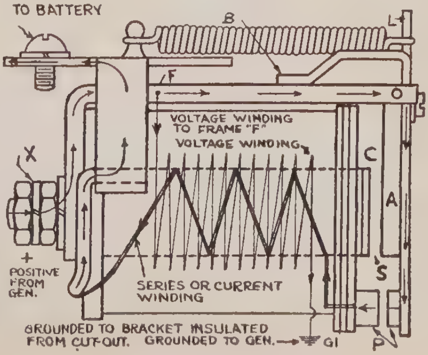
Around the core of the magnet is a double winding consisting of **a voltage coil** of a large number of turns of very fine wire, connected across the generator terminals, and a **current or series coil** made up of a few turns of very heavy wire.

The current coil is connected in the charging circuit in series with the contacts, and is energized only when the contacts are closed. The actual closing of these contacts is caused by the magnetism created by the voltage coil, or fine winding, when the generator operates at sufficient speed to charge the battery.

Adjustment of Delco Cut-Out

Should adjustment become necessary, the following directions should be carefully followed:

1. **The air gap** (S) (Fig. 23) between the armature (A) and the end of the core should be .025″ to .035″



TO BATTERY
B
L
F
VOLTAGE WINDING TO FRAME "F"

GI
P

Fig. 23. Delco 1921 type of cut-out.

when the contacts are closed. Secure this adjustment by properly bending with a pair of pliers the armature blade attached to the outside point of (P). This adjustment is important, as the amount of the air gap largely governs the "cut-in" point.

2. **The gap between the contacts** (P) is automatically taken care of by the adjustment of the air gap. This gap is .046″ to .062″ when the points are open, and it can be adjusted by bending the brass stop (B). Contacts should meet squarely, and the brass blade carrying the moving contact should be straight and parallel with the surface of the armature (A).

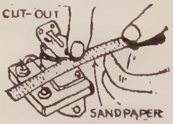

Fig. 24

To clean the contacts or square them up, a strip of fine sandpaper should be drawn between the contacts while they are lightly closed by hand. The end of the blade carrying the moving contact may be prevented from rubbing inside of the relay cover by grinding or filing off the end of the blade to a point 1/64″ from the side of the contact.

3. **In checking the voltage** at which the cut-out relay points close, use a voltmeter capable of indicating at least 10 to 15 volts. Connect one of the voltmeter leads to the terminal (X) (Fig. 23) and the other lead to the cut-out relay base, or generator frame. If the needle of the voltmeter deflects in the wrong direction, reverse the voltmeter lead connections.

4. Slowly speed up the engine and **observe the voltmeter reading.** The contacts should close at 7 to 8 volts on all relays, except those on Pierce-Arrow equipment, which are adjusted to 6¼ to 6½ volts. Any necessary adjustment should be made by bending the lug (L) slightly (a thumb-nut adjustment is provided on the springs of the earlier relays of this type). Increasing the spring tension will raise the "cut-in" voltage. Decreased tension lowers it. An ideal adjustment is an air gap as small as the limits will permit, so that there will be an appreciable tension in the spring.

5. **The cut-out relay contacts** should be closed above a car speed of approximately 6 to 8 miles per hour in high gear, or a correspondingly lower speed in lower gears.

6. **Contacts should separate** with the discharge from the battery through the relay at less than 3 amperes. The correct condition will be indicated by the ammeter on the cowl indicating approximately 4 amperes with all lights off. This reading includes current used for ignition which does not pass through the relay.

As soon as the cut-out relay contacts close, the ammeter on the dash should indicate that the generator is beginning to charge the battery.

If it becomes necessary to drive the car in high gear at a speed materially faster than 7 to 9 miles an hour before the ammeter shows, by indicating a "charge," that the relay points have closed, do not judge conclusively that the cause is a defective relay or that its adjustment is incorrect. The real cause of the trouble may be **an oily generator commutator** resulting from excessive lubrication of the generator bearings. This condition may prevent the generator building up sufficient voltage to close the relay contacts, though the relay be in perfect condition and adjustment.

Before making any changes in cut-out relay adjustment, clean the generator commutator carefully of any oil, grease, or black greasy coating, and examine the spring tension and seat of all generator brushes, particularly the third brush. If the generator is given this attention without any improvement in the performance of the cut-out relay resulting, the cut-out may then be carefully adjusted in accordance with previous instructions.

Should a considerable amount of trouble be experienced on an individual generator through the presence of an oil film on the commutator, it **may be necessary to install a new third brush to eliminate the effect of excessive oil on the commutator.** Take care to avoid excessive lubrication of the generator bearings; three or four drops of oil in each oiler every 500 miles is sufficient.

Delco 1920 Cut-Out

Should the cut-out not operate properly, the voltage at which the contacts close should be checked.

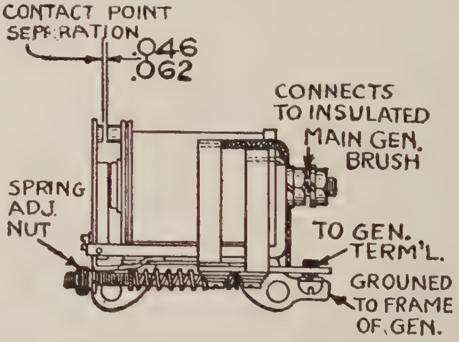

Fig. 25. 1920 type of Delco cut-out. The principle is the same as in Fig. 23. See Fig. 12, page 400, showing cut-out mounted on top of the generator; see also the wiring diagrams of the Marmon.

The contacts should close, completing the circuit between the generator and storage battery, when the voltage of the generator reaches approximately 7½ volts. This can be checked by connecting a voltmeter to the terminal on the cut-out (Fig. 25) marked "connect to insulated main generator brush," the other side of the voltmeter being connected so as to make a good contact with the generator frame at some point. By slowly increasing the engine speed, the voltage should gradually increase to approximately 7½ volts, and the contacts should then close. With the contacts open there should be a separation of from .046″ to .062″.

The cut-out can be adjusted by tightening or loosening the spring adjustment nut as the occasion demands.

Seating and Sanding Delco Brushes to the Commutator

This subject is treated farther on. See Index.

INSTRUCTION No. 36

A STUDY OF LEADING ELECTRICAL STARTING AND GENERATING SYSTEMS: Pointers for Studying Electric Systems; Wiring Diagrams[1]

POINTERS FOR STUDYING ELECTRIC SYSTEMS

The fundamental principle of the starting and generating systems has been treated in the preceding instructions. If the reader will master the principles as laid down in the foregoing pages, it will not be a difficult matter to understand any and all systems, because each system embodies one or more of the principles explained. Although the methods of operation or construction may vary, the purpose remains the same.

The external parts of the electric system consist of:

1. Battery.
2. Generator.
3. Ignition system.
4. Starting motor.
5. Switches: starting, ignition, and lighting.
6. Lamps.
7. Wiring system: the "single-wire" or the "two-wire" system.
8. Horn (electric), and push button.
9. Fuses.

The "single-wire" system is where one insulated wire is used and the frame of the car is used for the return circuit. This system is used most, and hence it will be noted in diagrams following.

The "two-wire" system is where there is no ground to the frame, but two insulated wires are used.

Although there are many different makes of cars, there are **only a comparatively few different makes of electric systems,** and each of the different cars uses one or a combination of these systems

The specifications of leading cars (see Index) will give the make of the particular electric systems that are used on the different cars.

The ignition system on a car is usually one of the following makes: Delco, Remy, Westinghouse, North East, Atwater-Kent, Connecticut, K-W Ignition Company, which employs the battery and coil system. This latter is explained under the head of "Ignition."

If **magneto ignition** is used, it will be of one of the makes mentioned in the list of magneto manufacturers (see Index). The K-W is a very popular magneto ignition used on trucks and tractors.

The ignition system most used is the battery and coil system. The interrupter is either an "open-circuit" or "closed-circuit" type, the latter being the most generally adopted system. Some few manufacturers of passenger cars use magneto ignition in addition to the coil and battery. Magnetos are used extensively on trucks and tractors.

Storage battery makes are the Exide, Vesta, Willard, Prest-O-Lite, U.S.L., Philadelphia, Witherbee, and several others. Some of the car manufacturers use 12-volt or 24-volt batteries, but most of the systems are 6-volt.

Electric starting motors and generators are usually of the Delco, Remy, U.S.L., Westinghouse, Bijur, Simms-Huff, North East, or other makes. The two last mentioned, and the Delco, have the motor and the generator combined in one unit. The motors and generators are also manufactured separately. The U.S.L. also produces a motor-generator.

The generator is either a plain shunt-wound generator, with an external electromagnetic principle of regulation, or a third-brush-regulated generator, or a combination of a third-brush and electromagnetic regulation. The third-brush-regulation prin-

---

[1] It is impossible to show wiring diagrams of all cars. See the advertisements on the wiring diagram book and the Service Manuals in the advertising pages of this book.

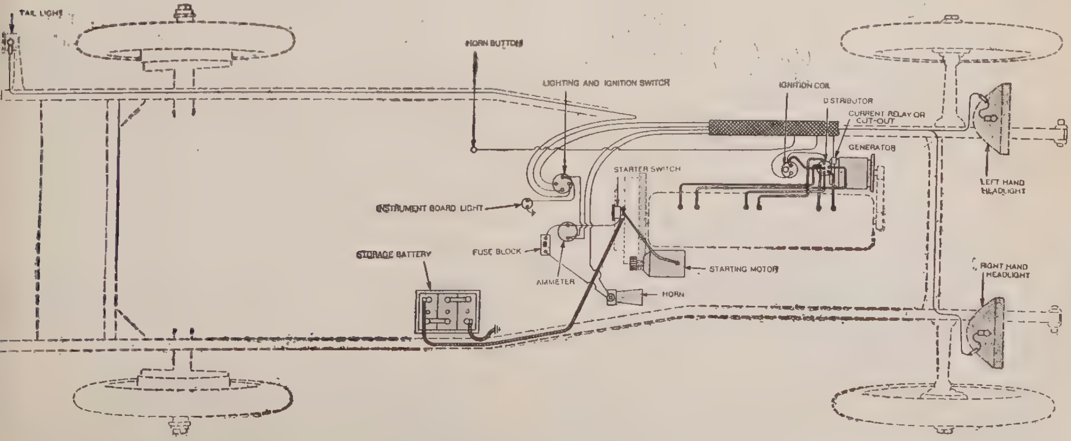

Fig. 1. Location of the electric parts on a car (Remy electric system on the Mitchell model "F," as an example). Note that the generator is driven by gears from the crank shaft of the engine. The distributor and the contact-breaker are mounted on the generator and are driven from the armature shaft.

ciple is used most. The Remy and Delco use a thermostatic control (see pages 362, 395) in connection with the third-brush regulation on some of their systems.

Ground connection of generator and battery. If the positive (+) terminal of the battery is grounded to the frame of the car, then the (+) terminal of the generator must also be grounded. Likewise, if the negative (−) terminal of the battery is grounded, then the (−) terminal of the generator must be grounded. Most manufacturers ground the negative (−) terminal of the battery and generator. The Westinghouse Co. grounds the positive (+) terminal in a number of its systems.

HOW TO STUDY WIRING DIAGRAMS

Electrical symbols: Before studying the different diagrams, the reader should become thoroughly familiar with the electrical symbols and abbreviations, as illustrated and described; for instance, the sign which denotes a "ground," or that which stands for a "storage battery," or for the point where "wires connect" or "pass over each other." They will be used quite freely in these instructions, as will also many of the other signs. The symbols vary slightly with the different manufactures of cars. It is also advisable to refer to page 415 for the addresses of the leading manufacturers of electrical systems. If the explanations are not clear, their catalogs will no doubt be of assistance.

In the illustration below, each symbol is numbered. The explanation of each is given with its appropriate number against it.

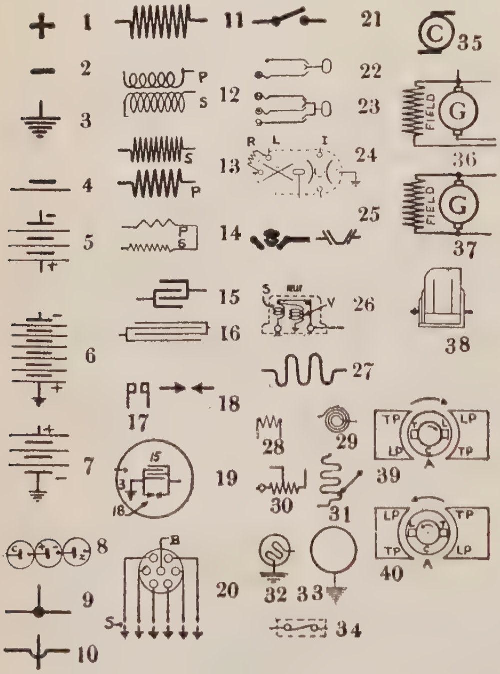

Fig. 2. Electrical symbols

Electrical Symbols and the Terms Applied to Them

1. **Positive terminal,** the point at which the electric current starts to flow.
2. **Negative terminal,** the point to which the electrical current returns.
3. **Ground,** where connection is made to metal, as the frame of the car, the engine or generator frame, etc.
4. **One cell of a battery:** A term usually applied to cells of a storage battery. The short black line represents the negative (−) terminal, and the long line the positive (+) terminal. On a dry cell the positive plate is the carbon, and the negative, zinc. On a storage-battery cell there are usually several positive and several negative cells, but this symbol represents the terminals of each group. Each storage-battery cell gives 2 volts when charged.
5. **Three cells of a storage battery connected in series:** Note that there are three sets of negative and positive terminals or cells. Thus this would represent a 6-volt storage battery.
6. **Six cells of a storage battery connected in series:** 12 volts. Note the (+) terminal of this battery of six cells grounded at the end cell.
7. **Three cells of a storage battery connected in series:** 6 volts. Note that the terminal of one end of this battery is grounded.
8. **Dry cells:** The illustration shows three connected in series. (C) is the carbon or (+), and (Z) is the zinc or (−).
9. **Wires connected.**
10. **Wires crossing,** but not connected.
11. **Coil:** Could represent a field-coil, or ignition coil. Supposed to surround an iron core.

12, 13, 14. **High and low-tension ignition coil windings:** There are several methods of showing the primary winding (P) and the secondary winding (S), as, for instance, those shown by 12, 13, and 14. The two windings are usually shown separate, although they are wound on one core. The current is induced into the secondary by lines-of-force produced by the primary winding, and there is no metallic connection between the primary and secondary windings. The secondary is a much finer wire, and consists of several thousand turns, whereas the primary has only a few hundred turns of heavy wire.

15, 16. **Condenser:** Placed across the coil points to absorb the spark when the points separate, and to permit the discharge back through the primary coil to demagnetize the core.

17. **Contact-points:** Usually refers to the cut-out or regulator points; also refers to the contact-breaker points.
18. **Interrupter or contact points** (as used by Delco): The Remy Co. uses this symbol to designate the spark jumping a gap at the spark-plug points, or at the safety-gap on an ignition coil.
19. **Interrupter or contact-breaker:** A method used by Delco. Note the "interrupter points" (18); also the "condenser" (15), and the "ground" (3).
20. **Distributor of high-tension ignition current to spark plugs:** (B) connects with the secondary terminal of the coil, and a high-tension current is distributed to the spark plugs and jumps the gap of the spark plugs (gap represented at S), then flows through the metal part of the engine back to the grounded secondary terminal.

21. **Lighting switch.**

22. **Delco ignition and lighting switch,** as used on some of the Delco systems.

23. **Double switch,** of the same type.

24. **Remy lighting and ignition switch** of the "pole-changing" type. Lighting switches (**L**) at left, with dimming resistance (**R**). Ignition switch (**I**) at right represents a "pole-changing" type of switch (see Index). Note the "ground" on the side of the switch case.

25. **Starting-motor switches.**

26. **Cut-out:** Also called a relay, with two windings. The "voltage or shunt" winding (**V**) is a winding, and is always placed **across** the circuit. The "voltage winding" of a cut-out can be found by noting that it has more turns of wire than the "series" or "current winding." The series or current winding (**S**) has a less number of turns and is a coarser wire and is always placed **in series** with the charging circuit. Cut-out windings are often on one core. Sometimes they are on two cores. The illustration shows two coils, or windings, on two separate cores (model 264-D Remy).

    Regulator winding: This is usually on one core and is a single winding. It is always placed in series with the "shunt-field winding." If it consists of a coarse heavy wire, this indicates that it regulates the **current output;** if it consists of a fine wire winding, this indicates **voltage regulation.**

27. **Resistance** coil.

28, 29. **Resistance** coil for dimming lights.

30. **Resistance** divided into two paths.

31. **Resistance** which can be varied.

32, 33. **Lamp bulbs:** Note that one side is grounded.

34. **Fuse** mounted on a fuse block.

35. **Commutator and brushes** for either a generator or a motor.

36. **Series-connection of field-coils,** with commutator and brushes of a motor or generator (internal circuit). The series connection is generally used on motors. If (**G**) appears as shown, it means that the connection is for a generator; if (**M**) appears in place of (**G**), the connection is for a motor.

37. **Shunt-connection field-coils,** with commutator and brushes (**G**) of a motor or a generator. (Internal circuit.) Shunt windings are generally used on generators; they are seldom used on motors for automobile work. (**G**) indicates generator, and (**M**), motor.

38. **Magneto.**

39. **Trailing** pole tips are indicated by (**TP**). **Leading** pole tips are (**LP**).

40. Same as 39; but since the armature (**A**) and the commutator (**C**) are in opposite positions, the order is changed.

    The **"trailing"** pole tip is the one (**A**) or (**C**) moves **from.**

    The **"leading"** pole tip is the one (**A**) or (**C**) moves **to.**

Abbreviations Commonly Used to Represent Electrical Terms

A: Ampere or Ammeter.
AC: Alternating current.
B: Brush; also used for Battery
BAT: Battery.
C: Current.
C or **COM:** Commutator.
CARB: Carburetor.
C.E.M.F.: Counter-electromotive force.
DC: Direct current (usually written d.c.).
DIS. or **DIST'R:** Distributor. The word "distributor" is often used to express the inclusion of the interrupter and distributor in one unit.
E.M.F.: Electromotive force.
GB: Generator brush; also grounded brush.
G or **GEN:** Generator.
G or **GRND** or **GR:** Ground.
HL: Headlights or lamps.
H.P.: Horse power (746 watts) (usually written h.p.).
I or **IG:** Ignition.
IS. or **IG.S:** Ignition switch.
INT: Interrupter.
KW: Kilowatt (1,000 watts).
L: Light, or lamps.
LS: Lighting switch.
M: Motor.
MB: Motor brush; also main brush.
N: North.
RES: Resistance.
S: South.
S or **Sec:** Secondary.
ST.M.: Starting motor.
SEF: Series field winding.
SHF: Shunt field winding.
3B: Third brush.

TRACING CIRCUITS OF WIRING DIAGRAMS

The electric system should be divided into circuits as follows:

1. Starting-motor circuit.
2. Generator circuit.
3. Ignition circuit.
4. Lighting circuit.

When tracing circuits, remember that the positive (+) terminal at the source of current is where to start. **If a battery** supplies the current, start at the (+) terminal. **If the generator** supplies current, start at the (+) brush or brushes of the generator.

Tracing Starting-Motor Circuits

See Fig. 3: The battery supplies the current, therefore start with the **battery** (+) **terminal,** thence to starting switch, to terminal (**T**) on the motor, to the field-circuit. In this instance the field-coils or windings on the four field-poles are connected in "series parallel." The current divides when passing into the field-coils, and flows through the two field-coils on each side, then to the (+) main brushes, through the armature, through the grounded (−) main brushes, to the grounded (−) terminal of the battery, thus completing the circuit.

Sometimes the (+) brushes are grounded instead of the (−) brushes. In this case, the (+) terminal of the battery would be grounded instead of the (−) terminal, and the flow of current would then be from the (+) grounded terminal of the battery to the (+) grounded terminal of the motor brushes.

Sometimes the fields are grounded. In every instance, however, start with the (+) terminal of the battery where the source of current for the motor starts.

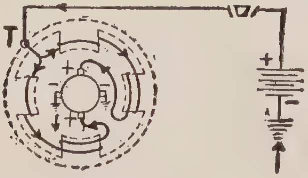

Fig. 3. Starting motor of the four-pole type, with the field-coils connected in "series parallel."

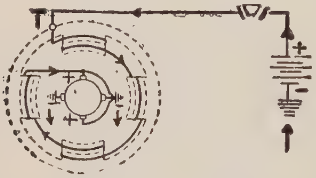

Fig. 4. Starting motor with the field-coils connected in "series."

See Fig. 4: This represents a four-pole motor with straight "series" field-winding. If the (−) brushes are grounded (they are, in this example), then **start with the (+) terminal of the battery.** The (+) brushes are sometimes grounded. The usual method, however, is to have the (+) current flow to the field-windings in a motor, although this is not always the case.

Tracing Generator Circuits

There are three circuits to consider always:

1. Field-circuit.
2. Voltage coil cut-out circuit.
3. Battery charging circuit.

The field-circuit is the winding around the field-poles, and is the circuit through which current passes to build up the magnetic lines-of-force around the field-poles. There is a slight amount of magnetic lines-of-force in the iron poles to start with (called "residual magnetism"); therefore as the armature revolves, it generates current from the lines-of-force and part (about 10 per cent) of the armature current flows through the field-windings. The faster the armature revolves, the greater the strength of the current in the field-coils; therefore the regulation of the field-circuit at high speed by cutting down the current in the field-coils is important, otherwise the armature would generate too great an output.

Under the subject of **"generator regulation"** this subject is fully treated. Three principles are involved:

1. Compound field (two windings and inherent regulation).
2. Shunt field, with external regulation system.
3. Shunt field with a third-brush or inherent regulation.

1. **The compound-field regulation** is explained on pages 354, 355, 356. There would be two field-circuits to trace.

2. **The straight "shunt-field" generator with an electromagnetic type of voltage[1] regulator is shown in** Fig. 5: The "shunt-field-circuit" would start with the source of current, which is the **(+) main brush of the generator,** to the regulator blade **(H),** to points **(E),** through the field-coils, to the (−) brush of the generator. If the generator speed is high, the points **(E)** will open and resistance **(M)** will be cut into the field-circuit, thus weakening it, through the generator speed producing a high voltage through the voltage winding **(H).**

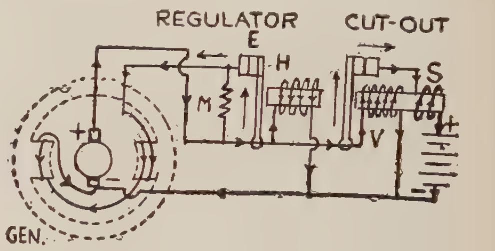

Fig. 5. Shunt-field generator using an electromagnetic voltage regulation.

The cut-out "voltage winding" circuit (V) is from the (+) main generator brush, back to the (−) main brush. This would be the next circuit. This builds up magnetism around the cut-out core.

The charging circuit to the battery is the next circuit, which is **from the (+) main brush of the generator,** through the blade and points of the cut-out, to the cut-out series or "current" coils **(S),** to the (+) terminal of the battery, to the (−) terminal of the battery, to the (−) main brush of the generator. At high speeds the voltage increases. Thus the regulator winding **(H)** exerts a magnetic pull on the blade, opening points **(E).** The shunt-field-circuit then has resistance **(M)** inserted in its circuit which reduces its strength.

3. **A third-brush regulated generator with a cut-out on top of the generator** would have its circuits as follows:

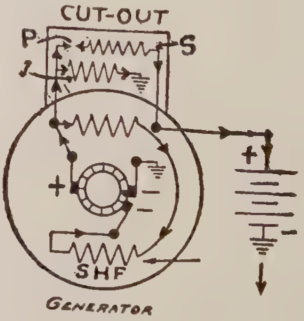

Fig. 6. Shunt-field generator using a third-brush regulation.

Shunt-field-circuit: Start with the (+) main brush of the generator, through the shunt-field-windings **(SHF),** to the (−) third brush. The third brush is always connected to one end of the field-windings and regulates the output of the generator at high speeds. It is sometimes on the (+) side of the armature.

---

[1] You can instantly tell when an electromagnetic regulator controls the voltage, because its winding is finer, and it is placed across the circuit, as at (H) (Fig. 5). When the regulator winding is in series with the circuit, it controls the amperage or current, and is usually of heavier wire.

The cut-out voltage winding circuit (V) **is from the (+) main generator brush,** to the cut-out fine wire voltage winding (V), through the grounded end of this coil (V), back to the (−) grounded main generator brush.

Charging circuit to battery: When the generator voltage reaches about 6.5 volts, or above battery voltage, the voltage coil (V) has sufficient magnetism in its core to close cut-out points (P). The charging circuit will then be **from the (+) main generator brush,** through cut-out points (P), through the cut-out series, or current winding (S), to the ammeter (not shown), to the (+) terminal of the battery, to the (−) grounded terminal of the battery, to the (−) grounded main brush of the generator.

If the (+) main brush of the generator was grounded, then the circuit would start at the **grounded (+) brush of the generator,** which would be the reverse of the circuit described. The (+) terminal of the battery would then be grounded.

Tracing Ignition Circuits

This circuit includes:

1. Ignition coil.
2. Interrupter.
3. Distributor.

Coil windings: There are two windings, the primary and the secondary (Fig. 7). The current must first flow through the primary winding.

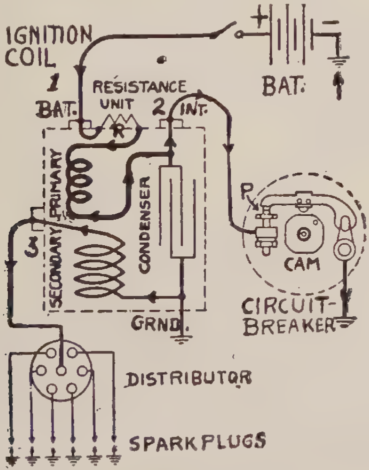

Fig. 7. A simplified diagram explaining how to trace the ignition system.

Coil terminals: Some coils have 3 or 4 terminals (see page 209). Most of the coils use 2 terminals as in Fig. 7.

Note. When referring to the number of the coil terminals, the secondary terminal is not considered.

Primary and interrupter circuit: Suppose the (−) terminal of the **battery and generator** was **grounded.** The flow of current would then be **from the (+) side of the ignition switch,** which is usually connected to the circuit at the ammeter. The current path would then be from (+) of the battery (or the generator if running fast enough to charge the battery), to the switch, through ignition resistance (**R**) on the coil, through the primary winding, out terminal (2), through the insulated and stationary interrupter point, through the grounded interrupter point and arm, to the (−) grounded terminal of the battery or generator.

If the (+) terminal of the battery and generator was grounded, then the circuit would be **from (+) of the battery,** to the grounded arm of the interrupter, through points (**P**), through the primary winding and resistance (**R**), to the switch, to the (−) terminal of the battery or generator.

Note that the interrupter is for a four-cylinder engine, because there are four high points on the cam. Thus it will raise the arm four times during one revolution.

The condenser is across the circuit of the interrupter points, as one end of the condenser is also grounded. (See Index for the construction and purpose of the condenser.) Condensers are often placed in the interrupter housing.

The secondary circuit is an induced current in the secondary winding from the primary winding, and would flow **from the secondary terminal** (3) to the distributor, through the spark-plug points, through the engine frame which would be termed a ground, to the grounded end of the secondary fine wire winding (**GRND**).

Note. In Fig. 7, owing to an error in drawing, a 6-cylinder distributor is shown. It should be a 4-cylinder distributor.

The primary and secondary coil windings are supposed to be on one soft iron core.

The foregoing explanation will give an idea as to the method of procedure in tracing wiring diagrams. All wiring diagrams do not have arrow points showing the path of the circuits. It is therefore necessary to make a point of starting with the **source of supply** of electric current which is **(+) of the battery or generator.** If (+) is grounded, then start at (+) just the same, and go to the grounded end of the part of the circuit you are tracing.

Tracing the Lighting Circuits

REMY ELECTRIC SYSTEM ON STUDEBAKER "EJ"

Studebaker (Model "EJ") Circuits

Starting motor: From the (+) ground of the battery to the (+) grounded motor brushes, to the (−) brushes, to the field coils, to the starting switch, to the (−) of the battery. A Bendix drive is used.

Generator field-circuit: From the (+) brush of the generator, to ground (G) of the thermostat, to the field coils, to third brush (3B).

Cut-out voltage circuit: From the (+) grounded brush of the generator, to ground (G) of the voltage coil, through cut-out series coil (S), to the (−) main generator brush.

Generator charging circuit: From the (+) grounded brush (G) of the generator, to the (+) ground of the battery (GB), to the starting switch, through the ammeter, to cut-out points (P), to cut-out series coil (S), to the (−) main brush of the generator.

Regulation of the shunt field of the generator is by means of a third brush.

Ignition primary circuit: From the (+) ground of the battery (GB), or the (+) ground of the generator (G), to ground (G) of the contact-breaker, to arm (A), to points (P), to primary coil winding (PR), through ignition resistance unit (RES), to the switch, to the ammeter, to the generator (−) brush, through the cut-out if the generator is supplying current, or from the ammeter to the (−) terminal of the battery, if the battery is supplying current for ignition, as is the case when starting.

The secondary circuit is from the secondary winding of coil (SC), to the distributor, to the spark plugs, to ground, to the grounded end of the secondary winding.

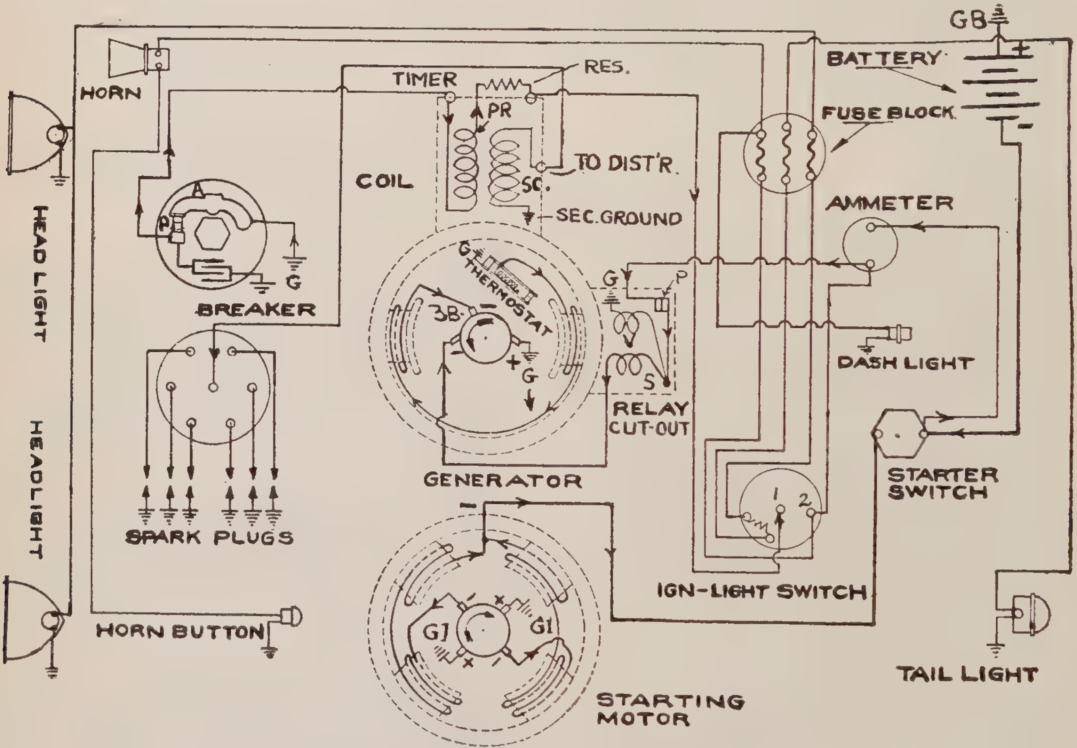

Fig. 8. Wiring diagram of the Remy-Studebaker model "EJ" electric system.

STUTZ SERIES "K": REMY GENERATOR AND MOTOR; DELCO IGNITION

Remy generator and starting motor with Delco ignition together constitute the system used on this car. The distributor principle is similar to that on the Pierce-Arrow, explained on page 216.

Stutz (Series "K") Circuits

Starting-motor circuit: From (+) ground (GB) of the battery, to (+) ground (G) of the starting motor brushes, through the field coils, to the starting switch, to the (−) terminal of the battery.

Generator field circuit: From the (+) main brush of the generator, to ground (G2) of the cut-out (relay), through fuse (F), through the shunt-field winding, to the third brush.

Cut-out voltage circuit: From the (+) generator brush, to ground (G2), through cut-out voltage coil (V), to cut-out series coil (S), to the (−) main brush.

Generator charging circuit: From the (+) main brush of the generator, to the (+) grounded terminal of battery (GB), through the ammeter, to cut-out closed points (P), through series coil (S), to the (−) main brush of the generator.

Ignition primary circuit (intake coil): From (+) ground of the battery, if starting, or (+) ground of the generator, if the generator is running at proper speed, to ground (G) of contact-breaker points at top, through points (P), through ignition resistance unit (R), through primary coil (P), to switch (6), to (B), to the ammeter. If the current is from the battery, then through the ammeter, which will show "discharge," to (−) of the battery. If the current

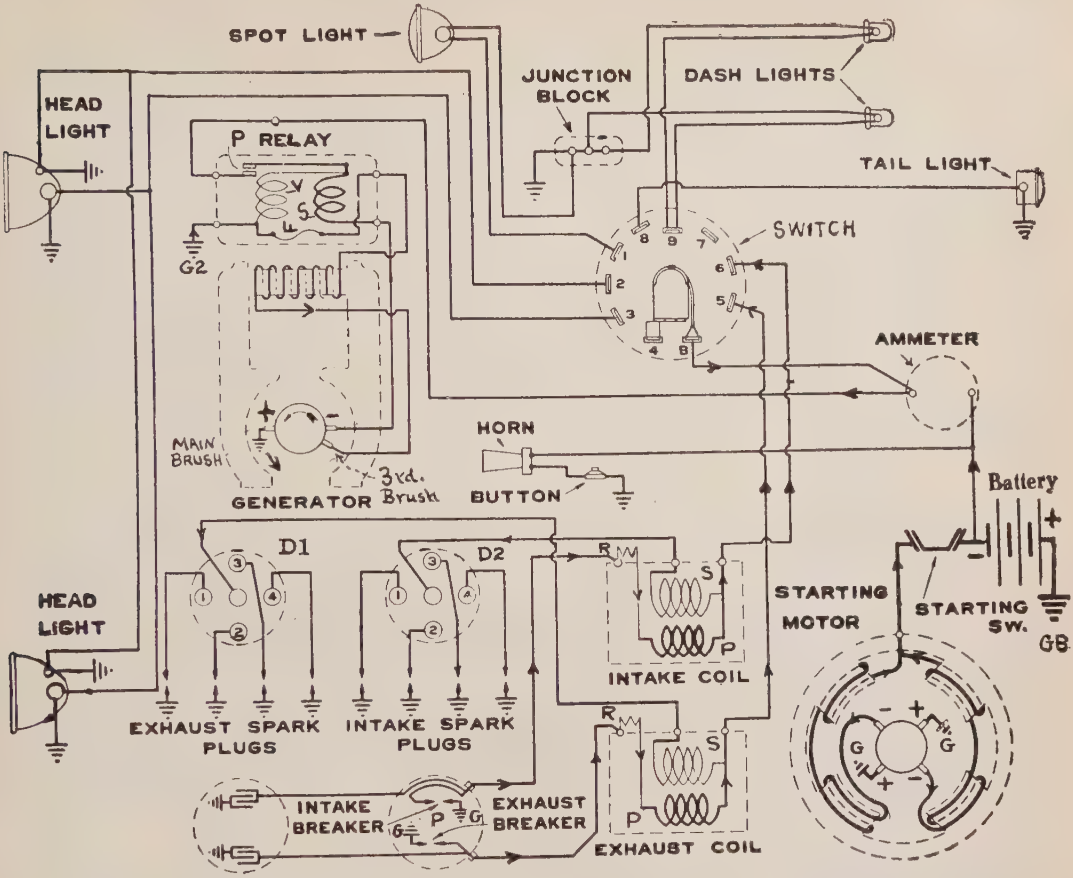

Fig. 9. Circuit diagram of Stutz series "K."

is from the generator, then from the ammeter, to the cut-out, to the (−) brush of the generator.

Ignition primary circuit (exhaust coil): The circuit is exactly the same as for that of the intake coil, except that contact-breaker points for exhaust coil are at the lower part of the interrupter, and circuit is through the lower, or exhaust coil, to (5) on switch. From this point it is the same as previously described.

The secondary circuit from the secondary coil (**S**) on both coils can easily be traced to the center terminal of the distributor, to the spark plugs, to ground, to ground of the battery or generator, to (**B**) on the switch, then to (5) and (6), to the other end of the secondary winding. (The contact points on the interrupter are open when the secondary spark occurs at the spark plugs. The circuit could not, therefore, pass back through this side.)

The Stutz engine is a dual-valve engine. The intake valves are on one side of the cylinder and the exhaust valves on the other.

There are two spark plugs per cylinder: one on the intake side, and the other on the exhaust side. See explanation of the Pierce-Arrow (Delco) ignition distributor on page 216, which is similar.

REMY ELECTRIC SYSTEM ON OAKLAND "34C," McLAUGHLIN "K-62," AND "K-63"

Circuits

Starting motor: From (+) of the battery, to the starting switch, to the series field-winding, to the (+) motor brushes, to the (−) grounded motor brushes, to (−) ground of the battery.

Generator field-circuit: From the (+) main brush, through (closed) thermostat points (**R**), through the shunt-field-windings, to the third brush.

Cut-out voltage circuit: From the (+) main generator brush, to cut-out coil (**C**), to voltage coil (**V**), to the (−) main generator brush.

Generator charging circuit: From the (+) main generator brush, to cut-out series coil (**C**), through (closed) points (**P**), to ammeter (**A**), through the ammeter to (**M**), to (+) of the battery, to (−) ground of the battery, to (−) ground of the generator (**GG**), to (−) main grounded brushes (**G**).

Ignition primary circuit: From (**A**) on the ammeter, which takes current direct from the generator without passing through the ammeter, if the generator is supplying current, or from (**A**) to (**M**), through the ammeter, which would show "discharge," if current is taken from the battery, to (1) on the switch, to (2), to the ignition resistance unit, to primary winding (**PR**), to the insulated contact-breaker terminal, through points (**P**), through arm (**A**), to ground (**G**), to (−) ground of the generator or battery.

Secondary ignition circuit: From secondary winding (**SC**), to the distributor, to the spark plugs, to ground, to the grounded end of the secondary (**G**).

The condenser is in the coil and across the points of the contact-breaker.

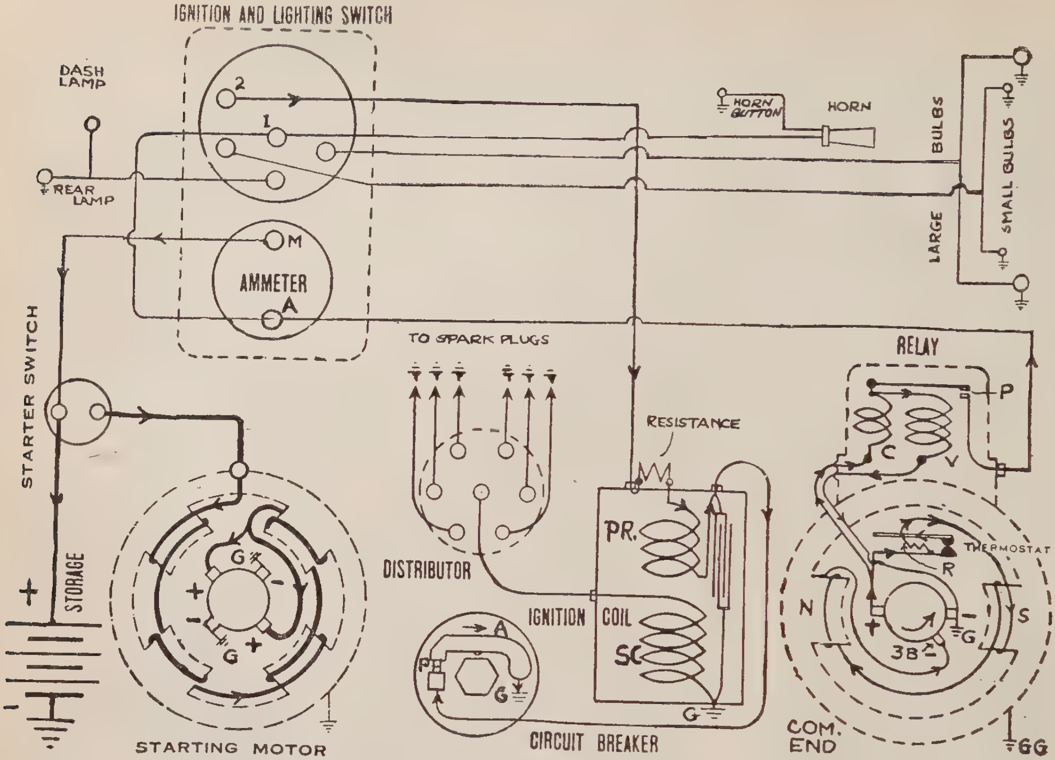

Fig. 10. Wiring diagram of Oakland "34-C" and McLaughlin "K-62," "K-63" (Remy system).

OVERLAND "4" ELECTRIC SYSTEM

Electric system: Auto-Lite two-unit, 6-volt starting and lighting system, with Bendix drive. U.S.L. Battery, 6-volt, 80-amp. hour. Model GK 1001 generator with third-brush regulation. Starting motor model MG 1001.

Ignition: Connecticut timer and distributor driven from the armature shaft of generator (Figs. 12 and 13).

See page 40 for engine illustration and description.

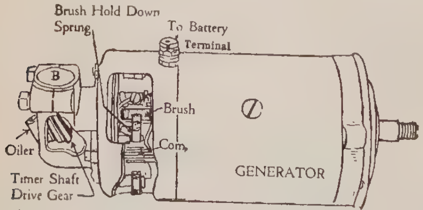

Fig. 12. Generator, driven from the right side of the engine, by helical gears, from the crank shaft.

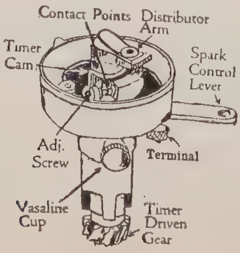

Fig. 13. Timer, driven from the armature shaft through opening (B, Fig. 12) by helical drive gear.

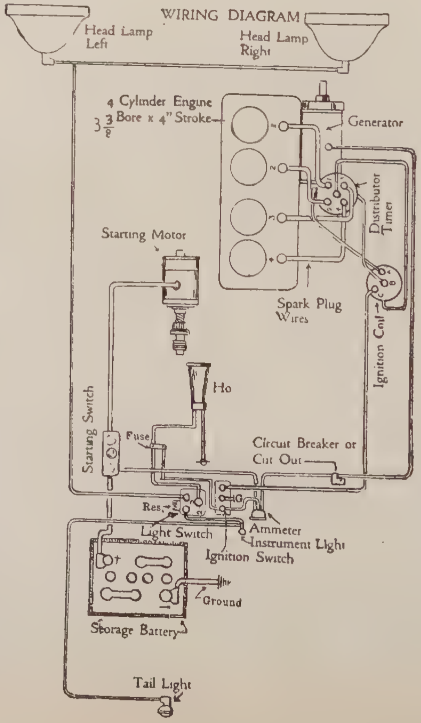

Fig. 14. External circuit of the electric system on Overland "4."

Overland "4" Circuits

Generator field-circuit: From the (+) third brush of the generator, through the field windings, to the (−) main brush.

Cut-out voltage circuit: From the (+) main brush, to the fine wire voltage winding (V) on the cut-out (circuit-breaker), to ground, to the (−) main grounded brush of the generator.

Generator charging circuit: From the (+) main brush of the generator, through cut-out points (P), to cut-out series coil (S), through the ammeter, to the (+) terminal of the battery, to the grounded (−) terminal of the battery, to the (−) grounded brush of the generator.

Starting-motor circuit: From the (+) terminal of the battery, through the closed starting switch, to the terminal on the starting motor, through the two "series parallel" windings on each side, to the (+) brushes, through the armature, to the (−) grounded brushes, to (−) ground of the battery.

Primary ignition circuit (from battery when starting): From (+) of the battery, to (D), to the ignition button switch, to the thermostat switch,[1] through wire (I) to the primary winding of the ignition coil, to the timer (contact-breaker of the closed-circuit type), through the timer points, to the ignition coil where the primary and secondary windings are grounded, thence to ground (G1), to (−) ground of the battery. On the circuit just described, the ammeter would not indicate, as the current is flowing **from** the battery, but not through the ammeter.

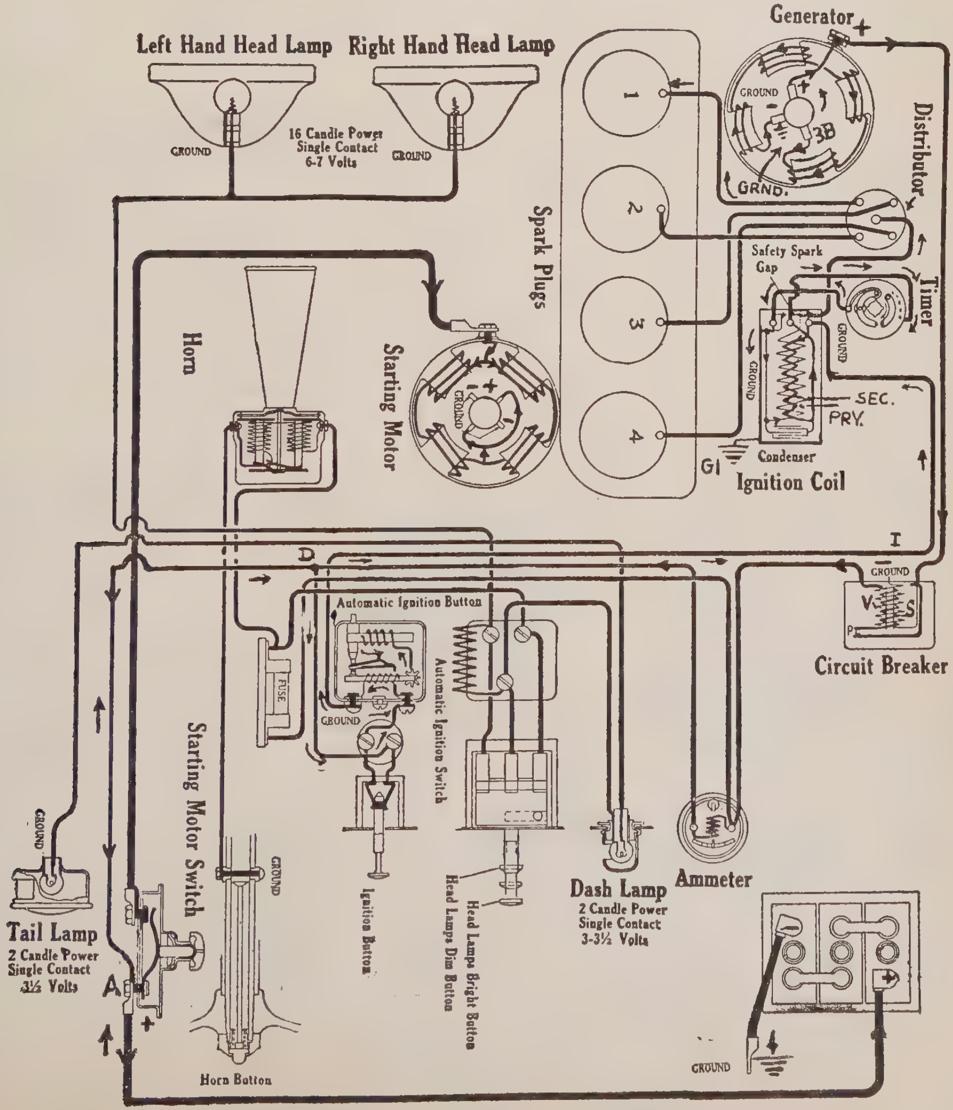

Fig. 11. Wiring diagram of the Overland "4"; Auto-Lite electric system.

---

[1] The "Connecticut ignition thermostat switch" is illustrated and described elsewhere. See Index.

Primary ignition circuit (from generator): From point (**D**), which takes current from the generator which must pass through the ammeter. Thus the ammeter would read on the "charge" side, because the current would be flowing from the generator to the battery, and the ammeter is between point (**D**), where the ignition is taken, and the generator. The rest of the circuit would then be the same from point (**D**), as explained above.

Light circuits, if from battery, would be from (+) of the battery, to the ammeter, then through the ammeter, to the inside wire at the right-hand connection of the ammeter, to the fuse, thence to the lighting switch, through the different lighting circuits. The ammeter would read on the "discharge" side.

If current for lights comes from the generator, then start with (+) of the generator, to the cut-out, to the ammeter (but not through the ammeter), to the wire from the same connection on the ammeter, to the fuse, and from this point on, as before. In this instance, the current for lights would not pass through the ammeter, but the generator would be charging the battery and supplying current for lights and ignition also. Thus the ammeter would read on the "charge" side, indicating the amount of current flowing to the battery and used for ignition.

Data Concerning Overland "4" Electric Equipment

Battery: USL CD 311, 11-plate, 6-volt, 80-ampere hour capacity; located underneath driver's seat.

Generator: Auto-Lite GK 1001, 4-pole, third-brush regulation type; mounted on right front side of engine.

Starting motor: Auto-Lite MG 1001, 4-pole type; mounted at side of engine.

Cut-out: Auto-Lite CB 1069, rectangular type; mounted on right gasoline tank bracket.

Switches: Auto-Lite XA 265 for ignition and lights, and resistance coil to dim head lamps, and with ignition cut-out; mounted on instrument board.

Starting switch: Auto-Lite SW 1600, mounted on left frame member, with button protruding through toe board in front of driver's seat.

Current indicator (**ammeter**): Auto-Lite XA 191, mounted on instrument board.

Ignition: Battery ignition, Connecticut GA type, spark coil with timer and distributor; mounted on right side of engine.

Horn: Vibrator type, mounted on left side of engine; control button on top of steering column.

Lamps: Four; head lamps, single-bulb, single-contact, 6-volt, 16-candle power; dash and tail lamps, single-contact, 3-volt, 2-candle power.

Fuse block: For lights; mounted on left gasoline tank bracket.

DELCO ELECTRIC IGNITION ON PACKARD "SIX," MODEL 116-1921

The Delco ignition is used on this car, but **Atwater Kent starting motor and generator** are provided for generating current and for starting.

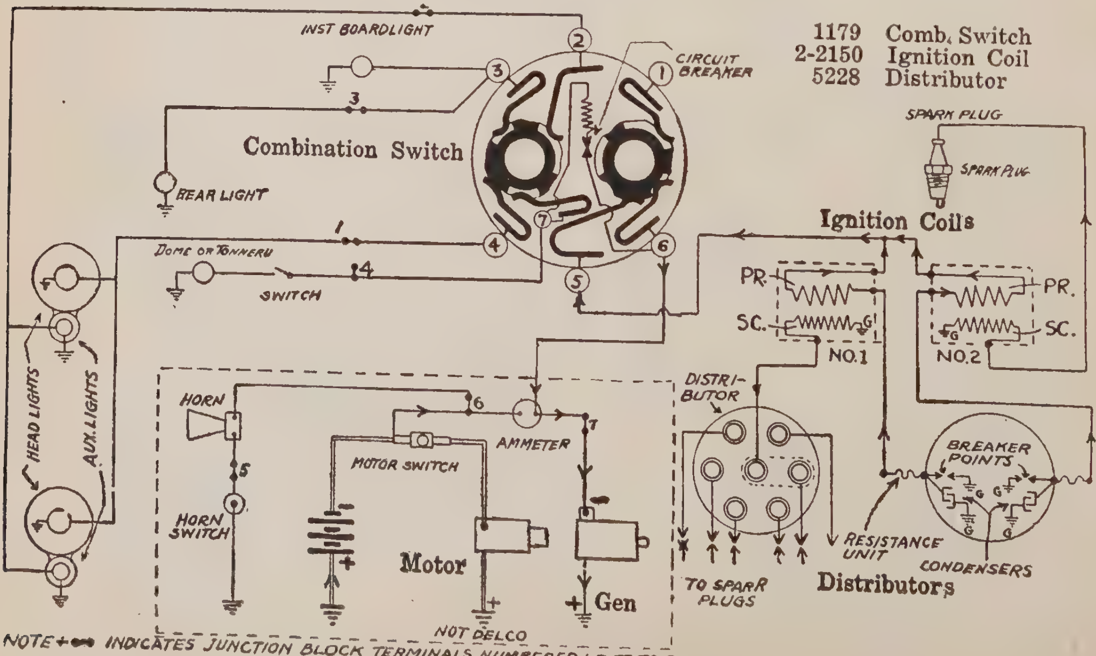
Packard (Model 116) Circuits

Starting motor: From (+) ground of the battery, to (+) ground of the starting motor, to the switch, to (−) terminal of the battery.

Generator charging circuit: From (+) ground of the generator, to (+) ground of the battery, to (6), through the ammeter, to (7), to (−) terminal of the generator.

Primary ignition circuit (battery): From (+) ground of the battery, to grounded (**G**) contact-breaker points (on the left), through the ignition resistance unit, to primary winding (**PR**) of the ignition coil No. 1, to (5) on the switch, to (6), through the ammeter, to (−) terminal of the battery.

Primary ignition circuit (generator): From (+) ground of the generator, to contact-breaker-point ground (**G**) on the left, and through the same path, but to the (−) generator terminal instead of to the battery.



NOTE ←•→ INDICATES JUNCTION BLOCK TERMINALS NUMBERED LEFT TO RIGHT

Fig. 15. Wiring diagram of the Delco-Packard (model 116) electric system.

Secondary circuit to ignition spark plugs: From secondary winding (SC), on coil No. 1, to the distributor rotor, to the spark plugs in the engine, to ground, to ground (G) of the secondary winding.

Fuelizer ignition coil is No. 2. This coil is used for the single spark plug used in the Fuelizer. (See pages 108 and 140 for an explanation of the Fuelizer.)

The primary circuit is the same as for the other coil, except that the contact-breaker points on the right of the contact-breaker are used.

The contact-breaker and distributor for this system are shown on page 219. Note that two sets of interrupter contacts are provided, each set being connected in series with a separate ignition coil.

PACKARD "TWIN-SIX" 1920-1921 ELECTRIC SYSTEM

The Delco ignition is used on this car. **Bijur generator and starting motor** are used. See also pages 217, 84, 85, 86, for other illustrations pertaining to the Packard "Twin-Six."

Packard "Twin-Six" (Models 325, 335) Circuits

Charging circuit: Start with the generator (+) grounded terminal, to (+) ground of the 6-volt, 120-ampere-hour battery, to combination switch (6), through the ammeter, to (−) terminal of the generator.

Ignition circuit: Start with (+) ground of the battery if the engine is running slow, or with (+) ground of the generator if the generator is charging the battery, to ground of interrupters (CP), but first through the resistance units.

Note that there are **three interrupter points** (CP), 1, 2, and 3. The Nos. 1 and 2 are for the No. 1 and No. 2 coils and distributors, and 3 is for the No. 3 coil and spark plug (3P) for the fuelizer. See also, pages 140, 217, giving an explanation of "Fuelizer" and "Distributor."

The engine ignition primary circuit of No. 1 distributor is through ignition resistance unit (R1), through contact points (CP–1), through primary coil (1), to junction (J), to the ignition switch, to 5 and 6, to (−) of the battery or generator. Note condenser (1) is connected across the points (CP–1). If the current is from the battery, it will not pass back through the ammeter. If current is coming from the generator, it will pass through the ammeter, but as the generator would then be charging the battery, the ammeter would indicate the current flowing from generator to battery and the ignition, and would indicate on the "charge" side of the ammeter.

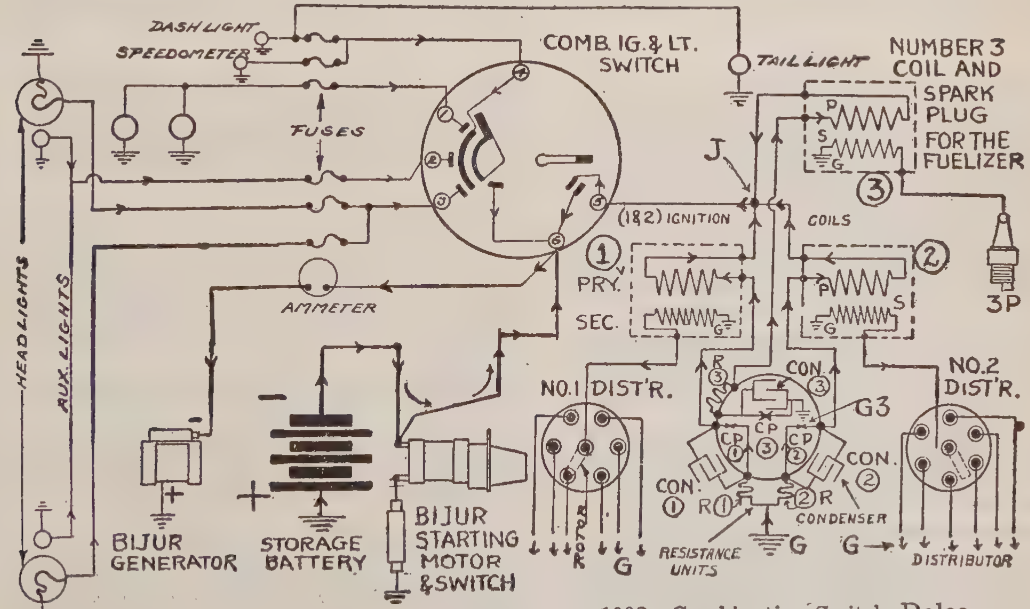
Secondary circuit of No. 1: From the secondary winding on coil (1), to the distributor arm or rotor, to the spark plugs, to ground, to grounded secondary terminal (G) on No. 1 coil.

Engine ignition primary circuit of No. 2 distributor is similar, except that the circuit is through resistance (2R), through points (CP–2), through primary winding (P) of coil 2, to junction (J).

The secondary circuit of No. 2 is similar to that of No. 1, except that it passes to No. 2 distributor.

The fuelizer ignition primary circuit is from (+) of the battery or generator, to ground (G3) of the interrupter, through points (CP–3), through resistance (R3), to primary winding (P) of coil 3, to junction (J), to switches (5 and 6), to (−) terminal of the battery or generator.

The secondary circuit for the fuelizer spark plug is from (S), coil 3, to spark plug (3P), to ground, to ground (G) of coil 3.



1092	Combination Switch-Delco
3-2150	Ignition Coil .... "
5220-5238	Distributor .... "

Fig. 16. **Packard "Twin-Six" wiring diagram:** Note the twin or dual set of interrupters. The breaker arms are operated by one three-lobe cam. There are three high-tension coils, one used for ignition for the right block of the cylinders, and the second, for the left block. The third coil (3) is used in connection with a spark plug (3P) in the fuelizer. An auxiliary contact-breaker mechanism, mounted on top of the distributor, is connected with the latter.

Starting-motor circuit: From (+) of the battery, through ground, to the ground terminal of the starting-motor switch, through the starting switch, through the starting motor, to (−) terminal of the battery.

The automatic gear-shift principle, connected with a flywheel is used. The starting motor is a 4-pole, series-wound motor.

Regulation of the output of the generator consists of a constant voltage electromagnetic device which cuts resistance into the shunt-field circuit. The generator regulator keeps a constant electrical pressure or voltage, slightly higher than the voltage maintained by a fully charged battery, this pressure being maintained regardless of speed.

The voltage being constant, the current generated naturally varies, being small when the battery is fully charged and increasing as the lights are turned on or the battery is partially discharged.

The cut-out is a reverse-current electromagnetic type of the usual cut-out principle. The generator field-winding is a straight shunt winding.

The cut-out and regulator are wound on separate cores and mounted on top of the generator. The circuit is not shown but is shown in the Wiring Manual, details of which will be found in the advertising pages of this book.

Fuse Board

All lamp circuits and the horn circuit pass through the fuse board on the front side of the dash. When the horn or lamps fail, examine the fuses. If the fuse is in proper order, then look for loose wires.

Fuses are of the glass-tube type. If fuses continually blow, look for a short circuit as the cause.

Ammeter

The ammeter is located on the instrument board. It is connected between the generator and battery through the switch; thus, with the engine idle, the ammeter does not indicate whether the lights are on or off. Should it register to the left of zero with the engine idle, remove the disconnect plug from the regulator, to prevent discharging the battery.

When the engine is running, the ammeter registers the amount of charging current passing from the generator to the storage battery and lights.

If the ammeter fails to register when the engine is running at about 750 revolutions, or over 20 miles per hour, look for loose connections or broken wires between the generator and battery; also see that the generator commutator is clean and that the brushes are making good contact.

If the ammeter shows a high current continuously of 25 or 30 amperes, it indicates a heavy ground or short circuit in wiring or battery. Disconnect the battery to prevent discharging, and examine the wiring for short circuits.

Electric Lighting

Light circuits can be traced by starting with (+) of the battery or generator, to ground of the lamps, through the fuses, through the switch terminals, to (−) of the generator or battery.

Auxiliary headlights are smaller than the headlights. They are placed in front, to be used in place of headlights. The headlights are 24 c.p., 7-volt and the auxiliary headlights are 6 c.p., 7-volt. See diagram of wiring. They are sometimes called dimmer lights.

REMY ELECTRIC SYSTEM ON OAKLAND "32" AND McLAUGHLIN "D-60"

The Remy "relay-regulator" system, described on page 350, was used on these cars (1916). The system is shown here in order to give an example of the Remy relay-regulator in connection with a plain shunt-wound four-pole generator using an "electromagnetic current regulation" of the shunt-field-circuit. See Fig. 17 on the next page.

Circuits

Generator: Plain shunt wound, with an electromagnetic vibrating-current type of regulator (see also page 350). This regulator is operated by the amount of current flowing from the generator to the battery through the regulator winding (D). It would thus be termed an electromagnetic "constant-current" regulation method.

Generator shunt-field circuit: From the (+) main brush of the generator, to the fuse, to (Y), to closed regulator points (E), to (H), to the shunt-field windings, to (−) main brush (G) of the generator.

Note. This is **not a third-brush regulated generator,** although there are three brushes. The brush on the left is used for grounding purposes. All brushes bear on neutral points of the commutator, and are therefore "main brushes." See, also, page 359.

Cut-out (relay) voltage circuit: From the (+) main brush of the generator, to the fuse, to (Y), to cut-out voltage coil (J), to ground (G1), to the (−) grounded generator brush.

Generator charging circuit: From the (+) main brush, to the fuse, to (Y), to closed cut-out (relay) points (A), through cut-out series coil (C), through regulator winding (D) (note that the charging circuit flows through the **regulator** winding), to (K), to the fuse block, through the ammeter, to (+) terminal of the battery.

When the generator speed is high, the regulator comes into action by cutting resistance (F) into the shunt-field circuit of the generator, thus reducing the magnetic strength of the field, and consequently also the output of the generator. The action is as follows: from the (+) brush, to (Y). Points (E) are now open, because of the high charging current value flowing through regulator coil (D), drawing points (E) apart. Thus the field circuit must then pass from (Y), through resistance (F), to (H), to the other end of the field winding.

Note. It will be noted in the diagram that half of the resistance coil (F) is shunted across one set of regulator points, and half across the other set (there are two sets of regulator points). It is essential that the two sets be adjusted equally, so that the same current through regulator coil (D) will separate both points at the same time; otherwise the generator output will be high. See Index for Remy "relay-regulator" adjustments, etc.

Ignition primary circuit (from battery, when starting): From (+) of the battery, to the ammeter, to the fuse block, to switch (Z), to (I), to primary winding (P) of the coil, to the contact-breaker (closed-circuit type), to the right terminal on the coil, to the switch, to ground (G3), to (−) ground of the battery.

The ammeter would now read on the "discharge" side, as the current is coming from the battery.

Note. This switch is termed a **"pole-changing"** switch. If switch blades (B) and (B1) were reversed, the current would flow through the contact-breaker points in the opposite direction. See page 203, explaining this type of switch.

Ignition primary circuit (from generator): The current would be taken from the fuse block, to (Z), and the same path would be followed. The ammeter would not indicate the ignition current, but would indicate the amount of current going to the battery.

Starting-motor circuit: From the (+) terminal of the battery, to the starting-motor straight-series field-winding, through the field-windings, to the (+) brushes, through the armature, to the grounded (−) brushes, to (−) ground of the battery (G2).

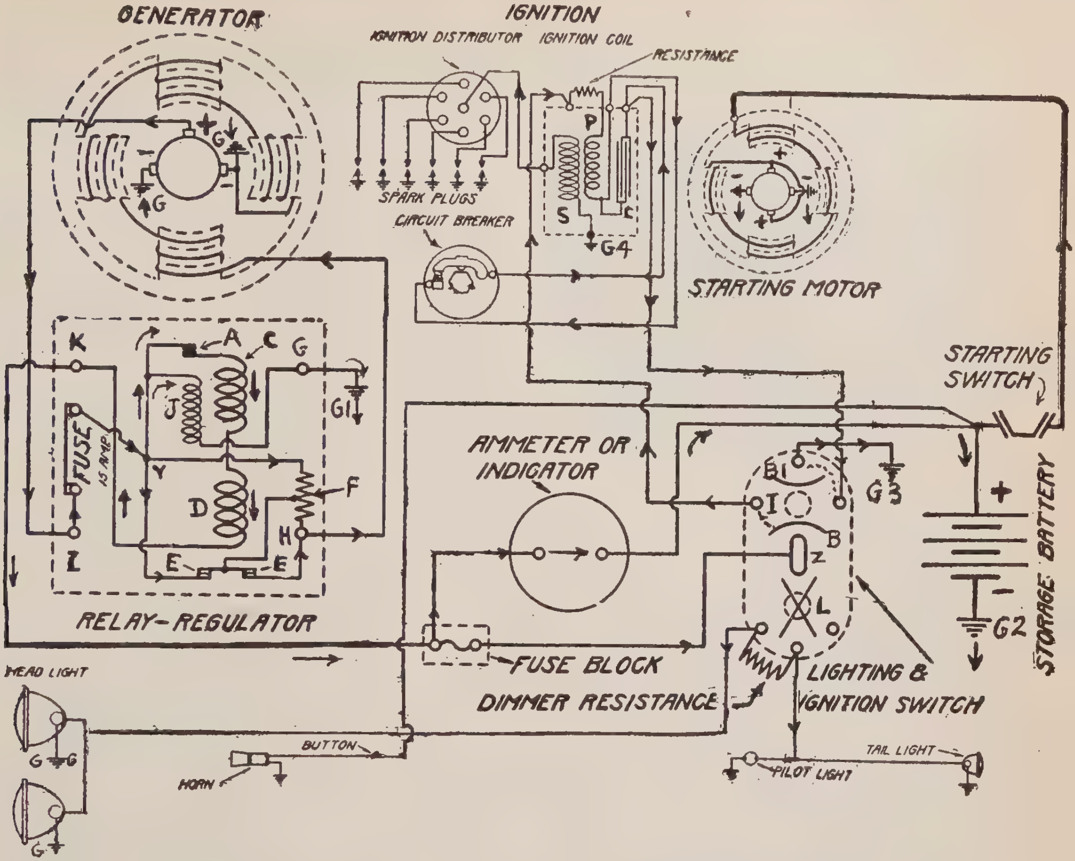


Fig. 17. Wiring diagram of the Oakland 32 and McLaughlin "D-60" explaining the Remy "relay-regulator" and the "pole-changing" switch (see Index for these subjects).

FRANKLIN (Up to July, 1921) ELECTRIC SYSTEM

The Franklin air-cooled, six-cylinder engine automobile electric system used on models "9A" and "9B" until July, 1921, is shown in the illustration (Fig. 18). Note that the **ignition system** is the Atwater-Kent **open-circuit** type. A master vibrator is used for starting purposes.

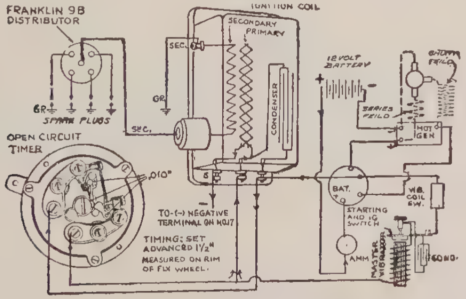

Fig. 18. Franklin electric system.

On later models, the Atwater-Kent **closed-circuit** ignition system is used, and the master vibrator is dispensed with. Instead, the switch is so arranged that on starting position, it cuts out a part of the primary coil winding, thus lowering the resistance of the coil, so that in cold weather, when the battery is used excessively for starting and is more or less weak during these periods, the ignition coil resistance is cut down, as mentioned above, and the spark is sure to occur. After starting, and when the battery is "boosted up" by the generator, the switch movement cuts in the full primary coil winding.

Motor-generator: The 12-volt single-unit **Dyneto motor-generator** is used. The motor-generator is directly connected to the crank shaft of the engine. The motor-generator acts as **a generator** at car speeds over 8½ m.p.h., and as **a motor** at speeds below this point.

The current output is regulated by a compound winding "differential in action," consisting of a series and a shunt-field winding which oppose, or "buck," each other, as a generator. This is termed "differential action," and the windings assist each other as a motor, or "cumulative action."

The regulation is also by a "third brush," which reduces the voltage through the shunt-field winding, which, in turn, is caused by "armature reaction" at high speeds.

Starting motor: A Dyneto motor-generator connected to the crank shaft of the engine by a silent chain; operated from the cowl board by the same switch that controls the ignition.

Generator: A Dyneto motor-generator; shunt winding, and a series-field winding are both used for the generator.

Ignition: Atwater-Kent open-circuit timer and distributor, using a box type of coil, with a condenser in the coil. A master vibrator is used for starting, which gives a continuous series of sparks instead of a single spark operated by a switch on dash. The distributor rotor takes care of the time at which the spark occurs. This device is used only for starting purposes.

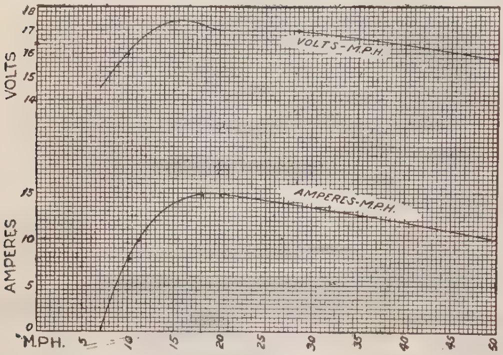

Fig. 19. The diagram or curve shows the voltage and amperage at various speeds of the car.

For instance, at a speed of 10 m.p.h. (lower line of figures), the amperage is 8 amperes; the voltage is 16 volts. At 18 m.p.h., the highest amperage peak is reached, which is 15 amperes, and at this speed, the voltage is 17 volts. The highest voltage is reached at 15 m.p.h.

The voltage begins to drop at a car speed of 28 m.p.h. (from 17 volts to slightly below 16 volts at 50 m.p.h.). The amperage begins to drop at 20 m.p.h., from 15 amperes to 10 amperes, at 50 m.p.h.

Circuits

Starting motor: From (+) of the battery, to the indicator,[1] through the indicator, to the switch, to the (+) terminal on the motor-generator, through the field-windings, to the (+) brush, through the armature, to the (−) brush, to the (−) terminal of the battery.

Generator shunt-field circuit: From the (+) main brush, or terminal of the motor-generator, to the switch, to the connection on the lower right of the switch, through a fuse (not shown), to the terminal on the motor-generator connecting with the shunt-field winding, to the (−) main brush of the generator. A 10-ampere fuse is in series with the shunt-field circuit.

Generator charging circuit: From the (+) main brush, to the switch, through the current indicator marked (**AMM**), to (+) of the battery, through the battery, to the (−) battery terminal, to the (−) brush of the motor-generator.

Ignition master-vibrator circuit: This ignition system is equipped with a master-vibrator coil which is used for starting. There is only one winding (primary) on this coil. When the switch or starting circuit is closed, the current is from (+) of the battery, to the switch, to the right-hand switch terminal, to the vibrator blade of the master vibrator, to the vibrator screw, to the primary winding of the master vibrator, to the lower center terminal of the coil, through the coil primary winding, to junction block (No. 17) which connects with (−) of the battery. This master vibrator gives a continuous succession of sparks to start with, and the distributor takes care of the time of the spark to the engine. The switch is thrown to the regular ignition after the engine is under way, and when the generator is "boosting" the battery.

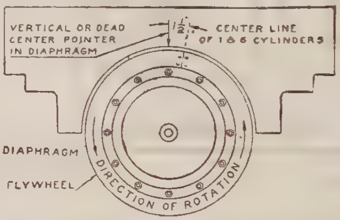
The primary ignition circuit of the ignition coil is from the battery or generator at the right-hand switch terminal in the illustration, to the left, to the first terminal on the coil, to the timer, through the points, to the center coil terminal, to the primary winding of the coil, to the left-hand coil terminal, to No. 17 on the junction block, to (−) of the battery.

The secondary ignition circuit is from the secondary winding, to the distributor, to the spark plugs, to ground, to ground of the secondary.

The ignition timing (Atwater-Kent open-circuit type): The timer is set so that it fires at 1½″ advance, measured on the rim of the flywheel.

To check timing: Remove the distributor cover and turn the engine over slowly until the click of the contact-maker is heard. Stop exactly at this point, raise the toe-boards, and see if any center line corresponds to the position of "C. L. 1–6" shown on the flywheel.

To reset timer: Turn the flywheel until No. 1 cylinder completes its compression stroke and the 1–6 center line is 1½″ ahead of the center point in the diaphragm (Fig. 20). Loosen the clamp screw in the aluminum base plate of the timer, so that the body can be turned in its bearing. For accurate setting, the body should be clamped tight enough to turn hard.



VERTICAL OR DEAD CENTER POINTER IN DIAPHRAGM
1½″
CENTER LINE OF 1 & 6 CYLINDERS
DIAPHRAGM
FLYWHEEL
DIRECTION OF ROTATION

Fig. 20. Flywheel markings for spark setting.

Turn the distributor-timer body in a clockwise direction until the distributor arm is opposite the terminal on the cover leading to No. 5 spark-plug wire. Then turn the body slowly and steadily counter-clockwise until the click of the contact maker is heard. Stop exactly at this point, and tighten the clamp screw.

Adjustment should then be checked by moving the flywheel backwards about 16″ on the flywheel rim, so that it is off the firing point. Then move ahead to the firing point again, and stop the moment a click is heard. If "C. L. 1–6" is then 1½″ ahead of the center pointer on the diaphragm, the timer is set right. Rewire the clamp-screw in the base plate.

Timer contact points are set .010″ apart on the open-circuit type, and .007″ on the closed-circuit type. To adjust the contact screw, take it out of the holder and remove one of the thin steel washers from under its head. This brings the points a little closer together (see also page 203). The points should be examined every 3,000 miles. **The spark-plug gap** should be set at .031″.

Firing order: 1, 4, 2, 6, 3, 5.

Master vibrator adjustment: When operating properly, the vibrator should buzz on an 8-volt circuit, i.e., on 4 cells of a fully charged storage battery. A more accurate way of setting the vibrator is to turn the ignition switch to "neutral" (the engine should not be running), take out whichever spark plug is firing at that time, and set the adjusting screw on the vibrator so that a spark of the highest possible frequency can be observed at the plug points. When the vibrator draws about 1.1 amperes on a fully charged battery, it will give the hottest spark.

For Franklin gear shift and controls, see Index. See the Index also for the Franklin engine.

---

[1] An ammeter of the usual construction generally used, cannot be connected in series with a starting-motor circuit. An **"indicator,"** however, which is used on the Franklin, is so designed that it is capable of carrying the starting current. See pages 469, 468 for explanation of the construction of an "Indicator" and also of an "Ammeter."

INSTRUCTION No. 37

WIRING OF A CAR: Starting, Generating, and Lighting

KINDS OF WIRE USED FOR AUTOMOBILE ELECTRIC SYSTEMS

Primary wire is used for **low-tension** (voltage) work, such as for the ignition circuit, from switch to coil, and from coil to timer, and is also used for lighting circuits. See Fig. 1 below. It is flexible, consisting of several fine strands covered with a waterproof insulation.

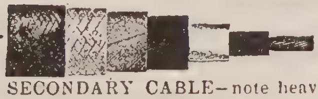
When wiring is used for **lighting purposes,** it can be "duplex" (Fig. 2), or it may even consist of four wires together in one double-covered insulation.

1— PRIMARY WIRE—Single

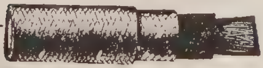
2— PRIMARY WIRE—Duplex

3— PRIMARY WIRE in metal armor

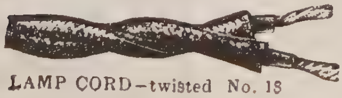
4— PRIMARY WIRE metal armor



5— SECONDARY CABLE—note heavy insulation



6— STARTING MOTOR WIRE note heavy wire



7— LAMP CORD—twisted No. 18

Flexible steel-armored wire is where the wire is protected by being covered in a **metal casing** (Fig. 3). This type of wire is extensively used for automobile work. It can also be secured in "duplex" form (Fig. 4). The wire cannot be withdrawn from the armor.

Secondary cable is used for **high-tension** ignition current from coil to distributor and from distributor to spark plugs. The wire itself is small and flexible, but the **insulation** (usually rubber) is **very heavy,** as it carries a high voltage, but a low amperage.

Starting-motor wire: This **wire** must be **very large,** because it carries a very heavy current. No. 0 is generally used on small and medium-sized cars, and No. 1 or 2, or 00, is used if the distance is greater; as on a large car. The No. 00 measures .36" diameter over the copper strands. This wire is flexible (Fig. 6), being made up of a large number of copper wire strands heavily insulated with rubber and with a braided cover over the rubber. This wire is much heavier than the secondary cable, as it carries a high amperage, but a low voltage.

For example, the **wire running from the storage battery to the starting motor,** when it is first starting, must carry from 80 to sometimes 400 amperes (the quantity of current, which depends on the size of the motor and condition of the engine). This is used only for a few seconds. But large wires must necessarily be used to carry this great quantity, even for a few seconds. Compare the size of the starting-motor wire (Fig. 6) with that of the primary wire (Fig. 1), which can be used for the generator or for lighting. Note the difference in size of the wire.

The wires running from the generator to the storage battery are much smaller (see Fig. 1), as the quantity of current which passes through this wire is only 5 to 25 amperes.

By way of a comparison, imagine water pipes. If you desired to pass 150 gallons of water through a pipe in one hour it would require a larger pipe than one through which you passed only 25 gallons in an hour.

Flexible lamp cord (Fig. 7.) is used **for extension or trouble lamps,** and is not suitable for any other part of the wiring system.

Voltage Drop and Wire Size

When current flows through a wire (conductor), a certain amount of pressure (voltage) is lost in overcoming the resistance that the conductor offers to the flow of current (amperage).

The greater the distance that current flows through a conductor, the greater the loss of pressure. This is known as **"voltage drop."**

The resistance of a wire depends upon two things: (1) the kind of metal in the wire (copper offers less resistance to the flow of current than iron); (2) the area or size of the wire. The resistance of a small copper wire is greater than the resistance of a large wire; that is, the resistance decreases as the size increases.

The size of wire to use depends upon the amount of current that must flow through it, and the length of the wire. The longer the wire, the greater the resistance offered to the flow of current. Therefore there will be too much drop in voltage at the wire terminus, if the wire is not of sufficient size.

A conductor must be large enough to carry the required amount of current to a certain point with less than 5 per cent drop.

Ohms multiplied by Amperes equals Voltage Drop.
Voltage Drop divided by Ohms equals Amperes.
Voltage Drop divided by Amperes equals Ohms.

Almost all automobiles are using a single wire with a grounded return system of wiring, and the length of wire in one direction is seldom over 12 feet.

Voltage Drop and Connections

All connections should be bright and clean, for a dirty connection will add **resistance,** and consequently will cause a **voltage drop.** Binding posts, screws, and the ends of the wire must be scraped clean before the wire is attached—this is very important, especially on low-voltage wiring.

Grounded connections should be filed or scraped bright before attaching the wire, and the connection when made should be firm in position—and tightly drawn up, otherwise resistance will be added, thus resulting in a **voltage drop.**

Ampere Capacity of Copper Wire

The carrying capacity of copper wires (B & S gauge)[1], as given by the National Board of Underwriters for rubber-covered wire, is shown opposite.

The higher the number, the smaller the wires. No. 0 is many times larger than No. 18. No. 18 is .04 or 3/64″ diameter; No. 0 is .32 or 5/16″ diameter.

---

[1] B & S gauge means Brown & Sharpe gauge, and is a recognized standard.

Carrying Capacity of Copper Wire

No. 18	B & S gauge.	3 ampere
No. 16	B & S gauge.	6 ampere
No. 14	B & S gauge.	15 ampere
No. 12	B & S gauge.	20 ampere
No. 10	B & S gauge.	25 ampere
No. 8	B & S gauge.	35 ampere
No. 6	B & S gauge.	50 ampere
No. 4	B & S gauge.	70 ampere
No. 3	B & S gauge.	80 ampere
No. 2	B & S gauge.	90 ampere
No. 1	B & S gauge.	100 ampere
Nos. 1 & 0	B & S gauge.	125 ampere
Nos. 2 & 0	B & S gauge.	150 ampere

AVERAGE LENGTH AND SIZE OF WIRE USED FOR WIRING A CAR AND EXTERNAL CIRCUITS

An example of the size of wire used for wiring a car and the length for the different circuits of an average car is shown in the accompanying illustration, which is the wiring diagram of the Lexington Series "S" model (Fig. 8). Connections of the wires to the fuse block and other details are also shown.

Generator: Third-brush regulated Gray & Davis.

Starting motor: Gray & Davis.

Ignition: Connecticut system using type 96Y switch.

Wiring system: Single wire, grounded return.

Eight External Circuits of an Electric System

The diagram (Fig. 8) **clearly shows the eight external circuits.** The internal circuits of the generator, and its field-winding circuit and cut-out circuit are not shown. The cut-out is mounted the generator, but is not shown.

Starting-motor circuit: From the grounded (- terminal of the battery, to the grounded terminal the motor, through the starting switch, to the (- terminal of the battery.

The ignition circuit, when starting, is from grou (**G**) of the ignition coil, to coil terminal (**A**), throu the primary wire, to contact-breaker terminal (T through the closed contact-breaker points, to (E through the coil primary winding, to (C), throu a jumper (J) on the fuse block, through igniti thermostat (H) on the switch, to switch (1G to ammeter (1), through a jumper on the fu block, to the (−) terminal of the battery at t starting switch.

If the generator is supplying the ignition curren the circuit is then from (+) of the generator, throu

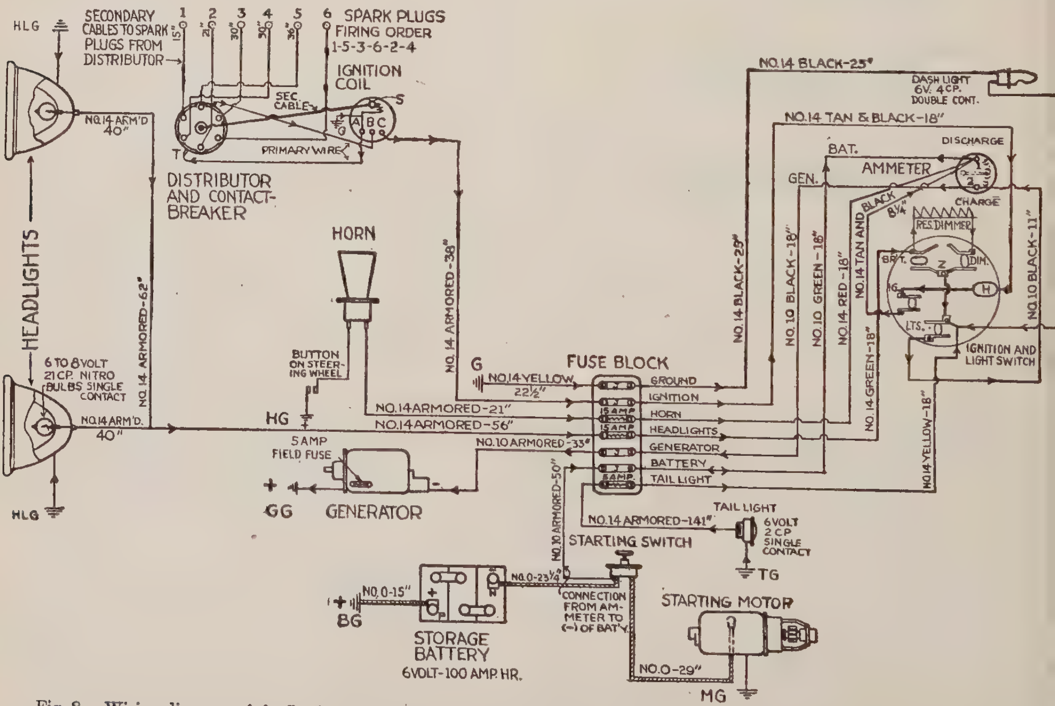


Fig. 8. Wiring diagram of the Lexington (Series "S"), showing the **size of wire used, length of wire,** size of lamp bulbs, fus block, and the various circuits. Note where armored cable is used; also how the connections are made to the ammeter, an where secondary cable is used. Note also the starting-motor cable and the size of it.

Note, too, that **No. 10 wire** is used in the **generator and battery** circuit; **No. 14** is used in **ignition and lighting** circuits, an **No. 0** in the **starting-motor** circuit.

The Connecticut ignition thermostat (see "H" on the switch) is incorporated in the ignition circuit, and is for the purpos explained under a similar principle but different arrangement, as used in the Connecticut ignition system on the Overland "4. See Index for "Connecticut ignition thermostat."

he same circuit to (1) on the ammeter, through the mmeter to (2), to jumper (J) on the fuse block, to he (−) terminal of the generator. The condenser s in the coil.

The secondary circuit is from the coil of the econdary terminal (S), through the secondary cable o the center, or rotor of the distributor, to the spark lugs, to ground, to ground (G) of the coil, to the rounded end of the secondary at (A).

Generator charging circuit: From the (+) ground f the generator, to the (+) ground of the battery, o the fuse block, through jumper (J) on the fuse lock ("jumper" means that instead of a fuse, a traight connection is made), through No. 10 size reen wire (**BAT.**), to (1) on the ammeter, through he ammeter to (2), through (**GEN.**) black wire No. 10 size), to the fuse block, through jumper (J), o the (−) terminal of the generator.

Headlight circuit: From the (+) battery ground r (+) generator ground (whichever is in service), to round of the headlights (**HGL**), through the lamp ulbs in parallel, to the fuse block, through a 15-mpere fuse, through green wire (No. 14) size, to one side of the dimmer resistance. If connections are made at (**BRT.**), then resistance is cut out. If made at "Dim," then current must flow through the resistance and bright would be "off"; then to (**Z**), to (**LTS**), to (2) on the ammeter, and through the ammeter to (1), to the (−) battery through wire (**BAT.**) (if the battery is supplying the current), or, if the generator is supplying the current, not through the ammeter but direct through wire (**GEN.**), to the (−) terminal of the generator.

The other circuits, such as those of the horn, the tail light, and the dash light, can be traced in the same manner, starting with the (+) ground of the battery, if engine is not running, or is running very slow; or at the (+) ground of the generator, if the engine is driving the generator at sufficient speed to charge the battery, at which time all current is taken from the generator. (The starting-motor current, of course, is never taken from the generator.) From the (+) of the generator, or battery, it is then necessary to **start with (+) ground of all circuits because the (+) of the battery is grounded.** For this reason the **(+) of the generator must be grounded,** and the "lead" is from (+) to all grounds, back to (−) of battery or generator.

WIRING METHODS

There are three methods for wiring a car: (1) the ingle-wire, or grounded, return system; (2) the wo-wire, or fully insulated, system; (3) the three-ire system.

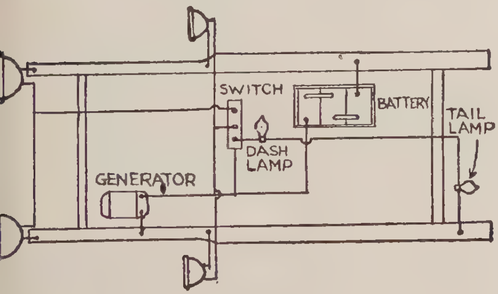

Fig. 9

The single-wire or grounded return system (Fig.): One insulated wire is insulated from the frame nd is termed the "lead" wire. The frame serves as ne return wire. However, when the (+) terminals f the generator and battery are grounded, then the ame serves as the lead. The ground connection om the battery wire or cable to the frame is usually heavy copper connection which is tightly bolted to cleaned surface with copper or brass washers on ich side. This connection, as well as all other rounded connections, must be clean and secure, so nat vibration will not jar it loose. This is the sysm in general use.

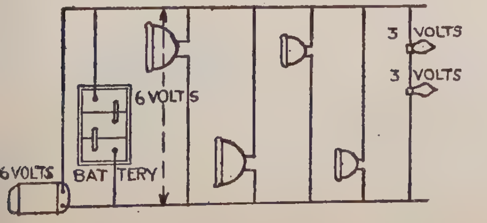

Fig. 10

The two-wire, or insulated, system (Fig. 10): In this system, both insulated wires—the lead wires and return wires—are kept away from the frame and from all metal parts of the car.

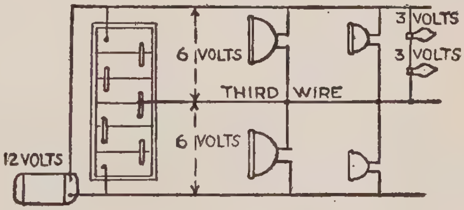

Fig. 11

The three-wire system (Fig. 11): This system consists of three wires, one being known as the **"neutral."** Note in this illustration that the storage battery is a 6-cell or 12-volt battery and the third wire divides the three cells to a circuit, making 6 volts for each side of the third wire.

It is important that the lights or load be equalized, for if three of the six cells are worked more than the other three, and both sets are charged from the same source and at the same rate, one set would get more charge than the other. When the load is properly balanced, there will be no flow of current through the neutral, which is the reason for so calling it. This system is now seldom used.

Wire Connections

The connections in electric wiring should be soldered. The unsoldered connection may work as well as a soldered connection at the time of being made, but the resistance always increases.

Soldering paste: Do not use acid when soldering electrical apparatus or wiring, as acid is an electrical conductor and destroys the insulation. It is much better to use a non-corrosive soldering paste.

Tape: Do not use friction tape on high-tension wiring or on other wiring where the grease or oil can get to it. It is much better to use linen tape and shellac. Friction tape will not insulate ignition current, neither will it hold when oily. Repairmen often burn the alcohol out of the shellac after coating with it. This causes it to harden, and makes a hard-coated insulation.

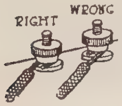

Fig. 12 Fig. 13

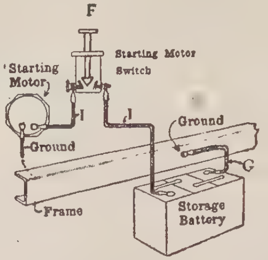

Fig. 14

When placing a wire terminal under a terminal nut, twist the wire in the direction in which the nut turns, as shown in Fig. 12.

When connecting a wire under a screw or nut, use a brass washer.

Note. When stranded wire is used on any part of a car, sometimes one strand will play loose from the others and cause a short circuit. Always twist and solder the ends of stranded wires.

Use wires with different colored insulation when wiring the car; then they can easily be traced.

Starting-Motor and Battery-Cable Connections

Short circuits: Fuses, which will melt on a dead short circuit and open the circuit, are usually provided on all parts of the electric system, except from the battery to the starting motor. The current here is too great for a fuse.

It is plain, therefore, that if the insulated cable (1, Fig. 14) should become frayed and touch the frame or any metal part of the car, a dead short circuit would result. If this were left shorted for several hours, the plates would be likely to become buckled inside of the battery and touch each other and cause an internal short circuit which could not be repaired. A battery is on practically a dead short circuit each time the engine is started, but only for a moment.

Result of Open Connections between Generator and Battery

Open circuits: If, on the other hand, the ground terminal (G) of the battery to the frame, or the wire from the battery to the generator, in fact all wires in the circuit from the generator to the battery and ground, are not in perfect contact, there will either be a resistance set up which will reduce the charge going to the battery and the discharge from the battery, or a complete open circuit.

If a complete open circuit should exist between generator and battery, especially on a constant-current-regulated generator, such as a third-brush-regulated generator, then this would have the same effect as if the battery were disconnected from the circuit. The result would be that the generator would build up a high-current value at high speeds and burn out the lights and possibly the cut-out winding, and might also damage the field windings.

How to Make Connections

Good connections from generator to battery and battery ground connection are, therefore, very important. The **battery ground connection** is not only used for the starting-motor circuit, but is used for the generator and all other circuits.

The ends of wires or cables should be "tinned" by dipping them in molten solder and then cleaned, and strong copper terminals should then be soldered thereto for attaching to the motor and to the switch. The **terminals** themselves should also be cleaned before soldering.

If the battery terminals are sulphated with a green corrosion, wash them off, as well as all surrounding parts, with carbonate of soda or some other alkali.

Clean the battery terminals inside with a round file and the terminal itself with a flat file. The acid of the battery tends to corrode the terminals, and after cleaning, a little vaseline will help to prevent this (on the lead terminals and the lugs of the battery).

The ends of wires connecting with the battery are fitted with copper terminals which are lead coated. On the cable leading from the battery to ground on the end of the cable which grounds to the frame, a heavy copper terminal is used. It is important that these lugs be properly scraped, cleaned, and soldered, and that all connections be drawn tight.

The frame, where the ground is made, should be scraped clean, and the connection should be drawn tight with a bolt.

Poor connections at battery terminals, or ground, will often result in slow cranking of the starting motor, in dim lights, and in a weak current supply in general from the battery.

Wiring Troubles

Wiring troubles are numerous if the wiring is not properly done. All connections must be soldered. Oil and grease destroy insulation. Moving parts must not touch wires. Protect wires from chafing. Avoid frayed ends. Tape all connections. Connections and terminals must be kept tight. Vibration often jars them loose.

WIRES AND ACCESSORIES FOR LIGHTS, HORN, ETC.

These wires should be protected from oil and dampness and from the frame. There are two methods, either or both of which may be used. One method is to use armored wire (Fig. 15), where the wire remains permanently in the metal armor. The other method is to use a conduit, where it is possible for the wire to be withdrawn.

Conduits (Fig. 16) provide a complete enclosed **runway for wires from which they can be withdrawn** if necessary and through which new wires can be installed. A conduit affords protection from mechanical injury, such as bruises, etc. The conduit is made of galvanized steel and is flexible. Conduit is now seldom used.

Flexible-steel armored cable is very popular. It can be purchased containing one or more wires. The wire **cannot be withdrawn.**

Fig. 15

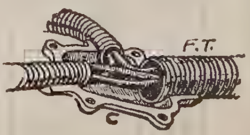

Fig. 16

Fig. 15. Armored cable.

Fig. 16. Showing wires run through metal, flexible tubing or conduit.

The coupling box (Fig. 17) provides a convenient and easily separable means for connecting together the wiring on the chassis and on the car body (seldom used).

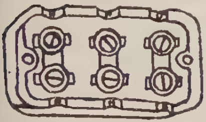

Fig. 17

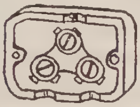

Fig. 18

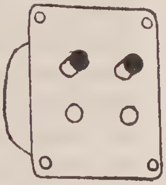

Fig. 19

Fig. 17. Coupling box.
Fig. 18. Junction box.
Fig. 19. Lighting switch.

The junction box (Fig. 18) is for use wherever a branch circuit is tapped off the main wiring. If it is used, no taping of joints is required, and proper connection is assured without soldering. It also affords a junction from which to make tests. (Now seldom used.)

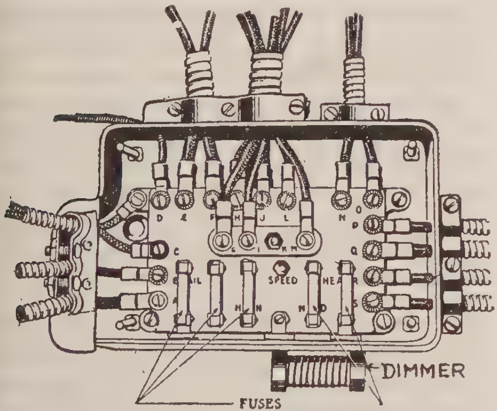

Fig. 20

A junction block, as used on the Studebaker "Big Six" car, is shown in Fig. 20. Note that the fuses are included in the junction box.

Ignition switches are made in many different forms and are usually placed on the cowl (dash) of the car, and are operated with a key. The ignition switch must be "on" when the engine is started.

Starting motor switches are usually operated by the foot. See Index under the caption, "Starting-motor switches."

Lighting switches are usually placed on the cowl (dash) of the car, and are of the **"push-botton"** type. They are usually termed "gang" switches. Fig. 19 shows a "two-gang" type.

A touring switch is sometimes provided on a car or the purpose of allowing the operator to discontinue the charge from the generator to the storage battery when the car is on a long tour, running mostly during the day.

Fuses

Fuses are used on many systems, particularly when the "grounded" or "single-wire system" is used. The purpose of a fuse is to melt and open he circuit in case of a short circuit, and thus to prevent discharge of the battery.

A fuse is never placed in the circuit between battery and starting motor, as the current consumption s too great.

Note. When a fuse "blows," it should not be replaced with a new one until the cause of its blowing (usually a short circuit or overload) is found.

Fuse wires are made in different diameters. The fuse is made of lead alloy and will melt at a given temperature.

If a lighting circuit required 10 amperes of current, then a 15-ampere fuse would be placed in the circuit. Therefore current up to 15 amperes could pass safely; but if more attempted to pass, which would naturally be the result if a short circuit existed, the fuse would melt and open the circuit.

Fuse blocks (Fig. 21) are usually placed inside of the cowl (dash), under the hood of the engine, or in the form shown in Fig. 22, which is placed on the cowl, and to which the different wires of different circuits are connected.

The illustration in Fig. 22 is the fuse box used on the Studebaker "EJ." It is placed on the cowl and contains three fuses: one for the headlights, one for the tail light, and one for the horn, and the dash lamp. It is also arranged to hold one spare fuse.

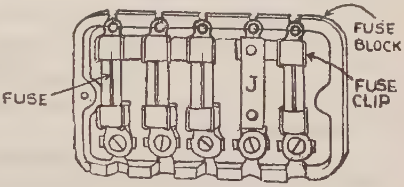

Fig. 21. Fuse block.

The fuse is placed **in series** with the circuit. If a fuse melts, or "blows," it is then an easy matter to insert another fuse, of which extras should be carried. Extra fuses are usually carried in a fuse clip on the fuse block provided for the purpose, and to which there are no wires connected.

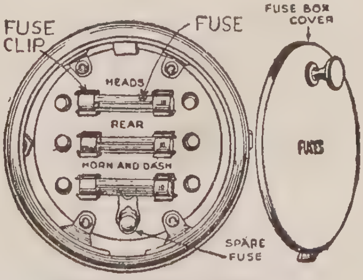

Fig. 22. Round-type fuse box.

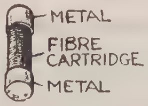
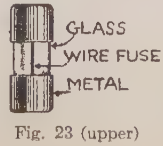
There are three types of fuses: (1) The cartridge, or enclosed type (Fig. 23) which consists of a fiber





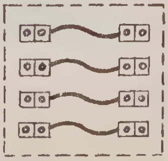


Fig. 23 (upper) Fig. 25 (upper)
Fig. 24 (lower) Fig. 25A (lower)

tube with the fuse enclosed, and which connects with the metal ends. The metal ends are then slipped into the metal fuse clips which should make good contact. With this type of fuse, when it blows, a hole is usually blown in the thin fiber shell.

(2) **The visible type** (Fig. 24) is the type most used. The fuse is enclosed in a small glass tube, and connects with metal ends which are slipped into the fuse clips.

(3) **The open type** (Fig. 25) is seldom used. The fuse block to accommodate this type is shown in Fig. 25A. A screwdriver is necessary to connect or to disconnect a fuse of this type.

Capacity of Fuses

The size of fuse to use is determined by the amount of current that is to pass through it. If the fuse is to be placed in the headlight circuit and 5½ amperes are required, then a 10-ampere fuse would be ample protection.

On an average, a fuse of about 10-ampere capacity is used in the **ignition circuit,** if one is used in this circuit at all, which is seldom.

Fuses in the **lighting circuit** are used on almost all cars, unless a circuit-breaker is used instead, as on the Delco systems. The capacity for **headlight fuses** is 15 to 20 amperes. The **tail-light** fuse is usually of a 5-ampere capacity, and the **horn circuit** of a 15-ampere capacity.

On many cars where fuse blocks are used, it will be found that, although there are fuse clips provided for fuses, a "jumper" is placed in the clips instead of fuses, in all circuits except the horn and lighting circuits.

Testing a Fuse

The enclosed type of fuse, if suspected of being blown, or **the visible type,** if connection of the fuse with the metal part is suspected of being loose, can be tested with a test light (2 c.p.), and battery, as in Fig. 26. If the fuse is blown or the connection is loose, the light will not light, as the circuit is open.

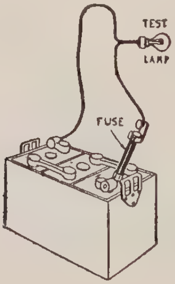

Fig. 26. Testing a fuse.

Fuse Clip Connections

The importance of good contact and clean fuse clips is very great. If the clips are corroded, or if the fuse is not making good contact in the fuse clips, resistance will be offered to the flow of current.

Fuse Between Generator and Battery

If a complete open circuit should exist betw fuse clip and fuse, and this fuse should be in se with the main charging circuit, between the gene tor and battery, this would have the same effect disconnecting the battery from the generator. A if the generator regulation was by means of a th brush, the result would be, at high speeds of generator, that the generator would build up a h value and burn out the lamps and possibly the c out voltage winding and shunt-field windings, if generator was run for a long period of time at a h speed. Thus the importance of occasionally exa ining the fuse clips to see if they are clean and they retain tight connection, must not be forgott

If a fuse should blow in the "main charging c cuit," between generator and battery, the sa result would probably occur. For this reason fuse is omitted in the main charging circuit on ma of the electric systems using a third-brush regula generator, unless there is a fuse in the "field-circu of the generator.

Shunt-Field Fuse

On almost all third-brush regulated generators fuse is placed in the "shunt-field circuit" of generator, in order to protect the generator in c an open circuit occurs in the "main charging circui

In other words, if an open circuit should occur the "main charging circuit" when the generator w running at high speeds, the generator would build a much higher output than normal. If a fuse placed in the "shunt-field circuit," then the fuse w "blow" and open the "shunt-field circuit," thus p venting the generator from reaching an abnorm value—providing the "shunt-field fuse" is of t proper capacity. If the fuse should be of a mu higher value than required, it would not blow time to prevent the generator building up, and t lights would be burned out. Hence the importan of using the correct capacity of fuse in the generat "shunt-field winding," and a fuse of a large enou capacity, or none at all, in the "main charging c cuit." As already stated, a fuse is seldom placed the main charging circuit from the generator to t battery where a third-brush regulation system used, and seldom in the ignition circuit. See Fig. page 426.

Delco Circuit-Breaker

A circuit-breaker is used on Delco electric sy tems in place of fuses. This device opens the c cuit when the current is above normal, as, f example, when a short circuit occurs. The circu breaker is not placed in the generator "ma charging circuit," however, but is usually placed series with the lighting or horn circuit. See Inde "Delco circuit-breaker."

Westinghouse Compensator

A small cylindrically wound resistance unit sometimes incorporated with the fuse block in so of the Westinghouse systems, and is termed "compensator" or "ballast-resistor." Its purpose to protect the side lights from over-voltage, wh the headlights are not lighted.

INSTRUCTION No. 38

LIGHTING A CAR: Electric Lighting; Gas Lighting; Oil Lighting

LIGHTING METHODS

There are three methods for lighting a car: By cetylene gas, by electricity, and by kerosene oil.

The gas light can be produced from carbide in a generator," or it can be stored in a "gas tank" and rried on the car.

Electric lights are supplied with electricity from a orage battery. When the storage battery runs own, it can be recharged from an outside source, or om a dynamo, run from the engine.

The old-style "carbon filament" in the electric obe consumed so much current that it was difficult obtain a storage battery of a reasonable size and eight which would supply current for any length of me. The carbon filament lamp used a filament emically treated and in a vacuum. The filament the "Tungsten Mazda" globe reduces the current nsumption, and is not liable to break with the sual motor-car vibration.

Lights on the car may be divided into those which are required by law (headlamps and rear lamps), and those which add to the convenience and comfort of the driver and his passengers. Side lamps are now seldom used, but small 5 or 6 c.p. lamps are used in the headlamps for city driving, and are often termed "dimmer lamps."

Although some of the older pleasure cars and some trucks and other slow-moving vehicles are still equipped with gas or kerosene lamps, **electricity is the standard method of car lighting** at the present time.

It is well worth knowing that any oil lamp can be quickly and inexpensively converted into an electric lamp by obtaining "adapters" from any of the accessory dealers.

Oil light and gas lights are now seldom used, but are mentioned farther on as a matter of information.

AUTOMOBILE ELECTRIC LIGHTING SYSTEMS

There are three methods of furnishing electric rrent for car lighting:

(1) By independent storage battery system.

(2) By the generator and battery system.

(3) By an independent generator system.

(1) Where an independent storage battery system used, the capacity of the battery must be great ough to run the headlamps and rear lamps for a asonable time before the battery has to be rearged.

A current consumption of approximately 7.85 nperes is required for headlamps and for rear and sh lamps, the equipment of the average car.

A 100-ampere-hour lighting battery would run ese lights for about twelve hours of steady burning. nder average conditions this would mean that the ttery would have to be recharged about once a eek. A 120 or 150-ampere-hour battery will not st much more than a 100-ampere hour and will ve longer service.

(2) Generator and battery system: The advantage this system is that it automatically keeps the batry charged, and permits more current to be used lighting without danger of running down the ttery while on the road. This is **the method now nerally used.** The generator is driven by the gine and charges the battery. The battery supes electric current for the starting motor, ignition starting, and also for lights, if the generator is t charging the battery. In such a case, current is pplied for ignition and for lights by the generator.

(3) Independent generator system: The Ford as example: The generator in this system delivers ernating current which is used for both lighting d ignition. The battery cannot be charged with ernating current, and on this account the lights n be run only when the generator is running. us the strength of the light varies with the speed the engine unless some type of regulator is talled. This system is used only on Ford cars of the model "T" type, which were not equipped with an electric generator and battery. The present Ford enclosed models are thus equipped.

Another type of magneto which, if run fast enough will light electric lamps, is the inductor type of magneto, shown in Fig. 12, page 246. The "shuttle" type of armature magneto will not light lamps.

Where Lamps Are Placed

Headlamps, of which there are two, are usually connected in parallel. The candle power varies from 15 to 21 c.p. each.

Side lamps are usually placed one on each side, and are usually connected in parallel. They are of 4 c.p. each, but are now seldom used, being placed in the headlamps as "auxiliary" or "dimmer" lamps, for use when the car is standing, or for city driving and to save current.

Spot lamp: Only one is used, usually a nitrogen lamp of 21 or 32 c.p. (not permitted to be used in several states).

Rear lamp, also called "tail lamp": Always with a red lens in the rear and a white light at the side, to illuminate the license number. It is usually 2 c.p.

The tail light and instrument lamp are often **connected in series.** If the rear lamp should burn out, the instrument lamp would not burn, and vice versa. This is an advantage, because the law requires that the rear light burn during the night. Since it is impossible to tell from the seat if the rear light should fail, this method is used. The voltage is just one-half of that of the regular lighting circuit when connected in series.

Step lamp: Two of these are sometimes placed just below the doors, and are usually 4 c.p.

Dash or instrument lamp: Placed over the instruments, such as the speedometer, ammeter, etc., and are 2 c.p.

Inspection or trouble lamp: A lamp and extension cord, carried under the seat, and, in case of need, is connected in the dash-lamp socket; usually 4 c.p.

Tonneau lamp: Placed back of front seat; 4 c.p.

Dome lamp: Placed in the ceiling of the car; 4 c.p.

Pillar lamps: Usually two of these, placed on the rear pillars, one on each side in rear of car; 4 c. p.

It is advisable to use the best grade of lamp, of as low a candle power, and with as few lights as possible, if the battery does not get sufficient charging from the generator.

Candlepower, Voltage, and Amperage of Electric Lamps

The candle power of a lamp is expressed as c.p. Although we speak of a lamp as being 21 c.p., we really refer to the spherical c.p. This means that 21 c.p. is sent out in every direction.

A reflector does not increase the brilliancy of the light from the filament. It simply takes the total amount of light which is thrown in all directions, and concentrates it in one direction (see Figs. 20 and 21, page 436). For instance, with a "spreading beam," the brilliancy is not as intense as from a "straight beam" (see page 436).

The voltage is usually that of the battery, but quite often, to save the lamp from burning out, a lamp of one or two volts higher is used. For instance, if a 6-volt lamp is used on a lighting circuit using a 6-volt battery, the light would be bright as long as the battery was fully charged. If a generator is used to charge the battery and supply current for the lights when the car is running over 10 or 15 m.p.h., then the probabilities are that the generator would develop a slightly higher voltage than the battery. The result would be that the higher voltage would increase the brilliancy of the lamps and cause them to burn out quicker than if the voltage was the same as or less than that of the lamp. For this reason lamps of a voltage of, say, 1 or 2 volts higher than the battery voltage are used.

The amperage, or quantity of current consumed, is governed by the candle power of the lamp—the c.p. averages from 2 to 32. The higher the candle power, the more voluminous is the light—if voltage or pressure is in accordance with that of the lamp—therefore the higher the c.p., the more current or amperes consumed per hour.

Watts: If you multiply the volts by the amperes the result is expressed in "watts." For instance: 6 volts multiplied by 2 amperes gives 12 watts (there are 746 watts to a horsepower).

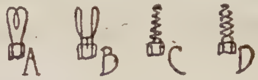
Automobile Electric Lamp Bulbs

Two types of lamps are used for car lighting: **the vacuum type,** usually known as Mazda B, and **the nitrogen-gas-filled lamp,** known as the Mazda C.

The vacuum lamp uses a "Tungsten" filament instead of a "carbon" filament. The carbon filament lamp requires more current and is now seldom used. The air is withdrawn from the bulb of a vacuum lamp, hence a vacuum.

The gas-filled lamp also uses a Tungsten filament, but the bulb is treated with nitrogen gas which increases the brilliancy by increasing the heating intensity of the filament. For this reason the "gas-filled" lamp is very sensitive to an increase of voltage and is best adapted for "constant-voltage" regulated generators.

The source of light is the fine wire at the center of the lamp bulb, known as the "filament." The current heats this wire white hot. If a bulb was designed for 6 volts, and the circuit was 12 volts, then this wire would become so white it would burn up. If designed for 12 volts and the circuit was 6 volts, the filament would be yellow and dim.



Filaments of lamps are made in different shapes: (**A**) is the type used for house lighting, and is not suitable for automobile use on account of vibration. (**B**) is a type used for rear, speedometer, side, and auxiliary lights, as the Mazda B, 62, 63, 64, 81 and 82. This lamp does not require focusing. (**C**) is a type used for headlight lamps, as Mazda B 1125, 1126. (**D**) is of a similar construction. Another type of filament is that shown in the Mazda C lamps. All bulbs for headlight lamps must be focused.

Mazda B lamps usually have this wire or "filament" made up in the form of a spiral about 3/16″ long, and ⅛″ in diameter. This gives a uniform distribution of light all around the spiral.

Mazda C lamps usually have the filament made up in the form of an inverted "V." In most types of C lamps the V is about ⅛″ high and about the same distance across the base. Some makers of type C lamps make the V about 3/16″ long and ⅛″ across the base. This form gives a much better distribution of light than the short V.

The voltage lamp to use depends upon the voltage of the system. If you do not know this, count the cells of the storage battery. Each cell gives 2 volts.

Use of the Mazda B and C Lamps

The Mazda B lamp is designed for all lights, such as rear, side, and headlights. It is made in 6 to 8-volt, and 12 to 16-volt sizes.

The Mazda C lamp is designed for headlight lamps and spot lights, and is made in 6 to 8-volt and 12 to 16-volt sizes.

The candle power of these lamps is given in tables farther on.

Where 21 c.p. or less is used in headlamps, the type B will usually give the best satisfaction, even though they take 20 per cent more current, owing to the sensitiveness of the C lamp. The spiral filament of the B lamp also gives a better distribution of light than the C with a short filament.

Where more than 21 c.p. is desired, type C must be used, but those with a long "V" are preferable.

The Mazda C lamp is brighter and gives more c.p. for the same amperage consumption, but is more sensitive to voltage variations, as previously stated.

Note. As the lamps become older, the current consumption increases. If the glass of the lamp bulb is blackened or the filament bends down, and if less than its rated c.p. is being used, it will be best to replace the lamp bulbs.

In order to tell what class of base of lamp bulb is required on a car: If the wiring of the car is a single-wire grounded system, then an "S.C." base is required. If the wiring is a two-wire system, a "D.C." base is required.

To ascertain the voltage: Count the cells of the storage battery. If there are 3 cells, a 6-volt lamp is required; if 6 cells, a 12-volt lamp is required. Each cell is counted as 2 volts.

To determine the candle power to use: First determine the voltage. Then refer to the tables following. For instance, if there are three cells to the battery, then the voltage is 6 volts. Refer to the table "6-8 volts." Note that the **headlamp bulbs** are made only in 15 c.p. in class B, and in 21 c.p. in class C. Therefore one or the other must be selected. The **rear and speedometer lamps** are 2 c.p., but if the rear light and speedometer light are in "series," then a 3-volt lamp is required. The **side and auxiliary lamp** is made only in 4 c.p.

Note that where lamps are to be used on a Ford magneto, two lamps (No. 1130) are connected in series.

A Double-Filament Edison Mazda Headlight Lamp

The purpose of this lamp is to dispense with two lamps in the headlights, and thus to do away with the separate "dimmer" lamp. This lamp, shown in the illustration, has a double filament using a DC base. It is a gas-filled Mazda C type, built in the S11 type of bulb, having a 21 c.p. filament as well as a 4 c.p. filament. Both filaments pass through the focal area of the reflector.

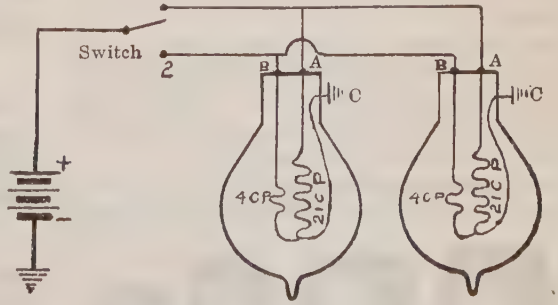

Fig. 6. Mazda No. 1158, double-filament lamp, showing the circuit (1) when the 21 c.p. filament is on and the circuit (2) when the 4 c.p. filament is on.

This type lamp is made only for 6 to 8 volts and is numbered Mazda 1158.

Two wires are used for connecting to the lamp socket from switches. (**A**) and (**B**) are terminals of the base and are insulated; (**C**) is grounded.

When the 4 c.p. filament is used, the circuit is through (**B**) insulated, and (**C**) grounded and the switch is connected on terminal 2.

When the 21 c.p. filament is used, the circuit is through (**A**) insulated and (**C**) grounded and the switch is connected on terminal 1.

Lamp Bulbs and Sizes for Motorcycles

There are only two lamp bulbs listed for motorcycles:

Class B, Mazda 63, S. C., 6–8 volts, 2 c.p., G–6.

Class C, Mazda 1129, S. C., 6–8 volts, 21 c.p., S–11.

Meaning of Abbreviations

The abbreviations used with the lamps, such as "G–6," "G–8," and "S–11," refer to the shape and size of the bulb.

For instance, "G" indicates that the bulb is round or globular; 6 means that many eighths of an inch, or 6/8″ or 3/4″ diameter. "G–8" would be a round bulb, 8/8″ (or 1″) in diameter.

Where the designation "S–11" appears, the "S" indicates "straight side," and the 11 designates the diameter in eighths of an inch, or 11/8 = 1⅜″ diameter.

Formerly all of the bulbs were round, but now only some are round, such as "G–6" and "G–8." The other bulbs are pear shaped and designated as "S." They are not really straight, but this term is used in order to distinguish them from the round bulb.

Where figures appear under the "voltage" of the lamp bulbs, as "6–8," or "12–16," this means that the lamp is intended for electric systems using a 6-volt battery, but will stand a voltage up to 8 volts. The lamp sometimes gets this—or near it—when the generator is charging the battery, as the generator voltage is slightly higher than the battery voltage.

The "12–16" lamp is for a 12-volt system, such as a Dodge, and the lamp is capable of withstanding a generator voltage as high as 16 volts.

Lamp Bases

There are four types of these: (1) double-contact bayonet candelabra; (2) single-contact bayonet candelabra; (3) candelabra screw base; (4) miniature screw base. Each of these is shown in the illustrations.

The lamp base is that part which is fitted to the end of the bulb and fits into the socket. Only two of the types mentioned above are in general use for automobile work: the "S.C.," meaning "single contact," and the "D.C.," meaning "double contact." The "S.C." is used most.

The double-contact base (D.C.) (Fig. 7) has two contacts (note the top) insulated from the metal base. These contacts are connected with the ends of the lamp filament; and when connected to the socket they make contact in the socket with the circuit. The "D.C." base and socket are used only for a "two-wire insulated" system of wiring.

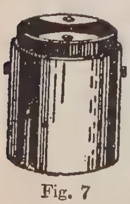

Fig. 7

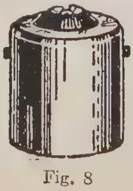

Fig. 8

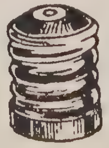

Fig. 9

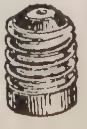

Fig. 10

The single-contact base (S.C.) (Fig. 8) has one contact in the center which is insulated from the metal base. One filament of the lamp connects with this center contact, and the other end of the filament connects with the metal base. When placed in the socket the center contact connects with an insulated terminal in the socket, which connects with the single insulated wire of the light circuit, and the rest of the socket and outside part of the base are grounded. The "S.C." base and socket are used only for the "single-wire, grounded" system of wiring.

The words "Bayonet" and "Candelabra," which appear in the tables to designate the type of base, are explained as follows:

Bayonet base: The "Candelabra" screw type base (Fig. 9) was originally used on miniature lamps, but owing to the vibration of the automobile, the lamps would loosen. A type of base was then designed as shown in Figs. 7 and 8, the single contact (Fig. 8) being used most and arranged as shown in the illustration (Fig. 11). The base (**B**) is thrust into the socket (**S**) through slot and is then given a turn or twist which locks (**T**) in place. The thrusting effect was what gave the base its name: "bayonet type." The word "candelabra" is also used with the word "bayonet," but a candelabra base is really a screw type, as shown in Fig. 9.

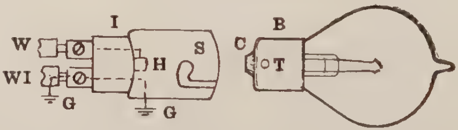

Fig. 11. (**B**) is the base, S. C. Type. The tip (**T**) locks in the opening of (**S**). Contact is made by (**C**) at (**H**), which conducts the current from (**W**) to one end of the filament, back to the grounded base, thence to ground (**G**), or to (**W1**) which is grounded. (**I**) is insulated from the socket (**S**), and (**C**) is insulated from the base (**B**).

The candelabra screw base (Fig. 9) is not used for automobile work, because of the vibration. This type is often used on trouble lamps, flash lamps, etc.

The miniature screw base shown in Fig. 10 is a smaller size, used principally for decorating purposes.

Lamps must be selected according to the type of sockets used on the car. On a single-wire grounded system, use an "S.C." base. On a double or two-wire system, use a "D.C." base.

Headlight Adjustment

The light you get on the road will depend on the candle power you get from the lamp in the reflector; on the focus or adjustment of the lamp in relation to the reflector; and on the direction in which the headlamp itself points.

Different Focusing Adjustments

Getting the lamp bulb in the proper relation to the reflector to give the best light on the road is called "focusing." All headlamps are provided with some means of moving the lamp bulb back and forth along the center line of the reflector, which line is called the axis. The four types of adjustments (Figs. 12, 13, 14 and 15) shown, should cover practically all of the headlamps used.

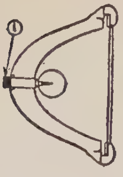

Fig. 12

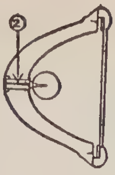

Fig. 13

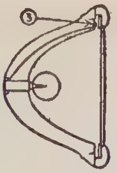

Fig. 14

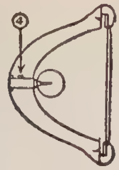

Fig. 15

Fig. 12 has an adjusting screw or knob near the center, on the rear of the headlight shell. The lamp bulb is moved forward by turning the screw or knob (1) to the left, and backward by turning it to the right.

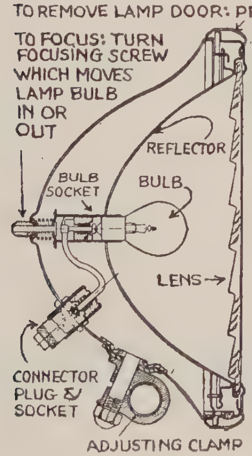
Fig. 13. The lamp is held in place by a ratchet device (2). The lamp is moved forward or back by grasping the bulb and either turning the bulb to the right or pressing it to one side or the other to disengage the ratchet, and then pulling or pushing the lamp in its socket to the next notch in the ratchet. If the lamp does not move easily, remove the reflector and see how the ratchet works.

Fig. 14. The adjustment is made by turning the large screw (3) in the rim of the headlight front just at the edge of the reflector. By turning this screw to the right, it will move the lamp forward in the reflector. Turning it to the left moves it backward in the reflector.

Fig. 15. The lamp is held in place by a set screw (4) in back of the reflector. When the set screw is loosened, the lamp may be moved backward or forward. The set screw must be tightened securely to hold the lamp in place.

Example of Headlamp Adjustment on the Studebaker

Fig. 16 shows the type of headlamp used on the Studebaker "Light Six" car, and Fig. 17 shows that used on the Studebaker "Big Six." Observe the two methods of adjustment; also the manner in which the door or rim is removed, etc.



TO REMOVE LAMP DOOR: PRESS IN ON RIM & TWIST TO LEFT

LAMP DOOR OR RIM
BRACKET TO FASTEN TO FENDER

Fig. 17

To remove the door (Fig. 16): Press in hard against the rim of the lamp, and twist in a counter-clockwise direction. The same applies to Fig. 17.

To replace burned-out bulbs: Remove the door; then remove the bulb by pressing it into the socket and twisting it one way until it is released from the catch. See Index, for lamp-bulb sizes for various cars.

If a lens breaks, and a new one has to be ordered, the name and size will usually be found moulded into the lens.

The "door" to the headlamp on various makes may be fastened on in one of several ways. There may be a hinge at the top and a screw clamp at the bottom, or the hinge may be at one side and the clamp at the other. If no hinge shows, and the "door" overlaps the shell of the headlamp, the "door" can probably be removed by pressing it in, and at the same time turning it to the left, as described above.

In some headlamps, the glass is held in place by a retaining spring, which slips in between the headlamp shell and the glass.

In other headlamps, the rim which holds the glass is held up against the shell by a band which fits over shoulders on both rim and shell, and is drawn up by a screw at the bottom of the headlamp.

Tilting Reflectors

On some makes of lamps the reflectors are arranged so that **the reflectors can be tilted.** One method is as shown in Fig. 18 (as used on the Lexington), and another method is the one used on the Cadillac (Fig. 19).

Bellows for Tilting the Reflector

The operation of the reflectors (Fig. 18) is controlled by a small three-way valve located on the instrument board, the partial vacuum created in the engine by the suction stroke of the piston being utilized to exhaust the air from the metal bellows connected to the reflectors when it is desired to illuminate the road for a long distance. To accomplish this the handle of the valve is turned to the letter (H) on the dial.

When it is desired to lower the reflectors to their tilted, or normal, position, the handle is turned to the letter (L) on the dial, which breaks the communication of the bellows with the engine and allows air to enter the bellows through a port in the valve. Communication is maintained between the inside of the headlights and the engine by ⅛″ O.D. annealed copper tubing, and between the end of the tubing and the bellows by rubber tubing, in order that the movable reflector unit may be easily removed.

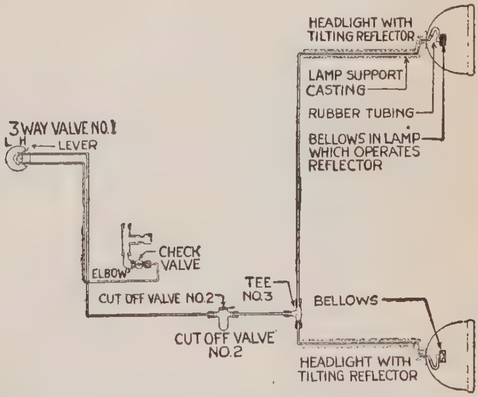

Fig. 18. **Tilting reflectors, as used on the Lexington.** The bellows has the appearance of a coil spring, and is just back of the center of the reflector. The bellows expands and pushes the reflector forward at the top, giving the focal point of the lamp a deflection of five degrees. This is what happens with the control lever at (L): When the lever is at (H), the bellows contracts by action of the engine piston and thus deflates the bellows and pulls the reflector back at the top, giving to the focal point of the lamp an elevation of five degrees.

A check valve is placed in the vacuum line between the three-way valve and engine to prevent a quick change to the tilted position when the throttle is opened quickly. **A cut-off valve** is provided to render the system inoperative from the driver's seat when necessary.

If the system should become inoperative at any time, it may be the result of a break in the line, a leaky connection, a break in the rubber tube connection to the bellows, or the three-way valve may have become dry, permitting air to leak in, destroying the vacuum. The three-way valve may be taken apart for inspection and lubrication. Care must be used in reassembling not to disarrange any of the parts. Use a small amount of commercial vaseline for lubrication.

Cadillac Mechanical Shifting Method of Tilting the Headlight

The reflectors are pivoted, in order that they may be tilted by means of a lever on the steering column connected with an arm (**A**) projecting from the bottom and connected with the reflector (**R**). The lever pulls the reflector down (as indicated by dotted lines), thus tilting the reflector (Fig. 19).

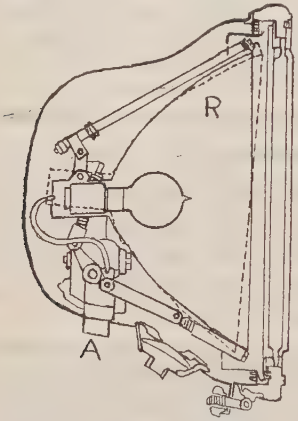

Fig. 19. Tilting reflector as used on the Cadillac.

The advantage of tilting headlights is explained as follows:

When there is a clear road ahead, the illumination of the road for a distance is desirable. Thus the reflector is so focused that the light is projected ahead for the greatest distance.

If a vehicle is approaching in an opposite direction, the reflector (**R**) can be tilted down by movement of the lever on the steering column connected to the arm (**A**), thus tilting the reflector at an angle as shown in the dotted lines. This deflects the rays below the level of vision of the occupants of the approaching car, and at the same time increases the illumination in front of the car, where it is needed most.

Reflectors: Principle of

A parabolic type of reflector, made of metal with a polished silver surface, is used in most head-lamps.

If a lamp were used without a reflector, the light which leaves the lamp filament would be thrown in every direction (Fig. 20).

When a reflector is used, the light from the lamp filament is concentrated all in one direction (Fig. 21). See also "Candle power" (page 432).

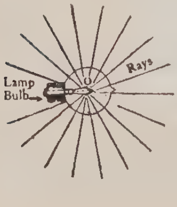

Fig. 20

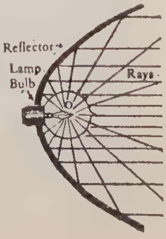

Fig. 21

A ray of light is the light which falls on any one point of the surface of the reflector, and is sent off from that point.

A beam is the total mass of light rays leaving the opening in the reflector.

One of the fundamental laws of light is, that the angle at which light leaves a surface is the same as the angle at which it strikes the surface. By referring to Figs. 22, 23, and 24, the angles which are made by the rays of light leaving the surface of the reflectors at (**H**), (**M**), and (**N**) will be seen to be the same as the angles made by the rays of light striking the reflector at the same point. The angles at which the rays strike the reflector are called **"angles of incidence,"** and those leaving the reflector are called **"angles of reflection."**

X—Focus Point O—Light Source

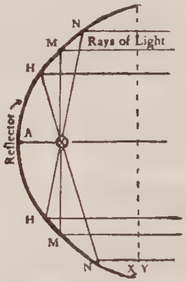

Fig. 22. Straight beam.

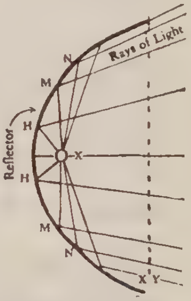

Fig. 23. Spreading beam.

The distribution of light leaving the opening of the reflector when lamp filament (**O**) is at the focal point (**X**) of the reflector is shown in Fig. 22. The rays which start from point (**X**) and strike the reflector at (**H**), (**M**), and (**N**) must be reflected parallel to each other to make the reflecting angles equal the striking angles. This gives a cylindrical or "straight beam." The beam is theoretically the same size (**XY,** Fig. 22) throughout its entire length. A **"straight beam"** gives a very narrow streak of light down the center of the road, like a spotlight; but no light is thrown to the side of the road.

The form of beam leaving the reflector when the filament (**O**) is back of the focal point (**X**). The rays spread or diverge from one another, and form a **"spreading beam,"** with its narrowest point at the opening of the reflector (**XY**). Note that the light rays which leave the headlamp at a rising angle are those which come from the upper half of the reflector.

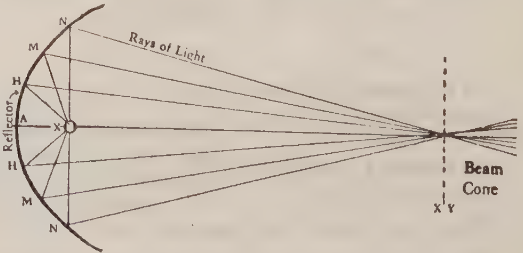

Fig. 24. Crossed beam.

The effect of bringing the filament (O) ahead of the focal point (X) is shown in Fig. 24. This forms what is termed a **"crossed beam."** Note that the light rays which leave the headlamp at a "rising angle" are those which come from the lower half of the reflector.

Anti-Glare Devices

In most states, **laws are being enforced to prevent glare.** The light which produces glare is that part which leaves the headlamp at a "rising angle" and so never hits the road, but does hit the eyes of approaching drivers or pedestrians. These rays may come from either the top or bottom of the reflector, depending upon the position of the lamp in the reflector.

Methods for Reducing Glare

(1) **By using a very low candle-power lamp, or dimming the headlamps;** using whiting, semitransparent paint, or colored glass. Low-candle-power lamps reduce the brilliancy, and colored glass or paint absorb part of the light and reduce the lighting effect desired, and are unsatisfactory.

(2) **By tilting the reflector down** enough to bring the upper edge of the beam below the average eye level (42 inches is the usual legal limit).[1] The distance along which the road will be lighted is very much shortened. If the reflector can be tilted back to normal position, as shown in Figs. 18 and 19, then the distance will be greatly increased.

(3) **By diffusing the light** by means of ground glass, office-partition glass, or by a specially designed "diffusing" lens, having its surface covered by a large number of small lenses or pyramids. With diffusing lenses there is a tendency to glare if the candle power of the lamp is sufficient to light the road, as the light is thrown in all directions.

(4) **By using "deflecting lenses"** which bend or deflect that part of the beam which leaves the headlamp at a rising angle and direct this part of the beam back to the road level. Devices of this kind have the advantage of being able to limit the glare without cutting down the distance along which the light will be thrown on the road. Some of the deflecting lenses which are constructed so as to affect all of the light leaving the headlamp make it hit the road nearer to the car than it would with clear glass, and are not desirable.

Classification of Some of the Anti-Glare Lenses [2]

In the accompanying illustration, A, B, C, and D, are **"diffusing" type lenses.** As these devices scatter the light in every direction, the adjustment of the headlamp has little effect on the road illumination. Both the light and the glare will be a little stronger if the **focus is for a straight beam.**

A

B

C

D

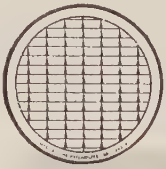
A, **Warner:** Both sides of glass covered with small lenses; adjust focus for straight beams for best lighting.

B, **Prismolite:** Front of glass covered with small pyramids except small spot near center; adjust focus for straight beam.

C, **Morelight:** Front of glass covered with short cylinders, arranged in circles; adjust focus for straight beam.

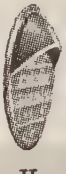
D, **Stewart:** Cup fitting around bulb; outside covered with small lenses; inside with ribs; adjust focus for straight beam.

F, G, H, I, shown below, are **"deflecting" type of lenses, which are intended to be used with a straight beam.** In making adjustments, adjust in accordance with directions for plain glass adjustment, page 438, except that the lamp must be moved to the point in the reflector which gives the smallest point of light on the screen or wall, instead of making the spot 3 ft. in diameter.



F

G



H

I

F, **Sun Ray:** Horizontal prisms throw light on the center of the road. Small triangular prisms throw a light along the sides of the road. Adjust for straight beam.

G, **Conaphore:** Horizontal prisms throw light on the center of the road; cylinders in the center throw a soft light along the sides of the road. Adjust for straight beam.

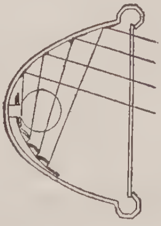
H, **Macbeth:** Horizontal prisms throw light on the center of the road, and cylinders on the inside spread the light to the side of the road. The hood at the top cuts off the light from that part of the lens. Adjust for straight beam.

I, **Holophane:** Circular prisms at bottom throw light on the road and give quite a spread. Horizontal prisms and vertical cylinders at the top throw diffused light along the sides of the road. Adjust for straight beam.

J, K, L, M, are **"deflecting" type lenses designed to be used with a spread or crossed beam,** depending on whether a part of the lens which bends the glare rays down is located at the top or bottom of the lens. The focus is adjusted to give a beam having some spread.

J

K



L

M

J, **Roadlighter:** A deflecting type of lens. Adjustment is for a spreading beam.

K, **Osgood:** Horizontal prisms on the back of the lens throw light down on the road. The cylindrical section on the center of the front of the lens is intended to add to the spread of the light. Adjust focus for spreading beam.

L, **Letts deflector:** A deflecting device. The corrugated reflector is placed below the lamp and changes the angle of the light striking the reflector so that all the rays are sent down on the road. Adjust focus for crossed rays.

---

[1] The most common "glare height" regulation in regard to headlamps is that, at a point 75 feet or more ahead of the car, the concentrated beam from the headlamp shall not rise more than 42 inches above the road level, when the car is standing on a level. In the latest headlamp regulations, the height has been raised to 60 inches from the road surface, and the intensity of the light is limited to a maximum of 800 candle power above this point. [2] See page 442 for **Bausch & Lomb lens.**

M, **Fractor:** A deflecting device. The prisms on the glass cup which is placed below the lamp change the angle of the light striking the reflector, so that all of it is sent down on the road. Adjust for crossed beam.

With any of the deflecting devices it is best to make the adjustment for either spread, crossed, or straight beam, while the plain glass is still in place in the headlamp.[1]

An Ideal Light

An ideal light is one which will meet the following requirements: (1) sufficient light to illuminate the road such a distance ahead that the driver would have ample time to stop before reaching an object, and so that it would have penetrative powers in dust and fog; (2) very bright light at the edge of the road and close to the car so that the road could be clearly seen and followed in spite of glare from an approaching car; (3) full width of the road from fence to fence lighted for at least 200 feet ahead of the car.

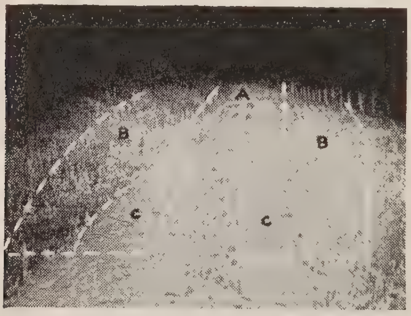


Fig. 25. One make of lens designed to meet these conditions is shown. This illustration was furnished by the manufacturers of the Roadlighter lens (J, page 437), who claim that this lens meets the ideal requirements mentioned above and have corroborated the statement with a photograph of the lens in use. Note that the prisms in the lower half of the lens (see J, page 437) concentrate the distance light, at (**A**). The diagonal prisms in the upper half of the lens bend the light, which would otherwise cause glare, to light the sides of the road from fence to fence (**BB**), and give the bright light on the edge of the road as shown at (CC).

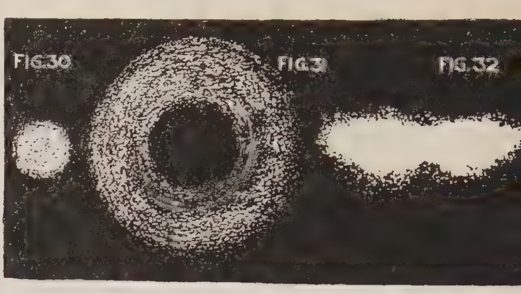
How to Focus Headlight Lamps

In order to secure the best lighting effects, headlight or spotlight lamps should be carefully adjusted in their reflectors every time new lamps are inserted, or, better still, at regular intervals.

Focusing may easily be accomplished by standing the vehicle on level ground not less than 25 feet, and preferably 50 feet, from a flat vertical surface, such as the wall of a house, a garage, or a fence. For an automobile, two points should be marked on the wall the same distance apart and at the same, or slightly less, height above the ground as the centers of the headlamps on the car. The cover glasses of lenses should be removed from the headlamps and the beams (preferably one at a time) trained on to the marked points on the wall. The lamps should then be adjusted in the reflectors by means of the focusing devices until the smallest possible spots of light are obtained. The headlamps should then b so set that the centers of these spots coincide wit the marked points on the wall.

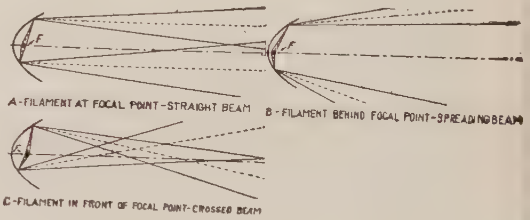


The appearance of the spot from **a well-focused headlamp** is shown in Fig. 30.

The spot from the same headlamp when **the bulb is either drawn too far back into the reflector or not far enough,** i.e., is behind or ahead of the focal point (either condition produces a similar effect), is shown in Fig. 31.

The same effect as shown in Fig. 30 is shown in Fig. 31, except that the glare-reducing lenses are now supposed to be placed in the lamp door. The illustration in Fig. 32 shows how the upward rays of light are turned down below the horizontal.

What actually happens to the light rays from the light source in a parabolic reflector, such as is generally used for automobile headlamps, is shown in Fig. 33.



F
A-FILAMENT AT FOCAL POINT-STRAIGHT BEAM
F
B-FILAMENT BEHIND FOCAL POINT-SPREADING BEAM
F
C-FILAMENT IN FRONT OF FOCAL POINT-CROSSED BEAM

Fig. 33. Beam characteristics of parabolic reflectors with light sources in three positions.

When that source is as shown at (**A**), (Fig. 33) the lamp bulb is **at the focal point** of the reflector. When the source is in position (**B**), the lamp bulb is **behind the focal point.** When the source is in position (C), the lamp bulb is **ahead of the focal point.**

Position (A) is the correct position for the lamp filament, and produces the smallest spot of light, or the most highly concentrated beam, as in Fig. 30.

When focusing headlamps with plain lenses, adjust to get the result shown in Fig. 30.

Height of Light on the Road

With the lamps in focus, the centers of these spots of light should be at the same height as the centers of the headlights themselves.

This adjustment can be made, by loosening the clamp bolts which fasten the lamps to the brackets, and twisting the lamps so that the rays are thrown straight ahead and at correct height. **The brightest part of the light should strike the road about 150 feet ahead of the car.**

On some cars, where brackets are provided for the headlamps, the brackets can be bent with a large monkey wrench.

---

[1] Addresses of some of the lens manufacturers: The Roadlighter lens is manufactured by C. A. Shaler Co., Waupun, Wis.; other manufacturers are: The Warner Lens Co., 914 Mich. Ave., Chicago; Macbeth, by Macbeth-Evans Glass Co., Pittsburg, Pa.; Legalite, by The Legalite, Corp'n., Boston, Mass.; Sun Ray, by Prismolite Co., Columbus, Ohio; Conaphore, by Edw. A. Cassidy Co., Madison Ave. and 40th St., New York; Clear Light Lens by Woodworth Mfg. Corp'n, Niagara Falls, N.Y.

Focal Adjustment for Different Lenses

There are three general types of anti-glare or glare-reducing lenses:

(1) The **diffusing type,** as A, B, C, and D, page 437, which requires a focal adjustment for a "straight beam," or where the lamp filament is at the focal point, as shown in Fig. 22, page 436.

(2) The **deflecting type** of lenses which require a focal adjustment for a **"straight beam,"** the same as the diffusing type, are F, G, H, and I, page 437.

(3) The **deflecting type** of lenses which require a focal adjustment for a **"crossed beam,"** as in Fig. 24, page 436, where the filament is ahead of focal point, are J, K, L, and M, page 437.

Therefore, when fitting lenses of either of these types, it is necessary to adjust the focal point accordingly, after first making the adjustments with the lenses removed, as shown in Figs. 30 and 31.

When **a "diffusing" type** of lens is used it makes no difference whether you have a crossed beam, a spreading beam, or a straight beam, except that where a straight beam is used there will be less diffusion, and consequently a stronger light ahead of the car.

When **a "deflecting" type** of lens is used it is absolutely necessary to know whether it is intended for use with a spreading, a crossed, or a straight beam, before the focus can be made to insure satisfactory results. Therefore the manufacturer's instructions should be followed carefully.

If that part of the deflecting lens which is designed to bend the "glare rays" down towards the road is located in the upper half of the lens, a "spreading beam" must be used; if located on the lower half, a "crossed beam" must be used.

If the device is made of prisms having a uniform angle on both upper and lower halves of the device, a "straight beam" must be used.

Checking Lamp Adjustment

To find out whether the lamp is set for a "spread" or a "crossed beam" pass a screen, such as a piece of oard or paper, down in front of the headlamp. If the shadow caused by the screen moves up as the screen moves down, the filament of the lamp is in front of the focal point (Fig. 34), and you have a "crossed beam." If the shadow moves down with the screen, the lamp is set for a "spreading beam."

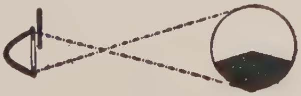


Fig. 34

Another method of testing whether the light is a crossed beam or a spreading beam: Let the light rom the headlight shine on a wall or screen 10 or 15 feet ahead of the lamp. Then move the lamp ulb back in the reflector.

If the spot on the wall grows **larger** as the lamp ulb is moved toward the back of the reflector, the amp is adjusted for a **spreading beam** and the filament is **back** of the focal point.

If the spot on the wall grows **smaller** as the lamp s moved back towards the reflector, the adjustment s for a **crossed beam,** and the filament is **ahead** of he focal point.

If the filament is moved from as far back in the reflector as it will go, to a point as far ahead as it will go, you will find that the spot of light will first grow smaller and then grow larger, as the filament passes the focal point. The point where the spot is **smallest** is the point where the filament is practically at the focal point (**X**), and the adjustment is for a **straight beam.**

These tests are, of course, made with plain lenses.

To Clean Reflector

Do not forget that dust or dirt on the reflector or on the glass lens may cut down the light on the road by more than half. The reflectors of head and side lamps are plated with pure silver.

To clean reflector, use a very soft, clean cloth, or powdered dry rouge and a chamois skin, without using pressure and rub in a circular motion. Never rub a reflector with a cloth or chamois skin which is covered with dust or grit. It will scratch the reflector and ruin it for service.

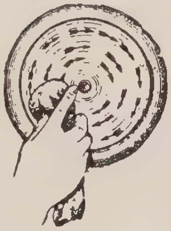

Fig. 35

If a reflector becomes tarnished or scratched, take it to a silver plater and have it buffed. It cannot be properly polished in any other way. An improvement can be made, however, where reflectors are tarnished, by moistening the rouge with alcohol and applying with a soft chamois. Do not use the chamois for any other purpose.

To Clean the Glass Lens

Absorbent cotton, dipped in alcohol and lightly rubbed in a circular motion over the surface, will be found efficient.

Dimming Headlights

There are four methods for reducing the brilliancy of headlights, which is required by law in most cities.

One method is to use resistance wire which is in series with the circuit, as shown in the Lexington (Fig. 8, page 426). See also Fig. 14 of Hudson, page 390.

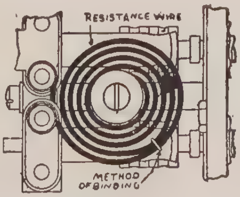

Fig. 36

To vary the intensity of the headlights when the dimmer is in circuit (Delco Hudson system) is merely a matter of shortening the path of the flow of current (the dimmer "resistance" wire, Fig. 36), which can be done by tying one coil together. This will make considerable difference.

To do this, it is necessary to **remove the switch.** Remove the four bolts passing through the housing at the back of the switch. The housing will then come apart. Remove No. 1 wire which connects with the generator, before dismantling the switch, otherwise a short circuit will result.

Another method (seldom used) is to have the switch connections so arranged that the two headlights which are always connected in parallel will be connected in series, thus reducing the voltage of each lamp one-half. For instance, if the two lamps are connected in parallel on a 6-volt circuit, each lamp would get 6 volts. If connected in series, each lamp would get 3 volts, thus dimming the lamps.

Placing auxiliary lamps of about 5 or 6 c.p. in the headlamps is the method in general use.

A double filament lamp is another method, as explained on page 433.

Frosting Compound

Q: Will you suggest a quick method for dimming headlights?

Ans.: Five cents' worth of epsom salts dissolved in a teacup full of water provides the neatest and most efficient headlight dimmer for automobiles, so far proposed. The solution is used on the inside of the headlight glass, where it is allowed to evaporate.—*Scientific American.*

A "Spot-Light"

The spot-light is a type of lamp which can be placed on the wind-shield, and turned in any direction by hand.

Where a great deal of night driving is done, or where a cross-country trip is made, a spot-light is of great convenience. It is fastened close to the driver's hand, and can be directed at any spot desired.

Adjustment is for a **"straight-beam,"** with the filament exactly at focus point.

Spot-lights are prohibited in some states, and in others the law requires that the light be thrown on the ground, not more than 60, 75, or 100 feet ahead of the car, and it must not be directed in the faces of persons approaching.

Electric bulbs used with spot-lights are usually of the nitrogen type, 20 or 32 c.p.

GAS LIGHTING (ACETYLENE)

Gas lighting is now seldom used, but it is explained here for the benefit of the reader. There are two methods of supplying the acetylene gas to the gas burners. One method is by means of a carbide gas generator, and the other by means of a tank containing compressed acetylene gas. The method whereby the gas is supplied to the gas jet by a gas generator is shown in Fig. 37.

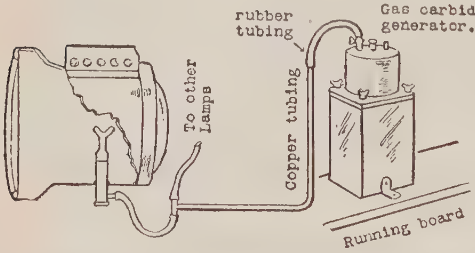

Fig. 37. **Showing how small 1/8" copper tubing and rubber tubing connects from generator to lamps.** Note that the rubber tubing connected from the copper tubing to the lamp drops in a curve. This places the rubber tubing at the lowest point. The gas condenses and turns to water, and the water clogs the pipes and gas tips. If this rubber tubing is disconnected occasionally, the condensed water will drain out.

It is always necessary that the line or leads from the gas generator to the lamps be on as much of an incline as possible. In fact, a draincock could be placed at the lowest point to advantage. The pipes to each lamp should be independent if possible.

There are two types of gas or carbide generators: the "drip" type, and the "automatic" type.

With the "drip" principle of generation, the water is usually arranged to drip directly on the carbide, and the amount of gas formed is regulated by a tap which allows more or less water to come in contact with carbide (Fig. 38).

A modification of this system allows the water to drip down a perforated metal tube, surrounded with carbide, and thus the water gradually soaks through the carbide.

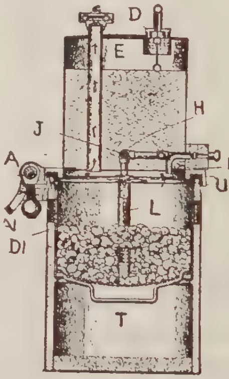

Fig. 38

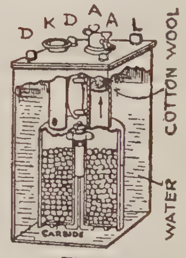

Fig. 39

Fig. 38. **Explanation of the "drip" type of carbide generator:** The tank (E) being filled with water at (D), the water saturates the cotton wick (H) in the tube (J) and the valve (F) being turned on, it drops into the screen tube (L), passing out of the holes at the bottom. As it comes in contact with the carbide, it forms gas which passes out at the top of the generator through pipe. The unused carbide held in the cage is separated by the screen in the bottom, and the dust or used carbide falls to the bottom (T) perfectly dry. Consequently the charge is always fresh while it lasts and is ready to light or extinguish. Cleaning simply means emptying the dry dust at the bottom and refilling the cage with carbide, and the tank with water. To shut off the light turn the valve (F) off. (F) being a two-way valve on the side (not lettered), the gas then contained in the generator passes out of the two-way valve into the air, thus insuring perfect safety.

Fig. 39. **The automatic type of generator:** In some respects this is simpler and gives a better regulation of the gas, but it does not seem to be always reliable.

The operation is as follows: The carbide is contained in a bell or chamber with perforated sides and bottom, to admit water freely. This bell has a suitable outlet for the gas. It is supported inside an outer vessel or tank to hold the water. Immediately the water comes in contact with the carbide, gas is generated and, if the supply tap (A) is open, this gas will pass on to the lamps. Should the tap be closed, the pressure exerted by the gas then acts inside the bell, and drives the water away from the carbide.

Should the generation of gas still continue, it will force its way through the water and escape into the atmosphere, through a small vent hole (L), so that no dangerous pressure can develop within the generator.

It will be seen that an automatic regulation of the gas is thereby obtained, because immmediately that more is being generated than can be used, the water is driven away from the carbide, but as soon as there is a demand for more gas the pressure inside the bell falls and water re-enters.

The gas outlet pipe and cotton wool or horsehair filter, whence the gas reaches the top, or to which the tubes are connected to the lamps is shown at (**AA**).

A gas bag is provided on the gas outlet pipe inside the generator to steady the pressure.

The carbide container lifts out of the tank by unscrewing the nuts (**DD**).

The tank is filled from the aperture (**K**), in the plug of which is a small vent acting as a safety valve. In this, as in other forms, the gas can be turned on and off any number of times till the carbide is all used up.

Gas Burners—Also Called Gas Tips

The gas burner is made up in various styles, and consumes from .25 to 1.5 cubic feet of gas per hour. By referring to Figs. 40 and 41, the reader will observe the construction.

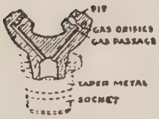

Fig. 40

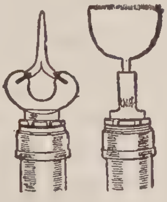

Fig. 41

Fig. 42

Fig. 40. Interior of a gas tip or acetylene burner. Tips are generally made of lava. Two small holes are in each end, only one of these being discernible to the eye. The hole, however, which becomes clogged is the small hole inside the large one.

Fig. 41. Showing end and side view of the flame when burner is in good order.

Fig. 42. Showing how to clean a gas tip.

If acetylene gas was used with an ordinary jet, it would have a yellow tint, but the oxygen drawn into the tip through the large hole raises the temperature of the flame to a point where a white blaze is obtained. It is therefore necessary that the smaller hole in the burner be kept clean.

If the flame is yellow and dim, the lack of oxygen is probably the cause, or the pipe line needs blowing out, or the generator needs cleaning.

If the independent generator is used, it is important that all parts be perfectly clean and fresh carbide be added daily, using whatever quantity is required.

The average gas tip consumes one-half foot of gas per hour. Gas tips are made in standard sizes as follows: ¼ foot; ½ foot; ¾ foot, and 1 foot.

Lighting the Gas

The usual method for lighting the gas is to turn on the gas at the generator or tank, and to light the gas at the burners with a match.

Another method is to turn on and light the gas from the seat. This is accomplished by a valve and electric spark (Fig. 43).

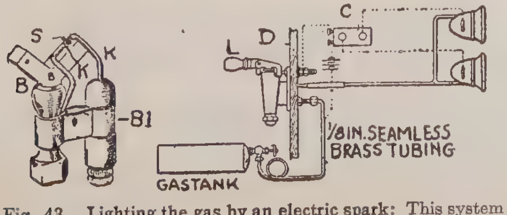

Fig. 43. Lighting the gas by an electric spark: This system consists of a special valve and switch placed on the dash-board (D), a high-tension coil (C), and a special gas lighting attachment shown in the cut.

The connections are as follows: The gas tank is piped to the valve and connected to a union under it. After gas passes through the valve it is then carried to the lamps. A wire runs from switch to coil and from there through primary winding to battery; through battery to ground.

An attachment (**B1**) is placed on each gas tip to be lighted. When lever (**L**) is pressed down, this opens the gas and also makes a temporary electric contact, and a spark jumps across points (**S**) and lights the gas. An ignition battery or dry cells will do this work.

Non-Freezing Solution for Gas Generators

Use plain alcohol in the proportion here given. Alcohol is a fuel, but not explosive. It will, therefore, probably give a slightly stronger gas than water, and for this reason less will be required. Do not use glycerine, as this is an explosive.

Percentage of alcohol to water: At 18 degrees, 10 per cent; at 5 degrees, 20 per cent; at −2 degrees, 25 per cent; at −9 degrees, 30 per cent; at −15 degrees, 35 per cent; at −24 degrees, 40 per cent.

Note: The − in front of the figures are minus signs, meaning below zero.

Carbide—Used in the Generators

The chemical formula for Acetylene is C_2H_2 (i.e., a compound of carbon and hydrogen). It has a characteristic pungent odor—which at once gives evidence of any leakage—and is a poison if inhaled in any quantity.

Approximately one pound of good quality calcium carbide will generate six cubic feet of acetylene gas. It can readily be liquified or compressed, but in this state it is highly explosive, and its use finds no favor in this country. What is known as dissolved acetylene, however, is safe.

The gas in a moist or impure state attacks copper or brass, forming acetylene of copper, which is exceedingly explosive; so much so that it will go off by slight friction or a blow. This accounts for the small explosions that are sometimes experienced when cleaning a generator.

The Pressure-Gas (Acetylene) Storage Tank

This tank is used instead of a gas generator, and is charged at the factory. When the tank is exhausted it is taken to the local agent and exchanged for a fully charged tank.

The gas used in the tank is acetylene gas, made from carbide—the same kind of gas used in a generator. Fig. 44 illustrates the Prestolite gas tank. The amount of gas in the tank is indicated by the pressure gauge. In this way the motorist can tell the quantity of gas in the tank. A key opens the valve which allows only a low pressure of gas to feed the lamps.

The piping of the gas from the gas tank to the lamps is just the same as that used with an independent generator.

The Prestolite gas tank is made in three styles: Style E, which weighs 23 lbs.; style B, 30 lbs., and style A, 50 lbs.

The pressure inside the tank (E) is based on a pressure of 15 atmospheres, or about 50 cubic feet of gas, which will supply gas for two ½-foot burners for 50 hours.

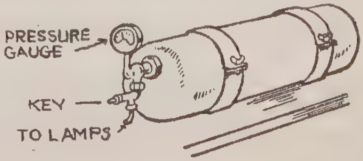

Fig. 44. The pressure-gas storage tank is usually placed on the running board of the car.

The tank should be placed on the car in such a vay that it can be easily removed. The running ooard is a convenient place. Always place the ank top side up.

Prestolite Gas Tank Pointers

Prestolite gauges, how to read them: Several tyles of gauges are used. Some register in atmosoheres, some in pounds and some in both (see Figs. 5, 46, 47). If you wish to determine the number of pounds of pressure in your tank, reading from a auge showing only atmospheric pressure, multiply he number of atmospheres shown by 14.7, which is he number of pounds to which one atmosphere is qual. The result will give you the number of oounds of pressure in your tank. All atmosphere auges are marked "ATM." **An atmosphere equals 4.7 lbs. at sea-level.**

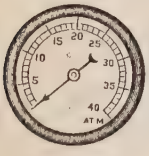

Fig. 45

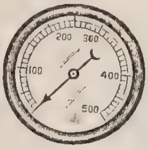

Fig. 46

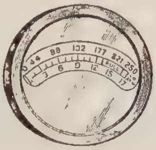

Fig. 47

Fig. 45. Gauge reading in atmospheres.

Fig. 46. Gauge reading in pounds.

Fig. 47. Combination gauge reading in pounds and atmosheres.

Prestolite tanks are charged to a pressure of 225 ounds (equal to approximately fifteen atmospheres) 65° Fahrenheit. If the temperature of a tank be creased 10° to 20° F., the pressure will be raised to 50 pounds. If the temperature be lowered, e pressure will be reduced in about the same ratio. is accounts for the rapid fall in the gauge pressure en a tank is taken from a warm garage into the ld air of the street. Change in temperature does t affect either the quantity or the quality of the s. Consequently, when the outside temperature is 65° F., a properly filled Prestolite tank will show a pressure of about 15 ATM (atmospheres) when using the atmospheric type of gauge, and 225 pounds when using the gauge reading in pounds, while the gauge showing both pounds and atmospheres will indicate a pressure of 221 pounds, or 15 ATM, with corresponding variations according to the outside settled temperature, despite the fact that the first two mentioned gauges show a capacity of 40 ATM and 500 pounds, respectively.

Where to look for leaks: Rub soap-suds along the pipe lines and over all joints and connections. Do not use a match any more readily than you would use one to hunt for a gas leak in your cellar.

The following may be the source of a leak: (1) union where attached to tank; (2) rubber hose connecting union with brass piping of car; (3) joints where rubber hose connects with union and with piping of car; (4) joints, T's, or crosses where piping branches; (5) where rubber hose connects piping with lamps; (6) part of lamp to which burners are attached; (7) any point on piping where there is a liability of chafing.

Sizes and capacities of Prestolite tanks: "A"—22 inches long, 7¼ inches in diameter; contains 70 cubic feet of gas.

Using two ½-ft. burners, 70 hours lighting

Using two ⅝-ft. burners, 56 hours lighting

Using two ¾-ft. burners, 46 hours lighting

"B"—20 inches long, 6 inches in diameter; contains 40 cubic feet of gas.

Using two ½-ft. burners, 40 hours lighting

Using two ⅝-ft. burners, 32 hours lighting

Using two ¾-ft. burners, 26 hours lighting

"E"—16 inches long, 6 inches in diameter; contains 30 cubic feet of gas.

Using two ¼-ft. burners, 60 hours lighting

Using two ½-ft. burners, 30 hours lighting

Oil Lighting

Inasmuch as electricity for lighting is now the adopted standard, and is almost universally used, it is hardly worth while to deal with the kerosene oil lamp. The oil lamp, when used in place of electric lights, is generally placed as a tail or rear lamp, to illuminate the license number and as required by law for protection of the fire department.

The brilliancy of oil lights can be improved by using a hard wick and placing cotton in the bowl of lamp. Then use gasoline or half gasoline and light cylinder oil instead of kerosene.

BAUSCH & LOMB LENS FOR AUTOMOBILE ELECTRIC LAMPS

The diagrams (Figs. 1 and 2) illustrate the path of light from mp fitted with the Bausch & Lomb lens.

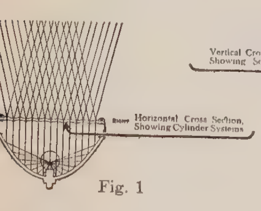

Fig. 1

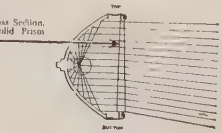

Fig. 2

he illustration in Fig. 1 shows a horizontal cross-section how the vertical cylinders (placed in front and rear of lens) w or spread rays outward sufficiently to illuminate a lateral of about 50 feet at a distance of 100 feet.

ote: The word **"cylinders"** used above refers to the flutings h are in both the front and back of the lens. The whole is in reality a **"prism,"** and in this example it is somewhat ker at the bottom than it is at the top.

e illustration in Fig. 2 shows a single or solid vertical n which deflects the light downward, or below the level ribed by law.

order to secure maximum satisfaction from these lenses necessary to adjust them properly, and this is explained llows:

e adjustment of a lamp consists in moving the lamp bulb ard or backward (see pages 435, 436). Some lamps have nal adjustments whereby the adjustment can be made the lens in place, and others where the lamp door must be ed. Adjustment should be made each time the lamp are changed.

r adjustment with the lens in the lamp, have the light on a 25 or 50 feet away. Cover or disconnect the other light. Cut out a circular piece of light-weight cardboard as in Fig. 3, with holes in it ⅞" in diameter and 4⅛" from center to center of holes. Hold it in front of the lamp so that the centers of the two holes in the card lie in a vertical line as shown.

If the bulb is **properly** set (focused or adjusted), the light on the wall will appear as one solid band, as shown in Fig. 4.

If the lamp bulb is too far away or too close from the reflector, two bands will appear, and the lamp bulb should be moved forward or backward until a single band is obtained as shown in Fig. 4.

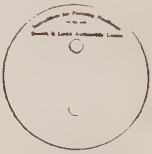

Fig. 3

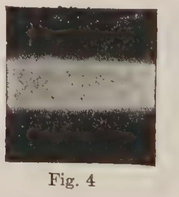

Fig. 4

Fig. 5

For adjustment with lamp doors open, which is necessary when the adjustment is inside of the lamp, the same procedure is followed. If the lamp bulb is properly focused with the reflector, a solid spot or patch of light will appear, as shown in Fig. 5.

If the lamp bulb is not properly focused, two images or spots will appear, and adjustment of the bulb should be made until only a single patch of light appears, as in Fig. 5. This adjustment is for a straight beam.

Next, place the lens in place in the door and then close it, and see if the adjustment is now as in Fig. 4.

The tilting of the lamps should be made in accordance with local requirements.

(Manufacturers are Bausch & Lomb Optical Co., Rochester, N.Y.)

INSTRUCTION No. 39

SIGNAL ALARMS; SPEEDOMETERS

SIGNAL ALARMS

There are a variety of devices properly designated as signal alarms, including: bells, bulb horns, electric horns, exhaust whistles, compression whistles, etc.

In the early days the **mechanical electric bell,** operated by the foot, was the applied method for warning the pedestrian—although possibly this was not necessary, as the cars in those days made sufficient noise to give warning a block ahead.

Then came the **bulb horn,** but the old-style bulb horn has about seen its day. It is seldom used, because of its difficult method of bulb operation and because of a tendency to get out of adjustment at the reed.

The compression whistle is the type shown in Fig. 1. It is desirable for use where there is no battery, or where the battery is not of sufficient size to operate an electric horn, or where it is desired to save battery current. It is screwed into the cylinder instead of into the relief cock. The pressure is obtained from the compression in the cylinder.

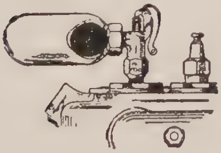

Fig. 1

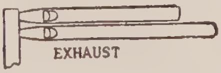

Fig. 2

The exhaust horn or whistle (Fig. 2) was used extensively at one time, but is now seldom used. It is connected to the exhaust pipe by means of a valve which is opened and closed by a foot pedal connection, which when depressed admits the exhaust gases to the horn. See Index, for "Fitting an exhaust horn."

The hand-operated horn (Figs. 3, and 3A) is not altogether desirable because it is operated by hand at an inconvenient place. It is usually placed too near the driver, whereas it ought to be nearer the front of the car.

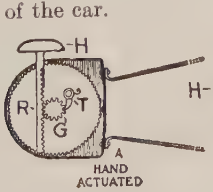

Fig. 3

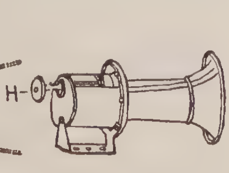

Fig. 3A

Fig. 3. Klaxon type 3, hand-actuated horn. Klaxon S-3 type is similar, except that it has a vertical push rack.

The hand-actuated horn is operated by pressing on the knob (**H**) (Fig. 3) connected with a toothed rod (**R**), thus actuating gear (**G**). This type of horn is used extensively on motor trucks.

Horn brackets for automobile use, as shown in Fig. 3B, are arranged so that the horn can be mounted at different angles. (**M**) and (83) are for motor-boat use. American Electric Co., Chicago, supplies the brackets.

Handles for hand-actuated horns (Fig. 3C) can be had o some of the horn manufacturers. They are suitable for long continued blasts when used on boats.

Fig. 3B

Fig. 3C

The Electric Horn

The electric horn is the most popular type, and i classified under two types of general construction (1) vibrating type; (2) motor type.

The Vibrating Type of Electric Horn

The vibrating type of electric horn produces sound resulting from the action of a vibrating arma ture (**B**) (Fig. 4) magnetically operated by th magnet cores (**R**). The vibrations are transmitte through rod (**A**) to a diaphragm (**D**), thus producin a sound which is greatly magnified by having a hor attached. This device looks very much like th shown in Fig. 3**A**, except that it is operated electr cally instead of by hand.

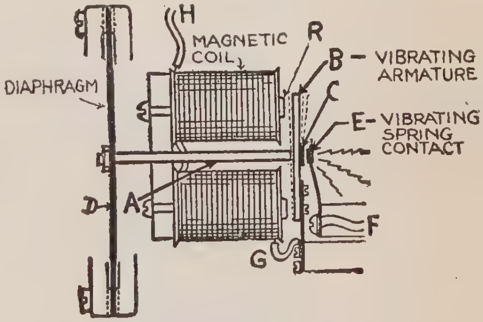

Fig. 4. Vibrating type of electric horn.

The electric circuit is to (**F**), from (+) of the battery, (generator), through the blade, through platinum iridium poi (**E** and **C**), through armature (**B**), to lower connection (**G**) the lower magnet coil, through the upper coil, to (**H**), to t push-button, to the (–) connection of the battery. Wh the push-button is depressed, the circuit is closed, and armatu (**B**) is drawn to coil (**R**), striking against rod (**A**). The mome this occurs, the circuit is opened and armature (**B**) is releas thus contact is made again at the points (**E** and **C**), and t armature vibrates back and forth as long as the push-butt closes the circuit. The action is similar to that of a vibrati type of ignition coil or electric bell.

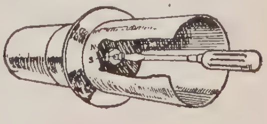

Fig. 4B

Adjustment is made by adjusting the rod (**A**) (Fig. 4**B**) relation to (**B**), to obtain a greater or less number of vibratio which increases or decreases the sound transmitted throu diaphragm (**D**).

Points (**EC**) should be of iridium platinum, otherwise th will wear down and stick. The amperage consumed is fr 4 to 6 amperes.

On some of the electric horns (Fig. 4B) this adjustment is made with a screwdriver by loosening locknut (N) and screwing adjusting screw (S) in or out while current is passing through the horn circuit, until the sound is as desired.

The Motor Type of Electric Horn

The motor type of electric horn also produces a sound transmitted through a diaphragm, but in a manner different from that of the vibrating type.

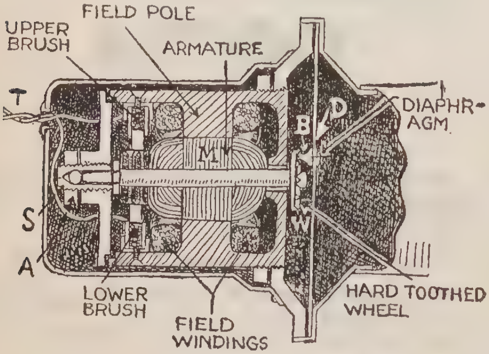

Fig. 5. Motor type of electric horn.

Construction: An electric motor (M) (Fig. 5) of small size is enclosed in one end of the horn. On the right end of the armature shaft a case-hardened steel-toothed wheel (W) operates against a case-hardened steel button (B) securely attached to the metal diaphragm (D) (see also Fig. 6). The sound produced by the wheel (W) operating against (B) is transmitted through the diaphragm (D) and greatly magnified through the horn which encloses the diaphragm.

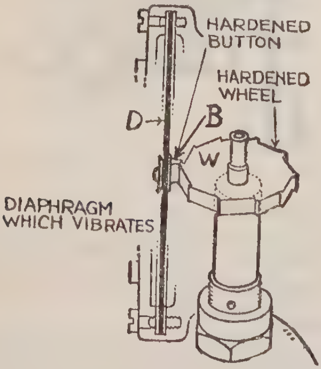

Fig. 6. Explaining how the wheel (W) actuates (B) on the diaphragm.

The intensity of this sound can be increased or decreased by moving the armature shaft so that (W) will make closer contact with (B) to increase the ound, or so that they will back away from each other, to reduce the sound.

This adjustment is made by loosening the lock-ut (A) and screwing the adjusting screw (S) in or ut, which moves the armature, as explained above. Do not adjust too tight at (B) and (W).

The motor is a series-wound motor. Note the eld-windings (shown in section), also the armature nd brushes and the commutator on which the rushes rest.

The circuit is from (+) of the battery (or generator) to one end of the field-winding, through the two field-windings to one of the brushes, through the armature, out the other brush, through push-button (P) (Fig. 7), to (−) of the battery or generator.

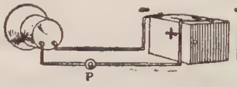

Fig. 7

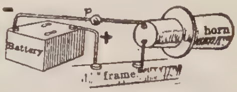

Fig. 7A

If the circuit is a "two-wire system," see Fig. 6; if a "single-wire grounded-return system," the frame is used as a ground or return, as shown in Fig. 7A.

Fitting an Electric Horn to Car

When fitting the electric horn to a car, the horn should be placed on the opposite side from the driver and as far away in front of the car as possible. The reason for this is that the noise is then away from the occupants of the car, and the signal is placed where it is most effective, usually under the hood, to the front. Being under the hood, it is protected from water when a car is being washed, and also from rain.

Connections for wiring are shown in Figs. 7 and 7A.

Klaxon Electric Motor Horn

The Klaxon is used extensively on various makes of leading cars, and its principle of construction is that explained in Figs. 5 and 6. Several different types of Klaxon horns are manufactured. Some of the leading types for automobile use are shown in Figs. 8, 9, 10, and 11.

Klaxon horns are made for **various voltages.** If the battery is a 6-volt battery, the voltage of the horn should be 6 to 8 volts. Dry cells can be used if necessary, about 6 to 8 dry cells being required.

The amperage, or current consumption, is fixed for each size of Klaxon horn, as stated under the illustrations.

To Adjust the Klaxon Horn[1]

To adjust Klaxon 20L (Fig. 8): Loosen the locknut (A), and start the current by pressing the push-button. While it is sounding, twist the motor case until no sound is heard except the buzzing of the motor. Continue twisting, in either direction, until the note is loud and clear. When the note is as desired, tighten the locknut.

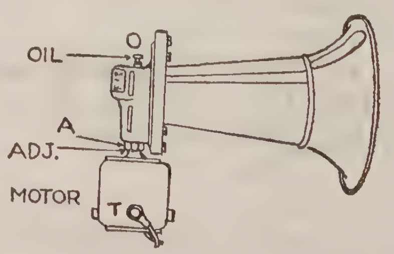

Fig. 8. Klaxon 20-L uses 7 amperes. It is a large, deep-toned horn.

To adjust the Klaxon 12-L and Klaxon-6 (Figs. 9 and 10): Loosen the screws and remove cover. You will find a locknut (A) (Fig. 5). While the motor is running adjust screw (S) until the note is

---

[1] Write the Klaxon Co., Newark, N.J., for instruction pamphlet on adjusting and caring for the Klaxon.

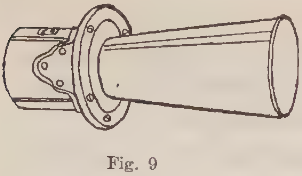

Fig. 9

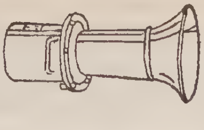

Fig. 10

Fig. 9. Klaxon 12L uses 8 amperes. A medium-sized and popular type; also a deep-toned horn.

Fig. 10. Klaxon-6 uses 5 amperes; the Klaxette, not shown, uses 3 amperes.

as desired. This action forces the armature shaft with its wheel (W) against the button (B). Replace cover and tighten screws.

Care of Electric Horns

To lubricate: Clean and lubricate the commutator once a month, as follows: With a dry cloth wipe the commutator clean. Apply a little vaseline with a clean cloth. Use thin oil in winter. Apply this to the commutator. The slightest film is all that is necessary. Every three or four months a little vaseline should be applied to the toothed wheel (W). Oil the shaft bearing once a month.

On the Klaxon 20-L, oil once a week through oil hole (O) (Fig. 8). Give two drops of "3 in 1" oil.

The tone of the horn is dependent upon the speed at which the motor can revolve, and also on the adjustment, and the speed is influenced by the care and attention given the horn.

The armature should always turn easily when made to revolve by the fingers.

Testing Electric Motor Horns

If, in testing the horn, it is found that the current or amperage consumption is greater than the fixed amount, this is probably due to dry or dirty bearings or commutator and brushes, caused by the instrument not receiving the proper lubrication.

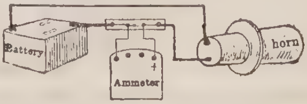

Fig. 11

The electric horn can be tested by placing an ammeter with the 30-ampere shunt (see Index for "Ammeters") in the circuit (Fig. 11). Then adjust to take the least possible current. The average horn draws from 3 to 8 amperes, depending on its size. The ammeter can also be used to test the horn for short circuit or open circuits, just the same as a generator or starting motor armature and field-windings are tested, as explained under these subjects.

SPEEDOMETERS AND ODOMETERS

Necessity of a speedometer: A speedometer is necessary in testing a car, to learn its speed capabilities under various conditions: in order to time trips over various distances, or to avoid violation of the speed limit laws, the penalty for which is arrest and fine.

Purpose of a speedometer: The speedometer for automobiles is an instrument for measuring and indicating—**in miles per hour—the exact speed at which a car is being driven.** The number of miles per hour shown at the dial of the speedometer is the actual speed at which the car is traveling at the instant of indication. For this reason the numbers shown constantly change as the car is driven faster or slower.

Necessity of an odometer: The odometer is usually embodied in the same case with the speedometer. It is necessary in auditing the cost of operating and maintaining a car. It enables the owner to tell how much gasoline is used per mile; how much his tire expense per mile amounts to; how much mileage he gets out of his car. Thus it enables the owner to make comparison of the cost of operating and maintaining his car, with the cost of operating and maintaining a car of another make. The recording and resetting features of the trip-register part of the odometer are a necessity in following a guide book when touring.

Purpose of an odometer: The odometer (combined with the speedometer) is an instrument for measuring and **recording—in miles and tenths of miles—the distance a car travels** in making a trip. It also records the entire or total distance traveled during an entire season.

Speedometer Principles

The magnetic principle (Fig. 1), as employed in Stewart-Warner and American Ever-Ready instruments, utilizes a revolving magnet positively driven from the car wheel or other part. The magnet exerts its influence on a metal part which is separated from it by an air gap, which in turn is connected with the indicating mechanism. The metal part is generally aluminum, as the inertia of the part must be kept as low as possible to make the speedometer quickly sensible to speed changes. A feature of the magnetic design is that the travel of the dial bears a direct ratio to the speed of travel of the magnet, and in order to compensate for changes in the drag, due to temperature differences, a compensating unit is fitted.

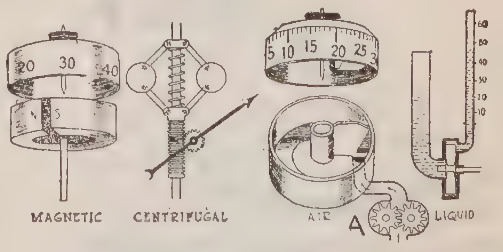

Fig. 1 Fig. 2 Fig. 3 Fig. 4

The four principles of speedometer operation: magnetic, in which a revolving magnet exerts its drag on the dial; centrifugal, in which revolving weights supply the energy due to centrifugal force; air, in which a current of air flows against a vane carrying the dial, and liquid, in which a column of liquid is lifted a height proportional to the speed of the pump drive.

Centrifugal control (Fig. 2), as utilized in speedometers, is very much the same as that on a fly-ball engine governor. Standard, Johns-Manville, Sears-Cross, Corbin-Brown, Hoffeker and Garford use this principle. Weights are mounted on the revolving shaft by bell crank levers which allow them to travel farther from the axis of the shaft as the speed of the drive increases. The centrifugal force of the weights increases as the square of the velocity of the shaft, meaning that at four times the speed the force doubles.

This tendency of the weights to fly from the axial center of the shaft under the influence of centrifugal force furnishes the basis of the indicating needle movement. An ingenious feature in centrifugal design is that although the movement of the weights would naturally vary as the square of the speed, the levers or cams governing the movement are so calculated that calibrations on the dial are uniform, or nearly so. Another feature which is carefully watched is the balance of the weights. The governors are made very sensitive, so that even at low speeds the correct rate of travel may be indicated.

The air principle (Fig. 3) is an instrument which calibrates an air current and translates the result into miles per hour. The air circulator (**A**) consists of two intermeshing aluminum gears housed in a chamber in which there are two openings, one from the outside and away from which the gears rotate, the other opening conducting the air into the speed dial chamber where the air is directed against a ight vane attached to the inside of the speed dial.

The speed dial is an inverted aluminum cup (**C**) mounted on a pivot set in jeweled bearings. The amount of air directed against the vane in the speed dial is governed by the speed at which the air circulator (**A**) is driven by the flexible shaft. The speed dial, when the car is at rest, is held at zero by the action of a nickeled steel hairspring.

The liquid or hydraulic principle (Fig. 4): One nstrument, the Veeder, which employs the hydraulic system, uses a centrifugal pump which is connected with the drive and which lifts a liquid to a height proportionate to the speed of the drive. The tube n which the colored liquid is lifted is calibrated to egister speed. See illustration. (*Motor Age.*)

Speedometer Drive Methods

Front wheel drive: The speedometer can be driven from the front wheel (Fig. 5), or off the propeller or transmission shaft, as in Fig. 6. The usual plan is to drive with gears.

SWIVEL JOINT
MUST BE KEPT TIGHT
(5) ALL BENDS IN FLEXIBLE SHAFT MUST BE A GRADUAL 8" RADIUS
DRIVEN PINION

Fig. 5. Drive from front wheel.

Transmission drive: Instead of placing the speedmeter drive on the front wheel, which has been he standard former method, it is now quite often placed just in the rear of the transmission, on the transmission main shaft. Fig. 6 shows how the driving gear is attached to the front of the forward universal joint. The swivel joint and gear section are clearly depicted. Other manufacturers are now adopting a set of gears inside of the transmission case, to drive the speedometer shaft.

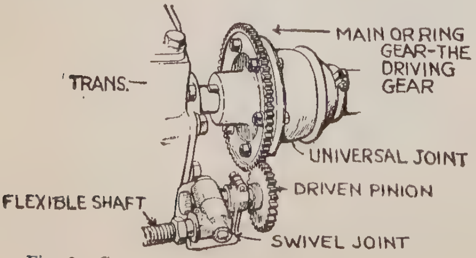

Fig. 6. Stewart speedometer, propeller-shaft drive.

The speedometer flexible shaft is shown in Fig. 7.

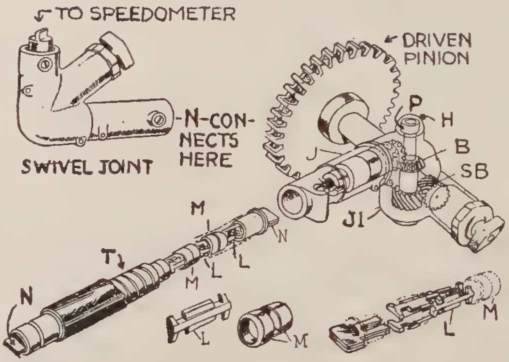

Fig. 7. The speedometer flexible shaft (Waltham, as an example) is made up of a series of links (**L**), which are held in position by a series of steel collars (**M**). The links (**L**) are covered with flexible tubing (**T**). The illustration shows the flexible shaft together with other fittings, including swivel and angle joints.

Ratio of Gearing

The ratio of gears for a speedometer when driven from front wheels is found by doubling the diameter of the tire. This gives the number of teeth necessary in the large **driving or road wheel gear.** For example, a 30 x 4 tire would require a 60-tooth gear, etc. **Driven** pinions (small) on all Stewart-Warner speedometers, for front axle drive, have the same number of teeth, viz., 16, and drive through a 2½ to 1 swivel-joint reduction.

The gear reduction in the swivel joint is mounted close to the driven pinion, as shown in Figs. 5 and 7. When installed on the left-hand wheel, a swivel joint is used which reverses the direction of rotation.

Calibration: The Stewart-Warner speedometer flexible shaft travels 1,009 revolutions per minute when the car is traveling 60 miles per hour.

On all Stewart speedometers the space between the main gear (1, Fig. 5) and the pinion gear (2), should be 1/16″. Also note that the main gear should have twice the number of teeth that there are inches in the diameter of the tire.

Speedometer Care and Troubles

The following matter refers to the Stewart speedometer, the instructions and illustrations being taken from the Studebaker instruction book.

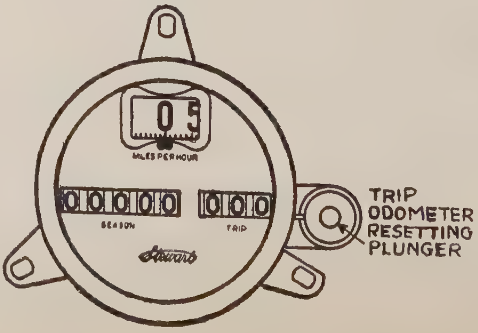

Fig. 8. Front view of speedometer.

Resetting odometer: Pull out the trip odometer, resetting the plunger (Fig. 8), after which turn to right or left as much as necessary to show the figures you desire to have appear. After resetting the odometer, do not fail to push the resetting plunger in as far as possible, or else the trip odometer will not register. The speedometer is a very delicately adjusted instrument, and must be handled carefully to insure continued satisfactory service.

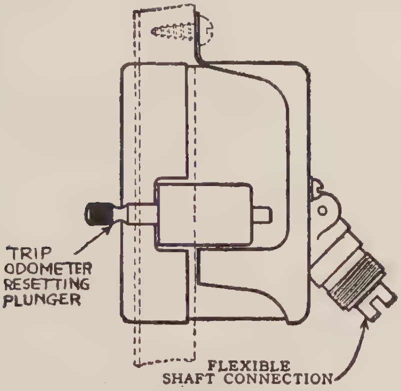

Fig. 9. Side view of speedometer.

Lubrication: Do not attempt to lubricate the speedometer head under any circumstances. Parts that required lubrication were attended to when it was assembled, and will last for the life-time of the instrument.

Speedometer Troubles

If the speedometer is not operating satisfactorily, look over the installation and see if it is in accordance with the following instructions:

Flexible shaft connection: Make sure that the clutch in the flexible shaft enters the slot in the neck of the speedometer (shown in Fig. 9, "Flexible Shaft Connection"). The sliding bar on the other end of the flexible shaft enters the slot in the driving shaft at transmission.

Speedometer Adjustments

Dial vibration results in failure to indicate speed and mileage. **Noisy instruments** are caused by any of the following:

1. Loose union connection between speedometer and flexible shaft connection.
2. Loose union connection between driving shaft at transmission and flexible shaft. (These unions on flexible shaft should always be kept as tight as possible.)
3. The flexible shaft may be bent at a sharp angle. This condition causes the shaft at times to bind, making the dial unsteady.
4. The worm gear and pinion at the drive end may be either meshed in part only or entirely out of mesh, due to speedometer pinion gear sleeve at the rear of the transmission being loose. The shaft should be shoved in the housing as far as possible, and the nut tightened.
5. The flexible shaft may not be well lubricated, which causes erratic shaft movement and unsteady indication. The manufacturer has a special grease for this purpose.
6. The chain in the flexible shaft may have broken. If so, it can be quickly repaired by replacing the broken link. **If the chain breaks,** unscrew both shaft connections and remove the chain from the outer casing. Then repair the break by hooking into place a new link—a very simple operation—replace the chain, and screw both shaft ends into place. Extra links may be obtained from Stewart-Warner Corporation branches or service stations at a nominal cost.

When speedometer pointers vibrate, look for loose unions, connection, flexible shaft bent too sharp, lack of lubrication, gears not properly meshing.

Failure to indicate speed: Look for the same causes as above; also for a broken link in the shaft.

Noise may be due to lack of lubrication or any of the causes described above.

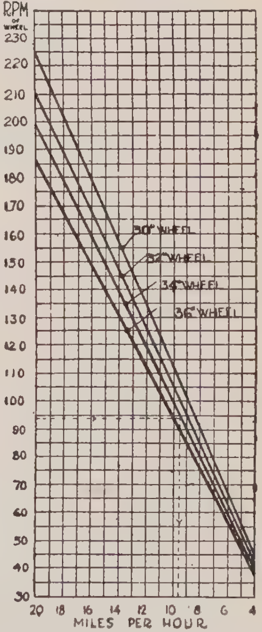
Checking a Speedometer

A simple test worked out by Mr. S. T. Williams of the *Motor World* is shown in the table below, and is as follows:

When the drive is from the front wheel, jack up the wheel. A chalk mark is then placed on the rim of the wheel, and the wheel is turned as fast as possible.

At a signal, one person reads the speedometer, and another counts the revolutions for one minute, as timed by a stop watch, or the second hand of a watch. The number of revolutions of the wheel, and the speedometer reading at the start and finish are noted. (By adding the two speedometer readings, and dividing them by two, the average speed as recorded by the speedometer is determined.)

Fig. 10



The actual speed may be obtained from the chart in Fig. 10. Supposing the revolutions in the minute to have been 94, a horizontal line is followed until it meets the slanting line representing the diameter at the front wheel, assume it to be 34". Dropping down vertically, the speed is seen to be 9.6 miles per hour—which should correspond to the speedometer readings. If carefully made, this test is quite accurate, and requires little time.

INSTRUCTION No. 40

ELECTRIC PARTS OF A CAR: Preliminary Instructions for Locating Troubles of the Electric System

DIVIDING THE ELECTRIC SYSTEM INTO PARTS AND TROUBLES THAT COULD OCCUR IN EACH PART

Before it is possible to diagnose properly or to test for any trouble in the electric system of a car, it is first necessary to know the fundamental principles underlying all the parts, their location, and the relation of one part to another.

The fundamental principles of all parts of the electric system have been dealt with in preceding instructions. We shall now deal with the division of the parts, the troubles that are likely to occur in each part, together with the effect that these may have on some other part, and also with the devices, instruments, and tools necessary to locate troubles and to remedy them.

Electric troubles may be in the external parts, or in the internal parts. If trouble occurs in the ignition system, then the point to begin at would be the source of electric supply of the ignition system, tracing through the **external** parts of this system. Then if the trouble is not located, the test should extend to the **internal** parts, such as the winding of the ignition coil, the condenser, etc. The same procedure would apply to the starting motor, the generator, the battery, the cut-out, etc.

Hence the necessity of dividing the electric system into component parts and testing the circuits of each part, and at the same time considering the relation of that part to some other part. In other words, intelligently to diagnose electric troubles requires a knowledge of the fundamental principles of all the parts and their relation to each other. The importance of separating the parts, in order definitely to be able to locate the trouble is the point to consider in this instruction.

If we separate the electric system of a car into its main external parts, we have:

1. The storage battery.
2. The generator.
3. The starting motor.
4. The wiring system.
5. Dash ammeter.

(1) Storage Battery

If we take the storage battery and divide it into its component and internal parts, we have:

(a) The storage battery plates.
(b) The storage battery separators.
(c) The storage battery jars.
(d) The storage battery electrolyte.
(e) The storage battery connectors and lugs.
(f) The storage battery ground connection.
(g) The storage battery terminals.

Any of the parts of a storage battery mentioned above could cause trouble, such as plates being internally short-circuited, separators becoming rotted, jars leaking, electrolyte falling below the level of the plates, connectors or lugs not being burned properly and thus making poor contact or open circuits, ground connection loose, and making poor contact or open circuits, and terminals also.

The construction, care, troubles, tests, and repairs of storage batteries are treated under the storage battery subject.

(2) Generator

If we take the generator and divide it into its component and internal parts, we have:

(a) The field poles and frame.
(b) The shunt-field windings.
(c) The regulation of the shunt-field winding circuit.
(d) The armature
(e) The commutator.
(f) The brushes.
(g) The cut-out.

Any of the parts mentioned, if defective, would interfere with the proper operation of the generator, for instance:

(a) **The field poles,** if loose where they are held to the frame by screws, would probably result in damage to the armature. The proper clearance between the ends of the field poles and the armature is a point to consider.

(b) **Field windings,** if grounded with the field pole, or if one coil is grounded with another, or if short-circuited, would either carry no current at all, or, at best, a weak current.

(c) **The regulation system,** such as the electromagnetic "voltage regulator," or the "current regulator," may not be properly adjusted. These regulators are usually connected with the shunt-field winding of the generator, and if not properly adjusted, they would permit too high or too low an output of the generator.

Furthermore, the regulator windings may be open-circuited or short-circuited, thus necessitating a test of the windings. Or the points of the regulator may be burned together and fail to open, or the resistance, usually connected with the points, may be burned out.

If the regulation is of the "third-brush" type, the brush may not be seating properly, or the brush may be worn too short, or there may be poor connection of the brush with the wire connecting with it, or an improperly adjusted brush.

All or any one of these troubles in the regulation system would prevent the shunt-field winding from building up lines-of-force properly and would thus affect the output of the generator.

(d) **The armature** troubles are principally either in a short-circuited or in a grounded armature coil; that is, one wire may be shorted to another wire internally of the armature, or one wire may be grounded with the core of the armature, or there may be open circuits, where the wire is broken, or loose at the commutator.

(e) **The commutator** gives more trouble than any other part of the generator. Eighty per cent of the generator troubles are indicated by the condition of the commutator.

A commutator blackened over its entire surface indicates too much grease and carbon dust. Rough commutators require turning down in a lathe or being sanded. Mica insulation, which is placed between each commutator segment, will protrude in time, as the copper, being soft, wears. As a consequence, the mica protrudes and prevents the brushes from making good contact, thus causing arcing at the brushes which, in turning, burns the commutator. There are other causes of commutator troubles, such as loose segments, loose wires to segments, etc., all of which will be taken up farther on. Oil should never be placed on a commutator.

(f) **The brushes** are a source of trouble, principally when they fail to make good contact, when there is improper spring pressure, when the brushes are stuck in the brush-holder or are worn short, when the brush-holder is loose or when there are loose connections. All these affect the operation of a generator. When new brushes are fitted, it is important that they be seated to the curvature of the armature (explained farther on).

(g) **The cut-out** has two windings: a "voltage winding" and a "series winding." The voltage fine wire winding connects **across** the main circuit of the generator. In some instances the cut-out points burn together and permit the current to flow back through this fine wire winding, which burns it out.

The cut-out series winding is connected **in series** with the charging circuit from the generator to the battery, and is a larger wire. It seldom burns out, but may become short-circuited, or open-circuited. The windings can be tested for open circuits, short circuits, and grounds, just the same as the generator field-windings, the armature coil windings, and the regulator windings; explained farther on.

The cut-out points sometimes stick together, thus permitting the battery to discharge back through the generator, which is usually indicated in the ammeter on the "discharge" side. This necessitates cleaning and adjusting points.

(3) Starting Motor

If we take the starting motor and divide it into its component and internal parts, we have:

(a) The field poles and frame.
(b) The field windings: straight "series" or "series parallel."
(c) The armature.
(d) The commutator.
(e) The brushes.
(f) The bearings.
(g) The starting switch.
(h) The ground connections.

(a) **Field pole troubles** are not common, but it is well occasionally to tighten the screws holding field poles to the frame, with a screwdriver.

(b) **The field windings,** like the generator field-windings, can be tested for open circuits, short circuits, or grounds, explained farther on.

(c) **The armature** troubles of a starting motor are usually due to the bearings giving way and permitting the armature to strike the pole pieces, thus injuring the armature windings.

The armature windings can be tested for open circuits, short circuits, and grounds, in the same manner as a generator armature, as will be explained farther on.

The armature shaft is sometimes bent or twisted, because of the back firing of the engine and hard strains. How to test and straighten this is explained farther on.

(d) **The commutator** on starting motor is subjected to a great amount of current passing through it. Thus if it is roughened, it should be turned down in a lathe. It is seldom that the mica protrudes, as in a generator commutator, because the starting motor is not used as much as the generator. Loose wires from the armature coils to the commutator segments sometimes come loose and require soldering.

(e) **Brush troubles** on a starting motor are usually due to poor contact on commutator, or to loose brush-holders. Brushes should seat properly.

(f) **Bearings** of a starting motor are usually plain bronze bearings which may become worn from the lack of oil and long service. Thus when a heavy charge of current (150 to 300 amperes) passes through the armature and the field-windings, as the armature revolves, it is forcibly drawn to the pole pieces, since the air-gap or clearance is very slight, with the result that the armature strikes the pole pieces and damages them. This usually necessitates a new armature and end-plates with new bearings.

(g) **Starting switch** troubles usually result from poor connections, loose parts, or burned contacts.

(h) **The ground connection** from battery to frame, which is a part of the starting circuit, should occasionally be examined. If not properly made when first installed, the connections will corrode and cut down the current supply, not only to the starting motor, but to all of the other circuits. Vibration often causes this contact to become loose.

(4) Wiring System

If we take the wiring system and divide it into its various circuits, we have:

(a) The starting-motor circuit.
(b) The generator charging circuit.
(c) The ignition circuit.
(d) The lighting circuit.
(e) The horn circuit.
(f) The ground connections.

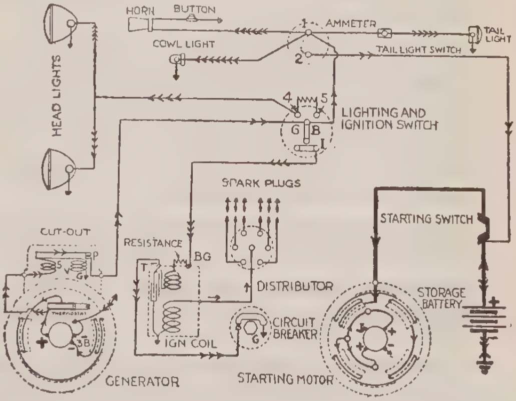


Fig. 1. Diagram of a Remy electric system as an example. The object of this diagram and the explanations is to point out where to start when tracing different circuits in order to locate troubles intelligently. Note the arrow points.

Single arrow: starting-motor circuit.
Two arrows: generator charging circuit.
Three arrows: ignition circuit (primary).
Four arrows: headlight circuit.
Five arrows: tail-light circuit
Six arrows: horn circuit.
Seven arrows: cowl-light circuit.
Single arrow to the side of wires: secondary ignition circuit.

Where to Start Tracing When Trouble Occurs

(*a*) **The starting-motor circuit:** The circuit in this example would start from (+) of the battery, thence to the starting switch, to the motor, to ground, to (−) ground of the battery, as shown by single arrows on the wires.

If the (+) terminal of the battery is grounded, then the starting of the circuit would be at the grounded (+) terminal of the battery, to the (+) grounded brushes of the starting motor.

The parts included, therefore, in the starting-motor circuit are the battery, the heavy wire, the starting switch, the motor field-windings, the brushes, the commutator, the armature, the ground connection of the motor, and the ground connection of the battery.

(*b*) **The generator charging circuit:** The point at which to start in the example (Fig. 1) is with the (+) brush of the generator, to the cut-out series winding, through the closed cut-out points, to the ammeter, as shown by two arrows on the wires.

If the (+) brushes are grounded, then the (+) terminal of the battery would also be grounded, and the start would be from the (+) grounded brushes, to the (+) grounded battery terminal, thence to the starting switch, where the main charging wire usually connects, to the ammeter.

Thus the parts of the generator main charging circuit include the generator armature, the brushes, the cut-out, the ammeter, the connection to one side of the starting switch, the battery, and the battery ground connection.

Troubles which are common in this circuit are open circuits, grounds, short circuits, and poor connections; and the poor connections would include poor brush contact, loose terminals, and loose or corroded battery terminals and ground connections. It is very important that the third brush of a third-brush-regulated generator be properly seated.

(*c*) **The ignition circuit** takes its current from the battery, at switch connection (B), when the engine is first started, or when it is running slow. When the engine is speeded up, the generator generates sufficient voltage to charge the battery, and the current for ignition is then **taken from the generator** at switch connection (G).

In the example shown in the illustration (Fig. 1) the (−) terminals are grounded; therefore the start for the ignition circuit is at the (+) terminal of the battery or at the (+) terminal of the generator, to the switch at (B) or (G), to (I), to the resistance unit on the coil, through the primary winding, to (T), to the contact-breaker, to ground (G), to the (−) ground of the battery or generator.

If the (+) terminal of the battery and generator are grounded, then the start would be from (+) of the battery or generator to the grounded terminal of the contact-breaker.

The ignition circuit is divided into two circuits, the **primary** low-tension circuit and the **secondary** high-tension circuit.

The primary or low-tension circuit includes the ignition switch, the ignition resistance unit, the primary winding and the contact-breaker, and also the condenser, which is always placed across the contact-breaker points.

The condenser is sometimes placed in the coil, and sometimes on or in the contact-breaker housing, but in every instance it connects **across** the contact-breaker points.

The resistance unit is sometimes placed on the coil and sometimes on the contact-breaker housing, and is always **in series** with the primary circuit.

The secondary circuit is an independent circu termed the "high-tension" circuit. It starts wi the secondary winding in the coil, through a ve heavy terminal, thence to the center of the distrib tor, to the rotor, thence to the segments or poin where it is distributed to the spark plugs in th regular firing order, thence to ground, to t grounded terminal of the secondary.

The parts therefore include the secondary win ing, the distributor, and the spark plugs.

The primary ignition circuit usually takes its cu rent supply from the switch (if (−) terminal grounded). Note in the diagram that the connectic to the switch is from the ammeter. If the batter supplies the current, then the current must pa through the ammeter on the "discharge" sid whereas, if the generator supplies the current, it taken direct at switch terminal (G), and thus do not pass through the ammeter.

Troubles which are common with the ignitio circuit are: open circuits, grounds, short circuits poor connections, both externally and internally c the coil, also burned-out resistance units, loose condenser connections, defective or short-circuite condensers, incorrect adjustment of contact-breake points, burned or pitted points, incorrect timing o opening of points of contact-breaker, defective distributor, incorrect spark-plug gap, leaky spark plugs fouled spark plugs.

(*d*) **The lighting circuit includes** the headligh circuit, the dimmer or auxiliary light circuit, th tail-light circuit, the cowl board or instrument ligh circuit, and, in a closed car, there will probably be dome light and tonneau light. In this example dimmer resistance is thrown in series with the headlights to dim the headlights. If switch connection i made at (5) (Fig. 1), the dimmer resistance is in serie with headlights. If connection is made at (4), th dimmer is not in circuit, and headlights are bright

The lighting circuit starts at the ammeter (1), to switch (B), if the battery supplies the current, and from the switch at (G) if the generator supplies the current; that is, on the assumption that the (−) terminal of the battery and generator are grounded, which they are in the example shown on page 449.

If the (+) terminals are grounded, then the circuit would start from the (+) ground of the battery and generator to ground of the lamps.

If current for lights is taken from the battery, the current in the example (Fig. 1) (and on many other systems) must pass through the ammeter (2) to (1), and thus it shows "discharge."

If current is being taken from the generator for lights, it is taken from (G) on the switch for the headlights, and one side of the ammeter (1) for the other lights, but does not usually pass through the ammeter.

The current passes through ammeter, however, from (1) to (2) (or in the opposite direction to that in which it passed when the battery was discharging). When the generator is charging the battery the needle will show "charge."

If the (+) of the battery and generator are grounded, then the start would be from this ground to the ground of all light circuits, as shown in Fig. 8, page 426.

Either a **fuse** (page 426, Fig. 8), or a **circuit-breaker** (see Delco system, Fig. 15, page 392) is always placed in the lighting circuit. A fuse or circuit-breaker is seldom in any of the other circuits except the horn, which always has a fuse or circuit-breaker in series with the circuit.

Troubles which are common in the lighting ciruits are open circuits, grounds, short circuits, poor onnections, burned-out bulbs, and blown fuses.

If all of the lights fail to burn, the indications are blown fuse. Therefore the first place to look is at ne fuse; if the fuse is not blown, then an open ciruit exists.

If only one of the lights fails to burn, the indicaons are that the bulb is burned out or an open ciruit exists on that line.

If the ammeter shows "discharge" with all witches off, then the indications are a "ground." f the discharge is heavy, a short circuit in the wiring xists at some point, and the fuse should "blow" if nere is one in the circuit.

When troubles of this nature occur, the trouble hould be located before a new fuse is installed.

(*e*) **The horn circuit** is usually taken from the mmeter (1), in the same manner as described under he subject of lights. A push-button is usually laced in the top of the steering column. A fuse is lways connected in the horn circuit, or else in the ircuit-breaker circuit, as on Delco systems.

Troubles of the horn circuit are open circuits, rounds, short circuits, push-button defects, and lso troubles internally of the horn. See Index for "Electric horns."

(*f*) **Grounded connections:** By referring to 'ig. 1, and to Fig. 8, page 426, and to all other viring diagrams of the single-wire, ground-return ystems, it is to be observed that the grounded onnection of the battery not only serves for the enerator charging circuit, but is also a return path r lead for all circuits. Hence the importance of eeing that this and all ground connections are tight.

(5) The Dash Ammeter

The dash ammeter might more properly be termed he cowl ammeter, as it is placed on the cowl or nstrument board of the car.

The purpose of this instrument is to indicate the mount of current passing from the generator to the attery, and indicates on the "charge" side of the ero (0) of the ammeter.

When current is being taken from the battery for ights and ignition (not for the starting motor), the urrent is from (2) to (1), and the needle of the mmeter indicates on the "discharge" side (see also age 334). Thus it is clear that if the ammeter hows "discharge" when it should show "charge," r if it shows "discharge" when all switches are off, t indicates something is wrong. This subject is reated on pages 471 and 472.

On some cars, for instance the Franklin, an indiator is used instead of an ammeter. This device ndicates when the battery is "discharging" or being "charged." Unlike the ammeter in one respect, lthough it serves the same purpose, it can be placed n the circuit of the battery to the starting motor. Owing to its construction, it will show "charge" or "discharge" on 2 amperes of current, yet it is capable of withstanding 300 amperes and any voltage. The ammeter, however, is universally used.

If the ammeter should be connected wrong, or if the battery is connected wrong, the ammeter needle will read in the opposite direction.

The point to note is this: Usually the ammeter is the point from where the ignition, lighting circuits, and horn derive their source of electric supply for either the battery or generator, and that the current runs thence to the switch.

Summary

The various parts and circuits of the electric system have now been fully dissected. The reader should bear in mind that the only successful method of diagnosing electric trouble is to locate the circuit or the part the trouble is in, and to eliminate one possible cause after another, until the probable cause is arrived at. We could fill this book with an enumeration of possible troubles, their cause and remedy, but the simplest method is to learn the fundamental principles of each part, the circuits, and the relation of one circuit and part to another, and then to THINK—and to use intelligent thought before deciding, or even starting to locate a trouble.

When making tests, first determine which one of the parts or circuits the trouble is in, and then test that part from the beginning to the end.

For instance, **if the generator fails to show "charge" on the ammeter,** start at the (+) of the generator, then the fuse (field fuse), then the cut-out, then the circuit. If the fuse is blown, there must be a short circuit. Find the cause.

If lights fail to burn, first examine the lamp-bulb to see if it is burned out; if not, then the lamp-socket, then the fuse; then start at the switch, and then test the wiring. If the fuse is blown, find the cause.

Points to Remember

Remember this same principle applies to a two-wire system.

Remember that when a fuse-block is used in a circuit, the fuses are merely cut into each circuit, which will melt and open the circuit if a wire or part becomes short-circuited. The cause of the "blowing" should always be learned.

Remember that a fuse is never used in the starting-motor circuit, but a fuse is used in the field-circuit in nearly all third-brush regulated generators. If the fuse is blown, the generator will not generate current. Also remember that the ammeter is never connected into the starter circuit unless it is connected with a "shunt."

Remember that the cut-out is often placed integrally with the generator. For instance, on the illustration, page 364, the cut-out is in the generator housing and is connected internally with the generator.

Remember that the regulation of the output of a third-brush generator does not have a separate mechanism to regulate the current, and that it is important that the third-brush, as well as all other brushes, should be properly seated to the commutator.

Remember that a generator which has a voltage regulation system does have a mechanism called a "voltage regulator," which controls the output.

Remember that a Wiring Diagram Book will tell you just what kind of a regulation system a generator has, and will also show the external and internal circuits.

OPEN CIRCUITS, POOR CONNECTIONS, GROUNDS, AND SHORT CIRCUITS

Throughout the preceding instructions, frequent eference is made to the subjects in this heading. Ve shall now analyze the meaning of these and their elation. In fact, practically all of electric troubles re due to open circuits, poor connections, grounds, r short circuits in some part of the electric system.

Open Circuits

Open circuits, as the name indicates, is a point where any part of a circuit is opened. It is an incomplete circuit, and thus it does not offer a passage for the current.

Low-tension (voltage) **direct current** is used in all circuits of the automobile, except in the secondary ignition circuit, which is an independent circuit of a high tension. The secondary circuit, however, is dependent upon the low-tension primary circuit for its existence.

In order that electricity may flow, it must have a complete circuit to flow in, even though it is not a copper path all the way. For instance, the steel frame of the car can be, and is, used for a part of the path.

Electricity starts at the positive or (+) terminal of the generator or battery, and returns to the negative or (−) terminal.

Thus if the circuit or path is open, the low-tension current cannot pass or jump across a gap, and this is termed an "open circuit."

Causes of open-circuits may be said to be loose connections or blown fuses, broken wires, or the fact that brushes on the generator or motor do not make contact; also open circuits may occur at the commutator where the armature coils are soldered to the commutator segments, or possibly on the armature coils themselves, or in the field windings, or in loose or poor connections at the battery or ground wire.

Indications of open circuits are: Lamps failing to light, ammeter failing to indicate "charge" or "discharge," the starting motor failing to start, absence of spark at the spark-plug points. In fact, an open circuit could exist in any one of the circuits, but seldom in all circuits at one time; hence the importance of knowing the different circuits and their relation one to the other.

There are several methods of testing for open circuits, all of which will be explained farther on. A few pointers are given below.

If any one lamp fails to light, it indicates an open circuit in that line. "Blown" fuses, a broken lamp filament, or a broken lamp wire may be responsible.

If all lamps fail to light when the engine and dynamo are speeded up, the open circuit is most likely located between the battery and the dynamo, or between the dynamo and the lighting switch.

The "blowing" or melting of a fuse opens the circuit and disconnects from the system the short-circuited wire which caused the fuse to blow. Therefore the cause should be located, before replacing a fuse.

An open circuit that often occurs, and that is difficult to find, is a broken wire inside of the insulation of the lighting wiring. The easiest way to find the break is first to determine which one of the wires is open and then temporarily to run another wire in its place and note if it remedies the trouble.

Testing current flow: Whether or not current is flowing in a given circuit may be determined by removing one of the wires forming the circuit, and then touching it to its terminal. If a spark occurs, current is passing through the line.

Loose and Poor Connections

It is also well to notice the close relation of open circuits and loose connections. If connections are poorly made, but not completely loosened from the terminal, then there will very likely be an "intermittent open circuit," that is, the circuit will be complete at times, and at times open.

Grounds

There are two kinds of grounds: one which is **intended** to ground the circuit, as from the battery to the frame of the car, and one which is **not intended** to ground, but does so for various reasons. It is with this latter ground that we shall deal here.

In speaking of an intended ground, bear in mind that it has no connection whatever with the ground or earth. It is merely a term used to indicate that a part of the circuit is connected to some metal part of the car, thus saving the necessity of using two wires for a circuit.

Wires that are grounded, but not intended to be grounded, can be the result of numerous causes. For instance, if the insulation on one or more of the armature coils is in such a condition that there is a leak of current through the insulation to the metal core of the armature, it would be termed "grounded."

Or if two wires are oil-soaked and close together, and if they leak current from one to the other, the circuit may not be completely short-circuited, but it will be "grounded," and thus reduced in value, owing to the leak, which results in a weak current supply.

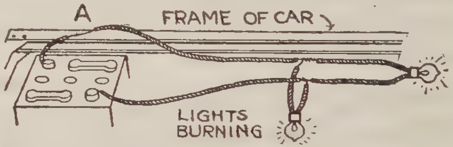

Fig. 2. A ground.

Another example of a ground is shown in Fig. 2, where a two-wire system from a battery is shown connected to two lights. If the wire was grounded to the frame at (**A**), the current could still flow to the lamps. **Therefore, a "ground" might be termed an electrical "leak."**

Short Circuits

A short circuit means that **two conductors** of current are in **metallic contact** when they **should not be.**

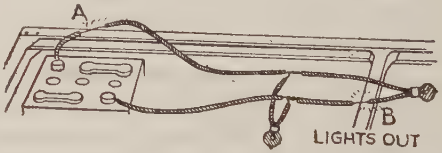

Fig. 3. A short circuit with wires which are supposed to be insulated from the frame.

For example, on a two-wire system, as in Fig. 3, if one wire was "grounded" to the frame of the car, as at (**A**), and the other wire of the circuit was grounded at (**B**), a "dead short circuit" would be the result, and the lights would not burn at all. The path of the current from the battery would be **shortened,** and as electricity takes the path of least resistance, it would flow freely through the frame of the car instead of through the lamps, which are of higher resistance. The result would be that the battery would discharge at a very high rate. In fact, the effect in this instance would be the same as connecting a wire across the terminals of the battery, and unless the wire was of very large size, it would get very hot, or burn into and thus damage battery internally. For this reason fuses or circuit-breakers are used in some of the circuits such as the lighting and horn circuits, which are longer and are more exposed, and nearer to the frame, to dampness, etc.

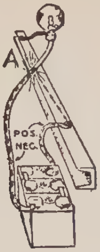

Fig. 4. A short circuit where one wire is insulated and the other grounded.

An example of a short circuit on a single wire or grounded return system of wiring is shown in Fig. 4. Under these conditions we should have the same result as in Fig. 3.

Note, for instance, that the circuit (when not short-circuited) is from the positive terminal of the battery, to the grounded connection to the frame, to the grounded connection at the end of the frame (which is intended), through the lamp, to the negative terminal of the battery.

Suppose the wire, as shown, becomes short-circuited or in contact with the frame at (**A**): the result is that the path is shortened and the current would flow from the positive terminal of the battery, through the ground connection, to the frame, through the wire in contact with the frame at (**A**), to the negative of the battery. Thus the current is short-circuited and would not pass through the lamp, since the easier path is through the wire where it makes contact with the frame. The effect on the battery would be the same as placing a wire directly across the battery terminals, which would be termed a "dead short circuit" across the battery terminals.

Indications of Grounds

If there is an ammeter on the car, it will show a "discharge" with all switches off. The needle should stand at "0" when all switches are "off."

Lamps when turned on will burn dimly, in case of a ground.

Testing for a ground is made by several different methods, but if the ammeter shows "discharge" with the switches "off," then it is a matter of finding which wire is grounded. This will be explained farther on.

If there is no ammeter on the car, and a ground is suspected, then turn all switches "off" and disconnect the wire at the terminal of the battery (as in Fig. 5), and strike the terminal in quick succession. If a spark occurs, even though very slight, it indicates a "ground." Grounds will cause the battery to discharge. The rate of discharge will depend upon the intensity of the ground.

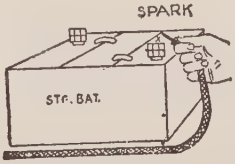

Fig. 5. One method of testing for a ground.

Indications of Short Circuits

If there is an ammeter on the car, the needle will probably go to the limit of the scale on the "discharge" side.

Fuses will blow repeatedly.

If a short circuit exists in the starting-motor circuit, it will probably be indicated by the wires getting very hot, and the smell of burned insulation can be noticed. In fact, a "dead short circuit" would cause the insulation to burn and smoke. This would seriously injure the battery internally if permitted to continue for a long period of time.

As previously stated, grounds, short circuits, and open circuits may exist in any part of the circuit, even to the armature and field-windings. The indications and appropriate tests will be taken up in their respective order farther on.

Before taking up the subjects of electrical tests and tools and devices to test with, a Digest of Troubles will be given in the next instruction, which is to be used as a reference.

INSTRUCTION No. 41

DIGEST OF TROUBLES: Electrical Troubles; Engine Troubles; Miscellaneous Troubles

MAKING A DIAGNOSIS

Diagnosing automobile troubles requires thought and reasoning. If a person understands the principle and construction of the various parts of a car and one of the hundreds of possible troubles occurs, then simply reason it out; ask yourself what the trouble is, what could cause that trouble, and why the trouble is there. Find out if it is ignition, carburetion, cooling, or just what the trouble is, and then figure it out the best you can before proceeding.

It is of little use to turn the engine over and over by the starting handle or by means of the engine starter, in an effort to get it going. If the engine will not start with a few turns, the chances are that there is something radically out of order, requiring intelligent attention. With the carburetor giving a correct mixture, the ignition system affording a hot and effective spark, and everything else apparently all right, it should be as easy to secure an explosion on the second stroke as on the sixtieth. So if the engine will not start with the second or third attempt, it is not likely to start with three or four hundred attempts; consequently it is better to find out the cause of the trouble than to turn the engine over indefinitely and run the battery down.

To Make an Engine Run Two Things Are Essential

Always remember, when diagnosing troubles, that **there are two essentials to the running of an engine:** first, gasoline; second, a spark.

The gasoline must reach the inside of the cylinders, and the spark must be there at the proper time to ignite the gas. If you have both, something is bound to happen, even though it is but a single explosion.

Next, remember that even though you have a spark and gasoline—**the engine will not run properly if the gas does not enter the cylinder at the right time** "and stay there," and be in a proper gaseous form.

The gas cannot be ignited regularly if there is not a good, hot spark at the correct time.

Next, remember that **if an engine is not properly lubricated and cooled** it will heat. If the engine is too cold, heat must be applied for proper carburetion.

Therefore, speaking generally, we find that **most troubles are found to originate in ignition, carburetion, and lubrication.**

If trouble occurs, first find which of the three headings the trouble comes under and then reason it out.

The object of this digest or condensed account of troubles and remedies is simply to give you an idea of what would be likely to cause certain troubles and what would be likely to remedy them. The reader will then decide which one is most probably the trouble confronting him, and if he does not know the meaning of certain adjustments called for, he will then turn to the Index, find the subject mentioned, and read up on that subject.

Systematic Trouble Hunting by a Process of Elimination[1]

In dealing with engine troubles, one should always try to figure out the possible cause of a trouble before starting to adjust something that does not need adjusting.

An adjustment never should be changed without a knowledge of why the change is made, the effect the change should have, and how to restore the mechanism to its original adjustment.

If one will **first reason out the probable causes** of a trouble, **the real cause can be quickly located.** For instance, if a single lamp fails to burn, you will know that the trouble is not in the battery or the generator if all the other lamps burn. Therefore the cause must be in that particular lamp, in the socket, or in the wiring of that particular lamp.

Similarly, **if the starting motor fails to start** the engine, yet you know that it is turning the engine crank shaft, and your lights burn brightly, you would not look to the battery for the trouble, but you would know that the trouble must be with the ignition or carburetion. It is then a matter of applying the process of elimination—that is, test each of the remaining probable causes until the final cause is the only one left.

When the possible cause of trouble cannot be imagined, then begin with a careful examination of all the features of the engine that are likely to give rise to the trouble.

If nothing out of order is found, then begin testing out the various features, beginning with the easiest and most accessible, and thoroughly complete each test before starting on another possible cause.

For example: If your **ignition system** is suspected, the easiest thing to test would be the spark plugs. First find the faulty plug; then proceed from the spark plugs to the wiring between the plug and the distributor; then examine the battery connections, the switch connections and, last of all, the adjustments of either the timer, the coil, or the magneto.

Do not examine a spark plug and then leave it and try a few carburetor adjustments, and later come back for another spell of tinkering with the ignition, etc.

If you suspect the ignition system, go to it from beginning to end in a **systematic** manner before proceeding with the carburetor, and likewise with all other parts.

---

[1] See Index for "Digest of lighting troubles" and see Index for "Storage battery troubles" and "Tire troubles," as well as for subordinate subjects involving "troubles." See also pages 512 to 519.

DIGEST OF GENERATOR TROUBLES[1]

When troubles occur in the electric system of a car, remember that the electric system is divided into four parts: **the lighting circuit, the generating circuit, the starting-motor circuit,** and **the ignition circuit.** The idea is then to determine in which of the circuits the trouble is, and then to test it from beginning to end, as previously explained.

The troubles and the indications and causes of **generator troubles** can be classed under two heads: those which are due to **mechanical defects** and those due to **electrical defects.**

Mechanical Generator Troubles

Indications: Noise; low current generated, or no current at all.

Causes: (1) Broken bearing (examine by turning armature by hand. If it sticks or turns hard, look to ball bearings and replace); (2) loose driving gear or pinion (if loose, key to shaft); (3) armature off center (may be due to loose pole pieces. See that the screws with counter-sunk heads on outside of generator are tight); (4) shaft bent (this is more common on starting motors than on generators. A new armature is required if shaft is bent); (5) commutator burst (when this happens the brushes and brush-holders, etc., are also damaged. A new armature, brushes and brush-holders are required).

Electrical Generator Troubles

Electrical troubles can be classified as: (*a*) open circuits; (*b*) grounded or short circuits; (*c*) defective regulation system; (*d*) defective cut-out.

(a) **Open-circuit indications** would be a low current generated, or none at all.

Causes: (1) Brush connections poor; (2) brushes stuck; (3) brushes worn too short; (4) brush spring broken, with consequently no spring pressure to hold brush to commutator; (5) dirty commutator; (6) if the armature is open by connection being loose at commutator, or owing to a broken coil, it would cause intense blue sparking at commutator and flattened commutator bars; (7) field coils, if open, will show no current at all, or if partially open, a low current generated.

(b) **Ground or short circuits** may be (1) at main terminals; (2) at brush connections; (3) at brush holders; (4) armature, if short-circuited, will cause excessive heating of armature, burned insulation, and low current; (5) field coils, if short-circuited, will cause field coils to heat and low current to be generated; (6) commutator, if short-circuited, will produce no current at all, or a low current output.

(c) **Regulation:** In this instance we shall deal with the "third-brush" system of regulation. If a "voltage-regulated" system is used, see Index.

Indications will be that the charging current is too low or too high, and does not remain constant at high speeds.

Causes: (1) Incorrect setting of third brush; (2) brush not sanded in; (3) spring pressure on brush not sufficient.

(d) **Cut-out remaining open at all times:** Result will be: (1) no current to battery; (2) generator will get very hot; (3) generator will burn out.

(e) **Cut-out remaining closed at all times:** Result will be: (1) battery will discharge back through generator at about 20 amperes (on the Ford), when the engine is not running or not running fast enough. This will discharge the battery.

GENERATOR TROUBLE CHART

- GENERATOR TROUBLES
  - **Mechanical Troubles**
    - Broken Bearing
    - Loose Pinion
    - Loose Pole Piece
    - Commutator Burst
    - Bent Shaft
    - Indicated by Noise, Low Current or No Current Generated.
  - **Electrical Troubles**
    - OPEN CIRCUIT
      - Brush Rigging
        - Brush Connections
        - Brush Stuck
        - Brush Too Short
        - Brush Spring Broken
        - Dirty Commutator
        - Indicated by Low Current Generation or No Current at All
      - Armature
        - Intense Blue Sparking at Commutator and Flatted Commutator Bars
      - Fields
        - No Current Generated
        - If Partial Open—Low Current
    - GROUND OR SHORT CIRCUIT
      - Brush Rigging
        - Main Terminal
        - Brush Connections
        - Brush Holders
        - Low or No Current Generated
      - Armature
        - Excessive Heating of Armature
        - Insulation Burned—Low Generation
      - Fields
        - Coils Heat
        - Low Current Generated
      - Commutator
        - No Current Generated or Low Current
    - THIRD BRUSH
      - Incorrect Setting
      - Brush Not Sanded in
      - Spring Pressure Not Right
      - Indicated by Charging Current Being Too High or Too Low and Not Remaining Constant at High Speed
    - CUT OUT
      - Open
        - No Current to Battery
        - Generator Very Hot
        - Will Burn Out Generator Quickly
      - Closed
        - Battery Will Discharge Back Through Generator at About 20 Amperes When Engine is not Running. This Will Discharge Battery

DIGEST OF STARTING-MOTOR TROUBLES[2]

Starting-motor troubles, their indications and causes may also be classified under two heads: those which are due to **mechanical defects** and those due to **electrical defects.**

Mechanical Starting-Motor Troubles

Indications: Excessive current draw, slow cranking or complete failure to crank, and excessive noise.

---

[1] The "Generator Trouble Chart" is reproduced here through courtesy of the Service Station Equipment Co., Chicago, Ill.

[2] The "Motor Trouble Chart" (page 456) is reproduced through courtesy of Service Station Equipment Co., Chicago, Ill.

Causes: (1) Worn bearings; (2) shaft bent; (3) commutator burst; (4) loose pole-pieces; (5) broken Bendix drive system; (6) armature off center (may be due to loose pole-pieces, in which case tighten screws).

Gummed oil on Bendix drive: It sometimes happens that oil has come in contact with the Bendix drive shaft and becomes gummed, thus preventing the drive pinion from moving to its position and engaging the fly-wheel gear. This condition can be remedied by squirting some gasoline with an oil gun upon the Bendix drive shaft through the opening at the rear of the starting motor.

Electrical Starting-Motor Troubles

Electrical troubles are classified under (*a*) open circuits; (*b*) ground or short circuits.

Open-circuit indications would be suggested by low current or no current, and by failure of starting motor to operate. If a partially open circuit is found to exist, the current draw will be low and cranking slow.

Open-circuit causes: (1) Brush pigtails loose; poor brush-spring pressure; brushes too short; dirty or burned commutator; (2) armature commutator blue sparking, or flattened commutator with slow cranking; (3) fields open; (4) starting switch open; (5) loose connections at battery, ground, or switch.

Ground or short-circuit indications are excessive current required, no cranking, or slow cranking.

Grounds or short-circuit causes: (1) Shorted fields cause excessive current and slow cranking; (2) armature shorted causes excessive current, burned insulation, slow cranking; (3) commutator shorted causes excessive current, no cranking; (4) when the brush rigging is shorted, the causes may be in the main terminal, in the brush holders, or the pigtails may be loose.

MOTOR TROUBLE CHART

- MOTOR TROUBLES
  - **Mechanical Troubles**
    - Worn Bearings
    - Shaft Bent
    - Commutator Burst
    - Loose Pole Piece
    - Broken Bendix
    - Armature Off Centre
    - All Indicated by Excessive Current Draw and Slow Cranking or Complete Failure to Crank and Excessive Noise
  - **Electrical Troubles**
    - OPEN CIRCUIT
      - Brush Rigging
        - Pigtails
        - Brushes Not Contacting
          - Brushes Too Short
          - Poor Spring Pressure
          - Dirty or Burned Commutator
          - All Indicated by Low Current or No Current and Failure to Crank. **If** Only Partial Open Occurs the Current Draw will be Low and Cranking Slow.
      - Armature
        - Intense Blue Spark at Brush and Flatted Commutator with Slow Cranking
      - Fields
        - No Current
        - No Cranking
    - GROUND OR SHORT CIRCUIT
      - Fields
        - Excess Current
        - Slow Cranking
      - Armature
        - Excess Current
        - Burnt Insulation
        - Slow Cranking
      - Commutator
        - Excessive Current
        - No Cranking
      - Brush Rigging
        - Main Terminal
        - Brush Holders
        - Pigtails and Connectors
        - Indicated by Excessive Current and No Cranking or Slow Cranking

STORAGE-BATTERY TROUBLES

This subject is treated under the discussion on the "Storage Battery." See Instruction No. 49: "Digest of Storage Battery Troubles; External and Internal."

See also, Instruction No. 48: "Testing Storage Batteries."

LOCATING TROUBLES OF THE ELECTRIC SYSTEM IN GENERAL

In addition to the electrical troubles enumerated above, the following data, graphically presented, will assist in quickly locating troubles in the electric system.

Assume That Battery Is Fully Charged

Trouble: Motor will not crank engine.
Possible causes:

1. Bendix drive or starting mechanism out of order.
2. Engine too stiff.
3. Open circuit in wiring.
4. Ground in wiring.
5. Defective starting motor.
6. Broken or loose wiring connection in starting-motor circuit or ground.
7. Starting switch does not close, or contacts burned out.
8. Open circuit internal to the motor: field, armature, or brush rigging.
9. Ground or short in motor: field, armature, or brush rigging.
10. See Motor Trouble Chart, under "Electrical Troubles."
11. See Motor Trouble Chart, under "Mechanical Troubles."

Assume That Battery Is in a Discharged Condition

Trouble: Battery not being charged at proper rate.
Possible causes:

1. Generator not working properly.
2. Generator charging at a low rate, or not at all.
3. Open generator circuit.
4. Grounded generator circuit.
5. Defective cut-out; will not close.
6. Broken or loose connection on generator line.
7. Shorted or open coil in cut-out windings.

8. Cut-out contact points defective, or improper spring tension.
9. Low charging rate.
10. Third brush not set properly.
11. No charging current.
12. Generator may be new, or perhaps has been operated for some time with field fuse removed. Field can be excited by momentarily connecting one side of the fuse clip with the metal part of the generator when the engine is running slightly above idling speed.

Trouble: Battery being charged at proper rate, but will not hold charge.

Possible causes:

1. No water over plates.
2. Battery has internal or external ground.
3. Excessive use of current in starting and for lights; very little day driving with lights off; mostly night driving with lights on.
4. Cut-out stuck.
5. Wiring defective.
6. Added electrical equipment using too much current.
7. Bulbs with too high a candle power.
8. Bulbs old and using too much current.
9. Stiff engine, using excess current, especially during cold weather.

Starting-Motor Trouble Tests

Trouble: Motor will not start:

Turn on the lights and try the starter. If the lights do not dim, then the battery is probably charged, as the condition of the battery is the first thing to test when the starting motor does not operate. **Then examine:**

(1) For an open circuit in the starting switch.

(2) For an open circuit at the motor terminals.

(3) For an open circuit at the ground connection to the frame of the car.

(4) The commutator; examine, and see if glazed.

(5) The brushes; see if they are bearing on the commutator, and if they are seating properly.

(6) The brushes; remove and inspect—they may be worn or stuck, or one of the brush-holders may be loose.

(7) The brush material; it may be of too high a resistance.

Trouble: If the ammeter shows no reading when lights are switched on; if the starting motor kicks over spasmodically or not at all; or if the lights do or do not dim when the starting button is depressed, examine the inside of the motor as follows:

(1) For a short circuit in the field or armature coils. This will cause the lights to dim, or the ammeter will show no reading when the starting switch is closed. The ammeter referred to is in the lighting circuit, not the starting-motor circuit.)

(2) For an open circuit in the armature where the coils are soldered to the commutator segments. (This will cause the motor to kick over spasmodically or not at all.)

Next, check the external motor circuit:

(1) To the frame. (If open, slow cranking or none at all will result.)

(2) To the switch. (If open, the lights will not dim; if grounded, the lights will dim excessively or the ammeter will show no reading when the starting switch is closed and lights are turned on.)

(3) To the battery. (Same indications as 2.)

Trouble: Starting motor starts, but not enough to turn engine over:

(1) Crank the engine by hand to see if it is unusually stiff.

(2) If the engine will not start readily by hand cranking, then look for engine trouble.

(3) Bendix drive may be stuck, or there may be a broken Bendix spring.

Next, if the engine, the ignition, the carburetion, etc., are in order, then look for:

(1) Poor contact at battery terminals.

(2) High resistance contact at brushes.

(3) Poor connection between brush and shunt-field.

(4) Poor connection between brush and brush-holder.

(5) All brushes not bearing on commutator.

(6) Brushes stuck in brush-holder.

(7) Grounded brush-holder.

(8) Loose ground connection (if car has a ground-return system).

(9) Battery below cranking capacity.

(10) Open circuit in armature coils.

Next, disconnect battery, and make a temporary connection to a fully charged storage battery. If the starting motor will then turn the engine over, the battery in the car is at fault.

Test storage battery with hydrometer. If the storage battery is low, look to the generator. (Note. Always make a hydrometer reading before adding distilled water. See "Storage Battery" instruction.)

If battery is low or lights are dim, test out the ampere charging rate of the generator. (Do not rely upon the ammeter on the car.)

Trouble: Lights and ignition are cut off entirely when the starting switch is depressed.

(1) Starting switch may be loose, where the wire connects from one side of the starting switch to lead to the ammeter, ignition, and lighting switch.

(2) A short circuit may exist at the switch, which will short this circuit.

Generator Trouble Tests

The following will explain where to test a generator for open circuits, short circuits and grounds.

Test for open circuit in:

(1) Generator terminals.

(2) Battery connection.

(3) Ground connection to car frame (if car has a grounded return system).

(4) Fuse.

(5) "Cut-out" or ignition and lighting switch.

(6) Field windings and armature coils.

Test for short circuit in:

(1) Generator itself; field windings and armature coils.

(2) In external wiring.

Examine brushes and commutator for:

(1) Pitted or burned segment surfaces and brush seats.

(2) Dirty or glazed commutator, high wired, rough commutator.

(3) High resistance contact at brushes.

(4) Worn-out brushes.

(5) Poor connections.

(6) Brushes not bearing on commutator (faulty spring or holder).

Examine generator for:

(1) Worn bearings causing unequal air-gap.

(2) Reversed polarity. (Storage battery is sometimes reversed in position in car.)

Examine regulator and cut-out for:

(1) Dirty or pitted contact points.

(2) Contacts out of adjustment.

(3) Regulator cuts out too soon or not soon enough, owing to gummed mechanical parts.

(4) If in a third-brush regulation, see brush connection or look for defective mechanism. The third brush failing to seat properly is a common cause of an open circuit and a low charging rate.

DIGEST OF ENGINE TROUBLES: CAUSE AND REMEDY[1]

Ordinary engine troubles are generally of three kinds:

(1) Engine will not start.

(2) Engine starts but misses.

(3) Engine starts and runs regularly but has no power.

The following matter refers principally to **ignition** and **carburetion** troubles.

ENGINE FAILS TO START.

(1) **Lack of gasoline:** See that there is gasoline in the tank and that the shut-off cock is open. Make sure that gasoline is flowing to the carburetor by priming or pushing down the carburetor float. If the carburetor is too full, the gasoline will drip. If the carburetor is not full enough, look for a stoppage in the gasoline pipe and see that the vent hole in the tank cap is open.

(1A) **Carburetor needs priming:** Either prime carburetor or close air intake valve.

(2) **Poor quality of gasoline:** Some of the gasoline offered for sale is of such poor quality that it will not vaporize when the engine is cold.[2] The gasoline may contain water, which will freeze in cold weather and clog the gasoline pipe. Old or stale gasoline may also cause difficult starting.

(3) **Too much gasoline:** The cylinder may be flooded with gasoline; the spark plug may be soaked. Open the relief cocks, cut off the throttle, and crank the engine until the excess is eliminated and an explosion occurs. Then close relief cocks, open throttle only partially and try cranking again; engine ought to start. Float may be loose; or a grain of dirt may be under the needle valve.

(4) **No pressure in fuel tank:** If the system is a pressure fuel system, then use the hand pump and try priming carburetor. See that the gasoline tank filler cap is tightly screwed on.

(5) **Lack of ignition current:** If battery ignition, see if battery is strong. Remove one of the spark-plug wires and hold it about ⅜″ away from plug and terminal, and see if the spark jumps the gap when the engine is cranked. If there is no current at all, then look for broken or loose wires at the switch and on the battery and the battery ground connection; Also on the connections on the coil and distributor and timer. If the spark is very weak, then look to the battery and test coil and the ignition resistance unit and the condenser.

(6) **If starting motor fails:** See Index under "Starting motor fails to start."

(7) **Spark plugs:** Spark plugs may have become sooted from over-lubrication, or if they have seen considerable usage the points may be burned and corroded. If water has been splashed on the engine when it was hot, the porcelain of the plugs may be cracked. See that the sparking points are perfectly clean and that the gap does not exceed .020″ to .031″.

ENGINE STARTS BUT MISSES.

(8) **Carburetion adjustments:** If on a cold day and engine has just been started, wait a few minutes for engine to warm up—closing air intake.

If missing still occurs, with popping back or "sneezing," this indicates that the mixture is too lean; give the needle valve of the carburetor a slight opening until the engine runs smooth. If no needle valve is provided, give less air in the auxiliary air valve.

(9) **Ignition:** If missing continues after engine is warmed up, and more gasoline is fed as directed in (8), examine the spark plugs and test as suggested in (7). Weak battery may be the cause, if coil and battery ignition.

ENGINE STARTS, BUT "POPS" AND "SNEEZES" IN CARBURETOR.

(10) **Carburetion:** See Index under "Carburetion troubles."

ENGINE STARTS, BUT WILL NOT PULL.

(11) **Carburetion:** See (8); or there may be an over-rich mixture. This would be indicated by black smoke.

(12) **The valves:** May be leaking, and there might be poor compression.

(13) **Ignition:** The spark may be weak. This, however, would be indicated by missing. Test battery.

---

[1] See "Digest of Lighting Troubles," and "Storage Battery Troubles."

[2] Very common in cool weather. See Index under "Carburetion troubles."

ENGINE RUNS REGULARLY FOR A FEW MINUTES AND THEN STOPS.

(14) **Carburetion:** In cold weather this is more liable to occur until engine is warm; give slightly more gasoline by closing air valve (if one is provided); gasoline may not be flowing freely to carburetor. Prime carburetor and see if it drips. There may not be enough gasoline; closing air valve will determine. May be too much gasoline (see 3).

(15) **Ignition:** Battery may be weak, Ignition may be retarded too much. If there are two systems of ignition, try the other one.

ENGINE STOPS SUDDENLY.

(16) **Carburetion:** Lack of gasoline. Stoppage of gasoline pipe (prime carburetor, and if no gasoline, examine tank, then fuel strainer). See (73).

(17) **Ignition:** Loose wire. Short circuit, loose switch connection. If magneto ignition, switch to coil and battery. Weak battery. Points of interrupter may be closed by pitting.

(18) A sudden stoppage is almost always due to ignition trouble, for gasoline trouble will stop engine slowly.

ENGINE STOPS SLOWLY WITH MISFIRING.

(19) **Carburetion:** See (16). The needle valve sometimes jars itself closed.

(20) **When an engine stops slowly, the explosions** becoming weaker and weaker until they cease, it is likely due to gasoline trouble. The fault will be found in the failure of the mixture to reach the cylinder. (See 73.)

(21) **Ignition:** Batteries exhausted; plugs fouled through over lubrication.

ENGINE LOPES OR LOADS UP.

(22) **Carburetion:** When the engine slows down irregularly, speeding up and then slowing down again as though fitted with a governor, and if throttle be closed further in order to slow down more, engine stops. Air has leaked in between carburetor and cylinders. Examine gaskets around the joints of inlet pipe or where carburetor is attached to intake manifold. Too much gasoline will also cause "loping." Cut down on the carburetor gasoline feed.

(23) **Ignition:** The spark may be set too far advanced. If this is the case, loping is likely to occur when spark is fully advanced. Therefore test the time of ignition.

LACK OF FLEXIBILITY.

(24) **Carburetion:** This trouble is almost exclusively a carburetor fault, and is due to the fact that the auxiliary air intake is so constructed that it furnishes an abundance of air on high speed, and is not sensitive enough on low. When the throttle is nearly closed the engine stalls; or when the throttle is suddenly opened there is no "get away," because the auxiliary air inlet valve allows an inrush of air forming a mixture good enough for high speed running, but too weak for "pick up" purposes. This calls for careful adjustment of the auxiliary air valve and gasoline needle valve, or for more gasoline.

ENGINE MISSES EXPLOSION.

(25) **Defective or dirty spark plug:** With the engine running idle, short-circuit the spark plugs one at a time by touching a screwdriver from the metal of the cylinders to the terminals of the plugs. (See page 238.) This prevents the plug from firing, and when one is short-circuited—that makes no difference in the running of the engine—you have probably located the plug at fault. If the spark-plug wire is properly connected to the distributor, either clean or install a new plug in place of the one that has been found defective. If a vibrator coil, see page 222 (also see 17).

(26) **Spark-plug gap too wide:** The distance between the spark-plug points should not exceed .025″. (See 7.)

(27) **Examine interrupter points.** Weak battery.

(28) **Too lean a gasoline mixture:** If the engine misses with a popping noise in the carburetor, the indications are that too much cold air is being admitted through the air-regulating valve; the carburetor jets have become clogged with dirt, or there is a partial stoppage somewhere in the gasoline pipe connections. See that carburetor intake header gaskets are perfectly tight, and do not admit air, which would thin the mixture.

(29) **Look for gasoline trouble:** Dirt in gasoline tank over outlet; dirt or water in carburetor; float leaking; jet in carburetor clogged up; supply cock loose; inlet valve sticking or leak in inlet pipe; weak exhaust valve spring; may be a leak of air in inlet pipe.

(30) If the engine misses, and the following explosion is accompanied by an explosion in the muffler, ignition is at fault, for the charge has reached the cylinder correctly, but has been exhausted without being exploded.

ENGINE MISSES ON HIGH SPEED.

(31) **Ignition:** Weak battery (if coil and battery ignition). If the engine misses at high, but not on low, or on a hard pull, then it is evident the spark plugs are in proper order but the contact-breaker needs adjusting.

A word of explanation on this: the engine may fire all right at lesser speeds, because the speed is slow enough and the contact is long enough to allow the coil to build up, but at high speeds the time of contact is so short that the coil does not have sufficient time to build up, thus indicating that the contact-breaker gap is too wide. See pages 296–303.

Try switching to the other ignition system, if a dual system is provided. This will determine which ignition system is at fault.

The coil may be defective internally, in its winding, or the resistance unit or condenser may be defective. See Index for "Testing a coil."

(32) **Carburetion:** The carburetor may have been adjusted for slow speed, but requires more gasoline on high speed, or it may be getting too much gasoline. Proper adjustment of carburetor ought to suffice.

ENGINE MISSES ON LOW SPEED.

(33) **Ignition:** If magneto ignition, the cause may be the slow speed of magneto, and weak cur-

rent generated. Try advancing the spark more. Also examine the interrupter points.

Examine spark-plug points (see 7). If not remedied, try switching to the other system of ignition. If missing still occurs, there are two other points to consider: loose connection, or a broken-down coil, if one coil is used for both systems, such as a low-tension magneto.

(34) **A spark plug may be fouled:** It has been known that often a bad plug will not cause missing at all speeds, but will miss at high speeds.

(35) **Carburetion:** Mixture at fault—readjust slow-speed adjustment. The float may be too low, giving over-rich mixture.

(36) **There may be a leak in the intake pipe:** This is a very common cause for missing at low speeds, and is best detected by allowing the engine to run at the missing speed. Take a squirt can full of gasoline and squirt around all the intake pipe joints. If you detect any difference whatsoever in the running, there is a leak. The remedy is obvious.

ENGINE MISSES AT ALL SPEEDS.

(37) **Ignition:** Defective spark plug (see 7 and 25). Loose connection. Weak battery. Loose switch parts. Broken wire. Slight short circuit. Defective coil, ignition resistance unit or condenser, pitted or incorrectly adjusted breaker points.

(38) **Carburetion:** See Index under "Carburetion mixture."

ENGINE DOES NOT DELIVER FULL POWER.[1]

(39) **Compression:** Leaky exhaust valves, scored cylinder, worn or loose rings, cause loss of compression. Timing of valve may be wrong. Exhaust and inlet may not open at correct time. See Index, under "Checking valve timing," "Valve grinding," "Valve clearance." Weak inlet or exhaust springs. Examine cams for wear.

The spark plugs will indicate condition of engine, as follows: If the end of the spark plug is oily it indicates too much lubricating oil or leaky piston rings. If black soft soot, like that which accumulates in a lamp chimney, this indicates that too much gasoline is being fed to the cylinder through intake, causing too rich a mixture. This may come from improper carburetor adjustment or an air leak in intake manifold. If the ends of the plugs are oily and sooty, this would indicate that the valves leak, as this permits burned gases being drawn into the mixture, which would result in poor combustion and lack of pressure in cylinder, which would permit oil to pass and foul plug.

(40) **Carburetion:** Too rich a mixture (see Index under "Carburetion mixture."

(41) **Overheating of engine:** Lack of oil. Circulation system defective (see Index under "Engine overheats; cause of."

(42) **Ignition:** Timing of ignition may be wrong—set too far retarded or too far advanced. Weak ignition. Defect in distributor.

(43) **Miscellaneous causes:** Dragging brakes, leaky piston rings, lack of lubrication. Tight bearings. Flat tires. If new piston rings fitted, they may be not fully set. Use plenty of oil.

ENGINE OVERHEATS.[2]

(44) **Valves:** The exhaust valve may not open early enough to permit the burned gas to pass out.

(45) **Carburetion:** Too rich a mixture (see Index under "Carburetion mixture"), or driving with throttle open too far and spark retarded too much.

(46) **Ignition:** Running on retarded spark invariably causes heating. Test the ignition timing.

The spark lever should be raised up or advanced as far as possible at all times without causing the engine to knock. See Index "Spark control and over-heating."

(47) **Lack of lubrication:** Examine the oiling system.

(48) **Cooling:** Constricted water circulation; examine the water circulation and pump. Under-sized radiator.

(49) **Carbon deposit:** See Index under "Relation of carbon deposit to lubricating oil." Choked exhaust.

(50) **Slipping fan belt:** Tighten the belt.

(51) **Brakes dragging:** Examine the brakes with rear wheels jacked up.

(52) **Bearings:** If engine is new or just overhauled, the bearings may be too tight. Put in plenty of oil and run the engine until loosened up.

(53) **Driving too long on low gear:** This is bad practice and should be avoided.

Note. Refer to page 148 and note the "motometer." This is an excellent device to assist in diagnosing overheating troubles. Overheating is always manifest when engine begins to run slow and pounds.

ENGINE KNOCKS.

(54) **Ignition:** The most common knock is the ignition knock, caused by too much advance of spark. Back lash in timing wheel teeth. See Index for "Knocks."

(55) **Bearings:** The connecting rod or main bearings may be loose. Lubrication may be poor. (See Index for "Testing," also "Tightening bearings.")

(56) **Carbon deposit:** This is also a frequent cause of knocking; see Index for "Carbon troubles."

(57) **Loose or worn pistons:** Will cause a "piston-slap." See Index. Loose piston pin also causes knocks.

(58) **Carburetion:** Too rich a mixture will cause a gas knock.

(59) **Engine overload on hill:** Shift to lower speed.

---

[1] See Index under "Engine Why It Loses Power."

[2] When the engine overheats by steaming, owing to frozen water, feel the radiator at bottom. If cold, it is frozen; if warm, then the circulation is right, and the trouble is due to lack of water or something else. See also pages 154, 150, 153.

ENGINE WILL NOT STOP WHEN SWITCHED OFF.

(60) **Ignition:** If firing is regular, the switch is defective. If firing is irregular, pre-ignition is the cause. Caused by poor oil. This carbon hardens and becomes red hot, hence "pre-ignition." (See Index under "Pre-ignition.")

Stop engine by closing throttle, and as soon as the engine cools, locate the cause.

(61) **Miscellaneous other causes:** Overheating, as explained from (44) to (53), may be the cause.

DIGEST OF ENGINE AND CHASSIS TROUBLES: CAUSE AND REMEDY

ENGINE RUNS WELL, BUT CAR DRAGS.

(62) **Clutch is probably slipping:** The spring needs tightening. If leather-faced cone type, too much oil on the leather. Clean with gasoline squirted on with an oil gun. If this does not hold, use Fuller's earth (last resort). If multiple disk type, clutch spring at fault or plates worn.

A slipping clutch is detected by the engine speed not conforming with speed of car when throttle is opened. This ratio between car and engine is soon learned by experience.

Brakes may be dragging.

CLUTCH DRAGS.

(63) **If cone type:** The clutch may not clear the fly wheel when thrown out. If multiple disk type, the oil may be too heavy and sticks to plates.

CLUTCH GRABS, OR IS FIERCE.

(64) **If cone type:** Leather too dry. Clean with gasoline (see 62); then put on castor oil or neats-foot oil to soften.

If multiple disk, use lighter oil after cleaning. Spring may be too tight (see repair subject, "Care of clutch," and Index under "Borg & Beck clutch").

CLUTCH SLIPS (Ford)

(65) See Ford instruction and Index.

CLUTCH BRAKE WORN, CAUSES TROUBLE IN SHIFTING GEARS

(66) See Index: "Borg & Beck, single-plate clutch".

OIL ON CLUTCH LEATHER (cone type). See Index "Clutch repairing."

(67) **Cause:** Too much oil in crank case—oil works out of engine bearing.

ENGINE BACK FIRES IN MUFFLER.

(68) **Ignition:** Usually occurs when coasting with spark off and retarded, and suddenly throwing on switch, thereby firing charges which have entered muffler unfired.

(69) **Carburetion:** Mixture too weak to fire, or mixture right but sparking wrong. One cylinder missing fire and pumping explosive charges into muffler which ignites from heat of the next exhaust charge. Missing of ignition, valves leaking. Gasoline supply failing.

Remedy: (1) Examine as in sections (25) to (30); particularly see if the plug points are too far apart. (2) See that all cylinders are firing regularly. (3) Adjust carburetor. (4) See if plenty of gasoline is in tank.

CRANK CASE BECOMES VERY HOT AND ENGINE WEAK.

(70) **Cause:** Serious leak of exploded gas past piston rings; rings worn or broken; crack in head of piston; piston pin loose in piston and allowing gas to escape along bearing. See Index under "Testing piston ring leaks."

OVERHEATING OF EXHAUST PIPE AND MUFFLER.

(71) **Cause:** Carburetor trouble; over-rich mixture; valves out of time; very late spark; running too long on low gear; using too much gas; exhaust throttled; insufficient lift on valve or choked muffler.

This condition is the result of the mixture not being completely burned in the combustion space, but continuing to burn in the exhaust pipe and muffler.

A mixture that is too rich or too poor, usually the former, will burn slowly and will still be burning during the exhaust stroke.

If the exhaust valve opens too soon, the charge will escape before it has done its work.

Very late ignition will not give enough time to permit the charge to be burned before the exhaust valve opens.

ENGINE MAKES AN UNUSUAL HISSING NOISE.

(72) **Cause:** Spark-plug porcelain broken; joint between engine and exhaust pipe loose; exhaust pipe cracked; compression cock worked loose; spark plug not tightly screwed into cylinder; valve caps may be loose; cylinder head may be loose. Probabilities are that the exhaust pipe or a spark plug is loose.

GASOLINE FAILS TO REACH THE CARBURETOR.

(73) **Cause:** Gauze strainer in base of carburetor choked; obstruction in the supply pipe; air lock at a bend in supply pipe; pressure leakage from tank, or, if a gravity tank, it may be air-bound; floating obstruction in gasoline tank covering the gasoline outlet; gasoline pipe near exhaust pipe causing a vapor lock; vent hole in filler cap clogged. See Index: "Vacuum-tank troubles."

CONTINUAL EMISSION OF SMOKE FROM MUFFLER.

(74) **Cause:** Engine being over-lubricated. Readjust lubrication to give a slower rate of oil flow. The emission of black smoke indicates that the carburetion is too rich. Piston rings leak. Cylinders may be "scored."

CRACK IN CYLINDER.

(75) **Effect:** Water in combustion chamber or in crank chamber; air bubbling through radiator on pulling engine over compression. (See Index.)

CARBURETOR DRIPS.

(76) **Cause:** Float-valve mechanism out of order. Examine float and reseat the float needle valve. Usual cause is dirt under needle valve, or float set too high. (See also Index.)

ABNORMAL NOISE FROM TRANSMISSION GEAR.

(77) **Cause:** (Other than unskillful changing of the gears)—want of lubrication of gears in change-gear box or bevel drive on back axle; pinions damaged; teeth broken or worn down; nut loose in gear box and fouling gears; clutch drum or flywheel loose; universal joints on transmission shaft badly worn or damaged; bearings in gear box worn, allowing shafts to rock about; sliding member of clutch out of alignment with cone (sets up harsh grating noise); wear of jaws of positive clutch in gear box.

SQUEAKS AND SIMILAR NOISES.

(78) **Cause:** Fork actuating clutch wants lubrication; one or more bearings overheating and want of lubrication; one or more of the brakes partly on; bearings of spring shackles want lubricating (on some cars the spring ends work in a slide, which requires occasional lubricating); valve stems running dry in the guides. Fenders and hoods are usually the cause of most noises. Spring leaves require lubrication between them.

LUBRICATOR STOPS WORKING.

(79) **Cause:** Oil pipe choked; feed nipples choked; pump shaft may be broken, usually due to clogged pipes—may need priming; loose connections.

OIL-FEED GAUGE DOES NOT SHOW FLOW OF OIL.

(80) **See if oil in crank case.** Clean strainer. Air leak. Examine pump and pipe connections. Oil may be too cold to flow (see page 164). Oil pump may need priming. When testing an oil-feed pipe for an air leak, remove and test with air pressure, submerging pipe in water to make the test.

OIL LEAKAGE FROM ENGINE.

(81) **Cause:** Bearings badly worn and passing out bearing journal; gaskets not tight; screws loose; crank case flooded with oil (lubricator working too rapidly); cap screws holding lower crank case not tight; gaskets leaking.

INSTRUCTION No. 42

TESTING DEVICES FOR ELECTRICAL TESTS: Ammeter and Voltmeter Construction and Tests

ELECTRICAL TESTING DEVICES

Most tests of any part of an electric system are for "open circuits," "grounds," or "short circuits"—that is, **electrical** troubles. There are, of course, many **mechanical** troubles which are not tested with instruments.

Devices used for testing circuits can be classified under two headings:

1. Visible circuit-testing devices.
2. Audible circuit-testing devices.

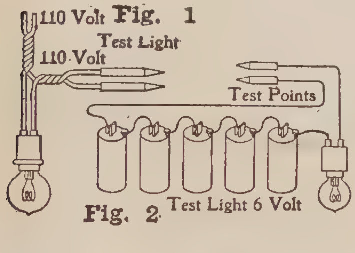

Fig. 1

Fig. 2

Fig. 3

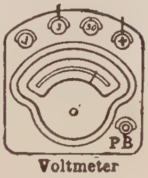

Fig 5

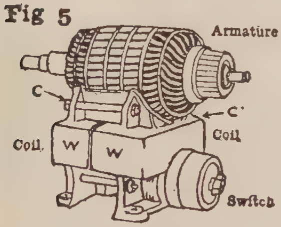

Fig. 4.

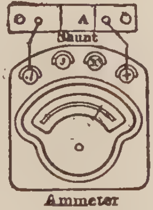

Visible circuit-testing devices include such devices as are mentioned below:

(a) Test-light and test-points in series with a 110 or 220-volt lighting circuit (Fig. 1), termed a "high-voltage test-light."

(b) Test-light and test-points in series with a set of dry cells or a storage battery (Fig. 2), termed a "low-voltage test-light."

(c) A voltmeter (Fig. 3).

(d) An ammeter (Fig 4).

Frequently the voltmeter and ammeter are combined in one instrument.

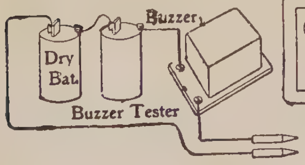

Fig. 6

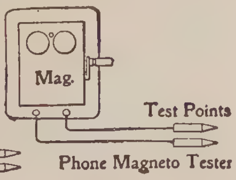

Fig. 7A

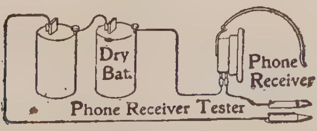

Fig. 7

Audible circuit-testing devices include such devices as a growler (Fig. 5) for testing armatures; a buzzer and test-points (Fig. 6); a phone receiver and test-points (Fig. 7); a magneto and test-points (Fig. 7A).

Test-Lights

The test-light and test-points can be used for testing for open circuits, grounds, and short circuits in the lighting, the horn, ignition, the generator, and, in fact, in all circuits, including the field-windings and armature. Tests will be explained farther on.

Next to the combination volt-ammeter, the most important testing arrangement for the electric mechanic is a set of "test-points," to use in connection with the electric light circuit. This is very easily made by tapping one wire of an ordinary extension lamp, and splicing the wires on to suitable points with insulated handles, in order that these may be handled with no danger of electrical shock, as explained below.

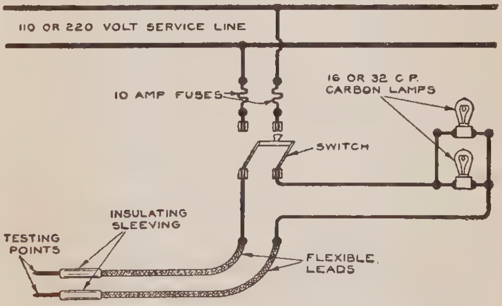

Fig. 8. High-voltage test-lamp with fuses in the circuit.

High-voltage test-lamp: The circuit shown in Fig. 8 is for a 110 or 220-volt circuit. Carbon filament lamps are used as they stand more vibration.

With a set of test-points as described, the lamp will burn when the test-points are together, or when there is an electrical connection between the points.

This will give more satisfactory results for testing for grounds, leaks, or open connections than will a bell or buzzer used with dry batteries, as the voltage is higher and it requires a small amount of current to operate the lamp.

With a bell or buzzer, a ground may exist, but the resistance is so high that enough current will not be forced through it by the dry batteries, to operate the bell or buzzer.

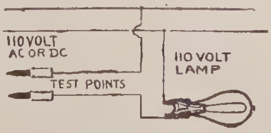

Fig. 8A. High-voltage test-lamp without fuses.

No harm can be done to any part of the apparatus by test-points as described above, when the ordinary carbon or tungsten lamp is used for testing purposes.

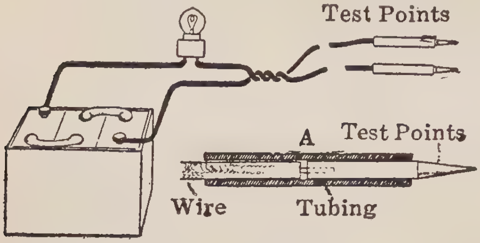

Fig. 9

Fig. 9A

Fig. 9. Low-voltage testing lamp.

Fig. 9A. Construction of the test-points.

A low-voltage test-lamp is shown in Fig. 9. In many instances it is advisable to use a small 2 c.p. lamp and a storage battery. Note that the lamp is in series with the circuit. The voltage of the lamp is the voltage of the battery used. Usually, a 2 c.p. lamp is used.

Test-points: An example of how the test-points can be made is shown in Fig. 9A. The end of the wire is scraped clean and inserted into a hole drilled into a brass rod about 6″ long, and soldered securely. The rod must have a very sharp point, so that it will make good contact. A fiber tube is then tightly fitted over the pointed brass rod and wire, as shown in Fig. 9A.

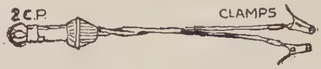

Fig. 10. Test-lamp for timing the ignition.

A test-lamp for testing the opening and closing of the contact-breaker points of the primary ignition circuit when timing the ignition is shown in Fig. 10. See page 371 for directions for use of this.

Buzzer, Phone Receiver, and Magneto Tester

The buzzer or bell (Fig. 6) **and the phone receiver** (Fig. 7) can be used with the test-points for testing out different sections of the armature coils.

The magneto tester (Fig. **7A**) generates a high voltage and is adapted for tests which will force a current through a high degree of insulation, such as poor connections or a leaky path and coil windings. This device is nothing more than a telephone magneto generator with a bell, test-cords, and test-points. It is cranked by hand (seldom used).

AMMETER AND VOLTMETER FOR DIRECT CURRENT TESTS

The ammeter and voltmeter can be used in many instances where a test-light can be used, and vice-versa. In fact, the voltmeter and ammeter are more often used for all general electric tests than any other type of testing device. Therefore, before taking up the subject of tests of the various parts and circuits, an explanation of these will be given.

A voltmeter is always placed **across,** or parallel with, a circuit to be tested, as in Fig. 12A.

An ammeter is always placed **in series** with a circuit to be tested, as in Fig. 13.

The positive or (+) terminal of each instrument is placed on the (+) side of the line, otherwise the instrument would read backwards.

Combination Voltmeter and Ammeter for Electrical Testing Purposes

Instead of having a separate voltmeter and ammeter, it is possible to combine both in one instrument using the same scale and moving coil. The Weston model 280 garage testing voltammeter will be used as an example (Fig. 12).

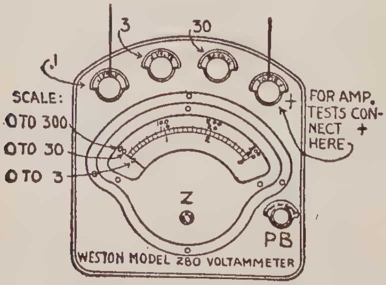

Fig. 12. Showing the three scales on the volt ammeter. The contact button (PB) is pressed when making readings. If it is desired to obtain a continuous deflection, the key (PB) should be given a turn, which locks it. When starting to use the instrument, see that the needle is at zero; if not, adjust with (Z).

As a Voltmeter

When using the instrument for voltage tests: See Fig. 12, and note that terminals are marked .1, 3, 30, +.

The positive or (+) terminal of the instrument is **always** connected with the positive (+) wire of the circuit being tested. When making connections where the polarity is not known, the needle will deflect to the left if wrongly connected—reverse connections.

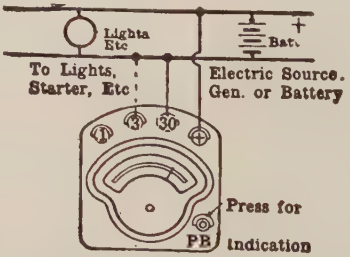

Fig. **12A.** **When used as a voltmeter,** the connections are always made across the line. The circuit of this is from (+) of the battery, to lights, to (−) of the battery. Note that (+) of the meter is connected to the (+) side of the line. Thus if the circuit is 3 to 30 volts, connect the other side of the line with meter terminal 30. If the voltage is from 0 to 3 volts, connect with terminal 3.

If the voltage to be tested is known to be between 3 and 30 volts, then connect the other, or negative (−) wire to terminal marked 30, and use the scale 0 to 30, the divisions of the scale being 0.5 volt for each line (the scale has 60 divisions).

If the voltage is known to be between 1 and 3 volts, connect the negative wire with terminal marked 3, and use scale 0 to 3, the divisions of the scale being 0.05 volt for each line.

If the voltage is known to be less than 1 volt, connect the negative wire with terminal marked .1, and use scale 0 to 3.

When making voltage or ampere tests, the button (PB) is pressed for indication.

The zero adjustment (Z), is merely used to line up the needle with zero or O, when starting to use the instrument.

A voltmeter is always connected across the line, as shown at (V1) and (V2), page 470, and in Fig. 12A. It is used to indicate the voltage pressure of an electric circuit.

As an Ammeter

When using the instrument for measuring amperes, it is connected in series (that is, the shunt is in series) with the circuit, and is intended to indicate the quantity or rate of flow of current.

It is important to note that a "shunt" (Fig. 14) must be connected as shown in Fig. 13. The reason for this is explained farther on. A shunt is not used with the voltage tests.

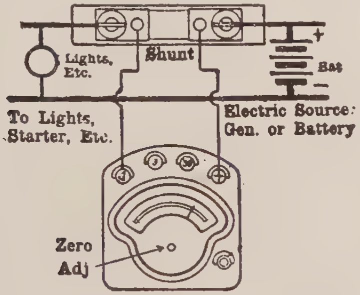

Fig. 13. When used as an ammeter, a shunt is placed in series with the line and the meter is connected to the shunt. The circuit is from (+) of the battery, to shunt, to light, to (−) of the battery. Note that the ammeter is connected to each side of the shunt.

An ammeter is a millivolt meter, adjusted to a known drop in the shunts used with it.

Shunts

Construction: A shunt consists of a special alloy, called manganin (Fig. 14), which, in this instance, is placed between two copper bars mounted on a wood or hard rubber base. The shunt is placed in series with the circuit being tested.

The meter is connected at each end of the manganin at (M) and (M1) (Fig. 14). Thus the manganin is shunted across the meter terminals, and this is why it is termed a "shunt." A shunt is used with the meter for ampere tests and not for voltmeter tests.

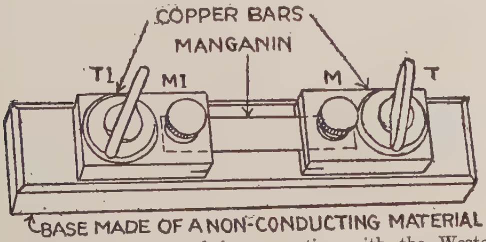

Fig. 14. A shunt used in connection with the Weston ammeter.

The manganin alloy was discovered by Dr. Weston. It possesses the faculty of holding a **constant** resistance, whether it is hot or cold, and directly proportional to the current flowing through it.

It is a well-known fact that other metals which are used for resistance purposes, when cold, offer less resistance than when hot. In other words, other resistance metals when heated offer greater resistance to the flow of current (some metals more or less than others).

The shunts which are used with this model 280 instrument are designed to give a **100-millivolt drop** between the terminals (**M**) and (**M1**), (Fig. 14A).

Explanation of Millivolt Drop

A millivolt is a one-thousandth part of a volt One hundred millivolts would then be one hundred times more, or one-tenth of a volt, expressed decimally as .1. The terminal of the meter (Fig. 12), at the left, which is marked .1, is then, the one-tenth of a volt, or 100-millivolt terminal of the meter.

The moving coil of model 280 voltmeter and ammeter is designed for a passage of 100 millivolts (or .1 of a volt) through the coil. If this amount of voltage passes through the moving coil (K) (Fig. 15), it will cause the coil to move its maximum distance of travel across the scale. As the needle moves with the coil, it would give a full-scale deflection of the needle, that is, the needle would move from 0 at the left of the scale, to the extreme right. Thus it will be noted that **one-tenth of a volt (.1), or 100 millivolts, which is the same, is the voltage required to cause the needle to give its maximum or full-scale reading.** This voltage is used for the instrument when it is used as an ammeter or as a voltmeter.

If less than one-tenth of a volt (.1) (or 100 millivolts) is passed through the coil of the meter, then **the needle will not move as far** on the scale. The scale is graduated to show in volts or amperes, although the actual voltage which is permitted to pass through the coil of the meter is only 100 millivolts, or one-tenth (.1) of a volt, or less.

This drop in voltage depends on the size or quantity of the manganin used in the shunt, when the instrument is used as an ammeter.

When the instrument is used as a voltmeter, the shunt is not used, but resistance is used as shown in the figure of the meter in Fig. 15.

For example: Let us assume that the instrument is to be used as an ammeter to test the rate of flow of amperes passing from the (+) brush of the generator to the (+) terminal of the battery, as shown in Fig. 14A. We will also assume that **30 amperes** will

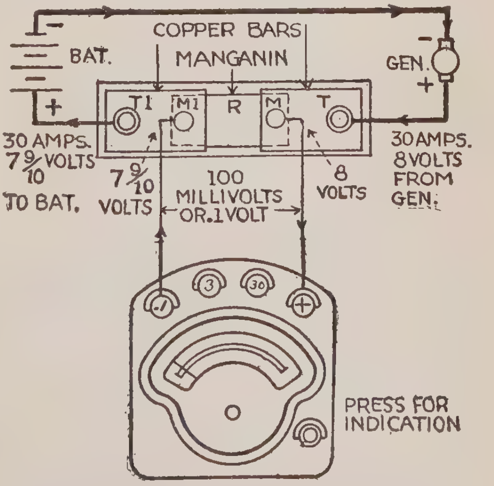

Fig. 14A. Illustrating how the voltage is dropped one-tenth of a volt (100 millivolts), when 30 amperes are passed through the shunt. Only one-tenth (.1) of a volt, or 100 millivolts, or less, passes through the meter—**never** any more.

pass from generator to battery when the former is generating its maximum current output,[1] and about 10 amperes when it is generating its minimum output.

A 30-ampere shunt is then placed in series with the main charging circuit, as shown in Fig. 14A. We use the 30-ampere size because we know the maximum current is not over 30 amperes, or is less. If it was more, then a shunt with a greater capacity should be used.

The main circuit is then as follows: The (+) current starts at (+) of the generator brush, to a copper bar terminal (T), through the manganin, to the other copper bar terminal (T1), to the (+) terminal of the battery, through the batttery, to the (−) terminal of the battery, to the (−) brush of the generator.

Thus we have, say, 30 amperes flowing in the main circuit and through the shunt. Therefore, 30 amperes will flow through the manganin from the (+) brush of the generator, and will **not be reduced,** and thus 30 amperes reach the battery.

The ammeter circuit: The meter terminals (when used as an ammeter) are always connected from one terminal (M) of the shunt, which is the (+) side, where the connection of the copper bar makes contact with the manganin, thence to the (+) terminal of the meter, through the moving coil in the meter (Fig. 15), to the 100-millivolt terminal, or .1 terminal, of the meter, to the terminal (M1) on the shunt (Fig. 14A) which is the (−) or other end of the manganin.

We will now see what would cause the needle to deflect a full-scale deflection and show 30 amperes. The reading is made on the second scale, 0 to 30 (Fig. 15), because we are using a 30-ampere shunt.

In the preceding paragraphs, it was stated that if one-tenth (.1) of a volt, or 100 millivolts, passed through the meter coil, this would cause the coil to travel such a distance in the direction of rotation as to cause the needle to make a full-scale deflection. Therefore we must now pass .1 of a volt (or 100 millivolts) through the coil, which is the purpose of the shunt.

For instance: If the voltage was 8 volts from the generator, then 8 volts would start into the manganin at (M), but after passing through the manganin, the voltage would have **dropped 100 millivolts,** or one-tenth (.1) of a volt, or to 7 9/10 volts at (M1).

Therefore, as the meter terminals are connected with the manganin at each end (M) and (M1), this difference of one-tenth (.1) of a volt, which represents the millivolt drop, would pass through the coil of the meter, and the needle would have moved to the extreme right and would read 30 amperes on the scale (Fig. 15).

Thus the shunts used with this meter are designed for **a 100-millivolt drop,** and it is this voltage drop which is used to operate the meter. It will be clear, therefore, that if the meter was connected in series with the circuit without the shunt, the full voltage (8 volts) would pass through it and damage it.

We will now assume that the output of the generator is but 10 amperes, instead of 30 amperes.

If it required 30 amperes of current to pass through the shunt to cause a drop in voltage of 100 millivolts, or one-tenth (.1) of a volt, then if only 10 amperes passed through the shunt, the millivolt drop would be proportionately less. Therefore, as only one-third of the current is passing through the shunt, only one-third of the 100 millivolts would drop. Instead of the voltage dropping to 100 millivolts at (M1), it would drop only one-third as much, and only one-third of 100 millivolts would pass through the coil of the meter. Thus the coil of the meter would move but one-third of the distance, and as the needle moves with the coil, it would move but one-third the distance on the scale, or to the reading of 10 amperes, as calibrated on the scale.

The same rule applies to all the other shunts. If a 3-ampere shunt is used, only 3 amperes must pass through it, and consequently it contains a proportionally less amount of manganin. If full 3 amperes pass through the shunt, the result will be a voltage drop of 100 millivolts, or one-tenth (.1) of a volt. The same applies to the 300-ampere shunt, or to any shunt designed for this instrument.

The point to bear in mind is that one-tenth (.1) of a volt, which is 100 millivolts, is what is required to give a full deflection of the needle on the scale, and that a shunt must be used, which will give a drop of 100 millivolts if the full amperage for which it is designed, is passing through it, or that it will give a proportionally less drop, if less amperage than that for which it is designed is passing through it.

Thus the shunt, which is shunted between the two terminals (+) and .1 of the meter, when used as an ammeter, is for the purpose of giving this 100-millivolt, or one-tenth (.1) of a volt drop, or less, in proportion to the current passing through it.

Internal and external shunts: Where currents are small, as on a dash ammeter, the shunts are usually **internal,** or contained in the meter case. But for large currents or for testing instruments, **external** shunts are used, so as to keep the heat developed in the shunts outside of the meter as well as for convenience, as the shunt can be located in the circuit wherever it is easiest, and can be connected with the meter by a small cable, thus saving the running of heavy wires to the instrument.

Note. When testing amperes, use the testing cables which come with the instrument, from the meter to the shunt, as the cable is figured out for the exact length and size. From the shunt to the part being tested, use a wire of sufficient size to carry the load or amperes which will pass through it; for instance, if 30 amperes, use No. 10 or 8 wire.

Capacity of Shunt to Use with the Model 280 Instrument, and Range of Scale

Shunts to use with this instrument:[1] There are three external shunts figured on a 100-millivolt drop between terminals.

1. **A 300-ampere shunt** with which use the scale 0 to 300. Each division or mark on the scale represents 5 amperes (see Figs. 12 and 15).
2. **A 30-ampere shunt,** with which use the scale 0 to 30. Each division or mark represents 0.5 amperes.
3. **A 3-ampere shunt,** with which use the scale 0 to 3. Each division or mark represents 0.05 amperes.

When testing where you do not know what the amperage is likely to be, as when testing for short circuits, it is advisable to assume that the highest possible amperage is to pass through the meter. In such cases use the 300-ampere shunt. If the deflection obtained is less than 30 amperes, then use the 30-ampere shunt and scale, to gain a more accurate reading. Should the indication now be less than 3 amperes, use the 3-ampere shunt.

---

[1] A generator seldom delivers more than 20 or 22 amperes maximum. We have arbitrarily taken 30 amperes to illustrate our explanation of how the needle will make a full-scale deflection from 0 to 30 when a 30-ampere shunt is used and 30 amperes are passing through it.

[1] Other sizes can be obtained.

The 3-ampere shunt and range are convenient for measuring single lights and ignition.

The 30-ampere shunt and range are convenient to measure current delivered by a generator to the battery as shown at (A1), page 470; for measuring current required by the lights, horn, etc., and also for testing short circuits and open circuits.

The 300-ampere shunt and range are convenient for measuring the current required by the starting motor, as shown at (A2) page 470 and also for testing for short circuits.

Shunts Not Used with Instrument as a Voltmeter

When the instrument is used as a voltmeter, the same coil winding as shown in Fig. 15 is used, and it is necessary to have the same 100 millivolts or .1 volt drop, just the same as when it is used as an ammeter, but the shunts are not used to obtain this drop. Resistances (C), (B), and (A) are used (Fig. 15). This resistance is in series with the meter circuit and its connections to the main circuit being tested. Note, however, that the voltmeter connections are across the line of the main circuit.

The (+) terminal of the meter is always connected to the (+) side of the circuit being tested, and the terminal .1, 3, or 30 is connected to the other side of the circuit.

This instrument is designed for testing the voltage of a circuit, from 0 to .1 volt (100 millivolts); 0 to 3 volts; and 0 to 30 volts.

By means of a multiplier, used in conjunction with the 30-volt range, the range is extended to 150 volts. This multiplier can be obtained of the Weston Electrical Instrument Co., Newark, N.J. (or of A. L. Dyke, Electrical Dept., St. Louis, Mo.).

Millivolt Reading

When testing a circuit of 100 millivolts or less, the connections are made for the (+) side of the circuit, to the (+) terminal of the meter, through the moving coil, to the .1 (100-millivolt) terminal on the extreme left.

If 100 millivolts (1/10 volt) pass through the moving coil, then the needle will deflect from 0 to the extreme right.

If 50 millivolts pass through the meter coil, then the needle will deflect half-way of the scale, and so on.

The millivolt connections are used for testing the voltage drop in armature and field coils.

The scale 0 to 30 is used, and it will be noticed that this scale has 60 divisions. The scale, however, is not calibrated for millivolt readings. Therefore a **comparative test** is usually made when using it.

For example: If each armature coil is being tested for short or open circuits, the procedure would be to test an armature coil that is known to be in good condition, and then to note where the needle goes on the scale. Then test all of the other armature coils, which should compare with the good coil in the reading. There will, of course, probably be a slight variation in the readings of the different coils, owing to the fact that they may not all be exactly the same length, but the variation should be very slight.

If there is a noticeable difference, where the reading is greater than in the good coil, then the coil is probably open-circuited. If the reading is noticeably less, then there is probably a short circuit in the coil.

As previously stated, **the scale is not calibrated for readings in millivolts,** but if the needle moves from 0 to the right of the scale, then we know that 100 millivolts are passing through the meter coil. The scale has 60 divisions, therefore one division would equal one-sixteenth of one hundred, or 1 2/3 millivolt.

Purpose of resistance in the circuit when testing armature or field-coils: It will be observed by referring to the subject of: "Testing armature or field coils with a meter" (page 488), that resistance, termed a **resistor,** is used in series with the circuit.

If the millivolt connections of the meter were made to an armature coil in good condition, the drop would be very slight and difficult to read, unless a meter with a millivolt scale was used.

The object is to place enough resistance in the armature or field-coil circuit to cause a **voltage drop** sufficient to obtain a **millivolt drop** which will be easy to read. A good armature coil is then tested, and the needle is deflected to a certain distance on the scale. This reading is then taken as a **standard** to go by; then the tests of all the other coils should **compare** with it, as previously explained.

This resistance is variable, that is, more or less can be used, in order to obtain the deflection of the needle to a distance on the scale where it can most easily be read.

This resistor can be purchased of Ward-Leonard Electric Co., Bronxville, N.Y., at a cost of $5.00. It is designated as "Weston Special 6–10." (It can also be obtained of A. L. Dyke, Electrical Dept., St. Louis, Mo.)

Sometimes a lamp is used in series with a 6-volt battery for the same purpose.

Readings 0 to 3 Volts

When testing a circuit of 3 volts or less, the connection is made at the (+) of the meter with the (+) side of the circuit, then from terminal 3, to the (−) side of the circuit.

The lower scale 0 to 3 is used, and if 3 volts are passing through the circuit, then 100 millivolts, or .1 of a volt will pass through the meter coil, because the resistance (C) and (B) will reduce the 3 volts to one-tenth (.1) of a volt. Therefore the needle would make a full-scale deflection from 0 to 3.

If less than 3 volts is passing through the circuit being tested, then the voltage passing through the meter coil would be proportionately less.

Readings 0 to 30 Volts

When testing a circuit of 30 volts or less, the same connections are made as in the 3-volt test, except that the 30-volt terminal of the meter is used instead of the 3-volt terminal, and the scale 0 to 30 is used.

The resistance (C), (B), and (A) would be in the circuit, and it would therefore be reduced to .1 of a volt, which amount would pass through the meter coil; and this amount would be required to give a full-scale deflection of the needle from 0 to 30.

If less current than 30 volts is passing in the circuit, then a proportionately less voltage than .1 of a volt will pass through the meter coil.

Internal Connections of Model 280 Combination Volt-Ammeter

Note on Fig. 15: When button (PB) is pressed down, the circuit is from the (+) terminal of the meter, through the moving coil (K), to the terminal being used.

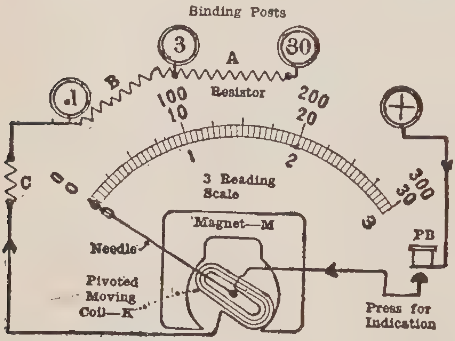

Fig. 15. Internal connections of the Weston model 280. The D'Arsonval or moving-coil principle.

Resistance (C) is the adjusting resistor for the 100-millivolt range; (C) and (B) are in series for the 3-volt range, and (C), (B), and (A) in series for the 30-volt range.

The scale is divided into three sections, and, unlike the dash ammeter, the 0 (zero) is placed at the extreme left, instead of being in the center. Therefore the needle and coil move to the right. It is well to mention that the scale of this instrument is carefully drawn and calibrated by hand. In order to do this and check the instrument with a master meter, three weeks' time is required. This instrument is guaranteed to be accurate within 1 per cent.

When connecting the meter, care must be taken to see that the connections are correctly made; that is, the (+) terminal of instrument should be connected with the (+) side of the circuit being tested, otherwise the needle will deflect to the left, indicating that the (+) terminal of the meter is connected with the (−) side of the circuit.

Cadmium scale: A scale for making cadmium tests of a storage battery, as explained in the storage battery instruction, has been added to the Weston model 280 instrument. This is not shown in the illustration (Fig. 15).

The scale in Fig. 15 has added to it four lines to the left of "0," the first line being one-half of one-tenth of a volt, or .05 of a volt, or 1/20 volt. The second line would be .1 (one-tenth) of a volt; the third line would be .15, or 3/20 volt, and the fourth line would be .2 or 1/5 volt. This scale is used for cadmium readings when testing a storage battery, and is explained in the storage battery instruction.

Principles of the Ammeter

Two principles are in general use: one is the "D'Arsonval type," which is termed a "moving-coil type," and which is the principle on which the Weston model 280 instrument is constructed.

The other type is the "polarized vane" type, which has a "stationary coil."

Moving-Coil Principle

D'Arsonval type: Refer to Fig. 15. Note the permanent magnet (M) which has a permanent N and S pole polarity. A fine, light spiral spring (not shown) serves to lead the current into and out of the moving coil (K), and also to keep the coil in its zero position and to provide a force against which the magnetic action of the current in the coil acts.

The electric current to be measured is passed through the moving coil (K) and magnetic lines-of-force are set up around the coil which becomes an electromagnet,[1] with the N pole at one end and the S pole at the other, depending upon the direction of flow. Therefore, as a N pole will atttract a S pole, or repel the N pole,[1] this principle is utilized. The coil endeavors to place itself in line with the **magnetic circuit** flowing from N to S from the permanent magnet. The coil is pivoted so that it can move, and the needle, being connected with the coil, moves with it.

The D'Arsonval, or moving-coil principle, is the type of ammeter and voltmeter in general use, especially for testing purposes, where close accuracy is required. This type of instrument is designed for only a fraction of a voltage to pass through it, and if a greater amount than a 50 per cent overload is passed, it will damage the instrument.

Stationary-Coil Principle

The polarized vane type of ammeter uses a fixed or "stationary coil." This type is more rugged and will withstand severe strains and shocks without damage, but it is not as accurate in its readings. This principle is often used for dash ammeters and indicators, **but not for testing purposes.**

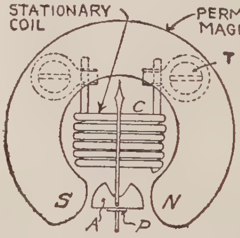

Fig. 16

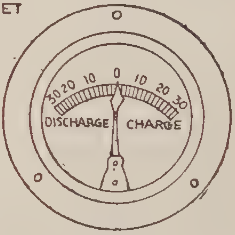

Fig. 17

The principle of its operation is shown in Figs. 16 and 17. A piece of soft iron, rigidly attached to a steel pivot placed equally distant from the poles of a permanent magnet, is attracted or repelled by the passing of an electric current in one direction through the coil of wire (C) fixed or stationary in the plane of the iron. The magnet, being of the permanent-magnet type, holds the piece of iron (called the armature) exactly in position, so that the pointer attached to the pivot is held at zero.

As current is admitted to the coil, it becomes an electromagnet, the N pole being at one end and S pole at the other, dependent on the direction of flow.

When the end nearer the armature is North, it repels the North end of the armature and attracts the South end, with the result that the needle moves across the scale.

As a result of the manner of the construction of this instrument it is capable of withstanding the current from the battery to the starting motor without damage, as the coil (C) is of very heavy construction.

Dash Ammeter

The dash ammeter of the moving-coil type (for direct current) is similar in principle to that shown in Fig. 15, except that it has internal shunts and its dial is calibrated to read in two directions. That is, the zero (0) is placed in the center of the dial, as shown in Fig. 18.

---

[1] Why the N pole attracts the S pole and repels the N pole is explained on page 179. See also, page 183, explaining how a coil becomes an electromagnet with a N and S pole polarity.

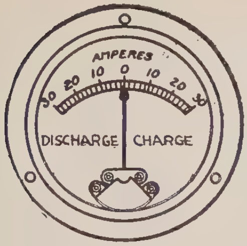

Fig. 18

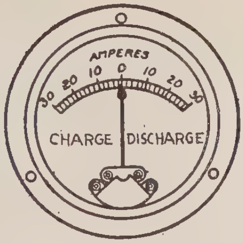

Fig. 18A

If the moving-coil type of instrument is used on a circuit of more than 30 amperes, it will be damaged. The starting-motor current is never taken through a dash ammeter of this type. The generator charging current is carried through it and as the generator seldom delivers over 22 amperes, the 30-ampere range is sufficient.

Meaning of Zero Center

Note that the "0" is in the center, and when no current is flowing the needle will remain at 0 or zero. The needle can read up to 30 amperes on the "charge" side, to the right, or to 30 amperes on the "discharge" side, to the left, and is termed a "30-0-30" scale.

If the generator is running at sufficient speed to charge the battery, the cut-out points will close and connect the generator with the battery and charge the battery. Then the needle will move to the right or "charge" side of 0—if correctly connected.

If the engine slows down, and the cut-out points open, then the battery is disconnected from the generator, and as ignition is being consumed from the battery the needle will move slightly to the left of 0, or "discharge" side of zero—as the battery would be discharging instead of taking a charge. If lights were on, then the needle would go farther on the discharge side, as more current will be discharging from the battery.

This shows that the needle moves in one direction when current is flowing from the positive connection (+) of the generator to (+) of the meter, to (+) of the battery. But the needle operates in an **opposite direction,** when current is flowing **back from the battery** to the meter, as connection is with the negative side (−) of the meter in this instance. This is the reason for zero (0) being in the center on the dash ammeter.

Note. The instrument just described, as is the case also with the other instruments illustrated in these instructions, shows the "charge" side on the right of "0" and the "discharge" side on the left of "0."

The **standard** now adopted by manufacturers of dash ammeters is to have the "charge" side on the left and the "discharge" side on the right of "0" (see Fig. 18A). There are many instruments which came into use before this recent standard was adopted, which read as shown in the illustration (Fig. 18). This makes no particular difference, however.

An Indicator

A battery indicator (Fig. 19) **is used for the same purpose as a dash ammeter,** that is, to show when the battery is being "charged" by the generator and when it is being "discharged." Instead of showing the rate of charge or discharge, it merely indicates what is taking place, by the movement of a cylinder inside of the instrument bearing the wordings, "off," "charge," and "discharge," which appear at an opening in the dial of the instrument.

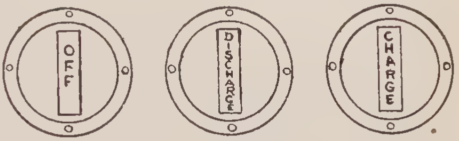

Fig. 19. Battery indicator showing its three indications.

This instrument will operate on as low as 2 amperes and, unlike the dash ammeter of the moving-coil type, it is capable of withstanding any voltage or amperage without damage.

This type of instrument **can be placed in series with even the starting-motor circuit** without injury, and will show "discharge" when current is flowing to the starting motor from the battery.

This type of instrument is used on the Franklin (see footnote bottom of page 424), and is placed in the motor circuit as shown in this diagram. The same type was also formerly used on the Dodge.

This type of **indicator** is termed the "polarized vane" type, with a "stationary coil" (of a principle similar to that shown in Fig. 16).

The Roller Smith Co., Woolworth Bldg., New York, manufactures a dash-type ammeter of the polarized vane type which can be placed in the starting-motor circuit. The same concern also manufactures instruments of the moving-coil type. Another concern manufacturing the moving coil or rotary type, as well as stationary-coil type instruments, is the Hoyt Co., the instruments being sold by Burton-Rogers, Boston, Mass.

HOW THE VOLTMETER AND AMMETER ARE USED FOR TESTING THE ELECTRIC SYSTEM OF A CAR; EXTERNAL TESTS

As an example we shall use the Weston, model 280 combination volt-ammeter. The **tests** shown in Fig. 20, **can usually be made on the car** without removing any of the parts. Internal tests of the different parts, or "bench tests," will be treated farther on.

The idea of this combination electric system is to show where and how a voltmeter and amperemeter can be used on the average electric system for testing circuits on the car. It is understood that the battery is a 6-volt, 3-cell battery, and also that the only instrument which is a regular equipment of the electric system in this example is the "dash ammeter." The other instruments (V1), (V2), (V3), (A1), (A2), are **testing instruments,** the use of which will be explained.

Voltmeter Tests

The voltmeter is always placed **across** the line, and shows the voltage or pressure of a circuit. The instrument used is the Weston, described on page 464 (Fig. 12), which read carefully.

Test V1: To test voltage of generator: Use the "0 to 30 connections" and "0 to 30 scale" of instrument. Place the test points (TP) on the connections leading from the two main brushes. The brush to the left leading to the shunt fields is the third brush and is a part of the shunt-field circuit, or the source of the shunt-field current supply. This test does not include the field circuit, but is for the voltage of the "charging circuit." The maximum voltage of the generator from its "main brushes" will be indicated when the generator is operating at from 7 to 10

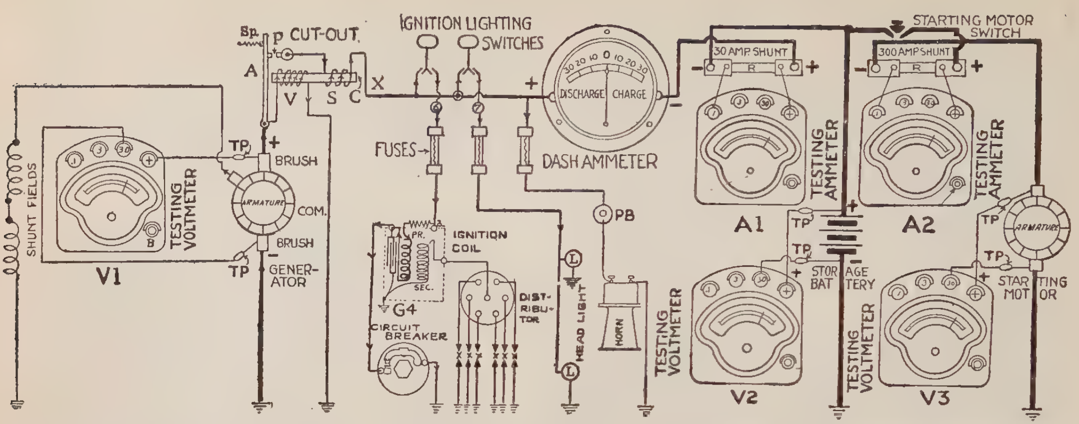

Fig. 20. The dash ammeter is so connected that it shows all current which would "discharge" from the battery, except starting-motor current. All current passing from the battery to the ignition or lighting circuit must first pass through the ammeter, which will show "discharge" on the left of zero in this example. Current passing from the generator to the battery will be indicated on the "charge" or right side of zero. The ignition circuit and light circuit will reduce the amount of charge going to the battery.

The testing meters (V1), (V2), (A1), (A2), and (A3), are not connected permanently in the circuits, but are intended to show how various tests can be made as explained in the text, and only one test is made at a time.

m.p.h. car speed, and the cut-out points (P) should be closed. The voltage of the generator should be slightly more than that of the battery, otherwise the generator will not have pressure enough to overcome the battery voltage. The battery voltage can be tested as shown at (V2).

If the generator voltage is found to be less than the battery voltage, then the cut-out points (P) will probably not close, because the purpose of the fine wire voltage winding (V) of the cut-out is to magnetize the core (C), thus drawing (A) to it and causing the points (P) to close. This winding is so wound that it does not exert sufficient magnetizing effect to draw the points (P) so that they are closed, until the generator voltage is slightly more than the battery voltage.

If the generator voltage is lower than the battery voltage, then the first place to examine is the "third brush" to see if it is seating properly. If it is seating only enough to make slight contact, or if a new third brush has been fitted without properly seating it to the curvature of the armature, the field strength cannot build up sufficiently to assist the armature in building up its full voltage.

The proper seating of the "main brushes" is also important. The commutator may have the mica protruding, or dirty, or the commutator may be rough, or the armature or field windings may be grounded.

If there is no indication of voltage at all, at the generator, then loose connections or open circuits exist, either at the brush-holders, the brushes, or the field-windings.

It is seldom that there will be no indication of current at all, if one armature coil is open, because, they are connected in parallel, and while one armature coil may be open, some indication would come from the other coils. Tests for internal troubles of the generator will be shown farther on.

If the generator voltage is above that of the 6-volt battery, and cut-out points (P) fail to close, then the cut-out spring tension may be too strong, or the cut-out voltage winding may be open-circuited or grounded, or there may be loose connections.

If the cut-out armature (A) makes a feeble effort to close, but does not close tight, when the generator voltage is 6+, then it indicates that the spring tension is too strong, or that there is a ground, or a partial short circuit in the windings.

If the generator voltage is over 6 volts and the cut-out armature (A) makes no attempt to close at all, then the cut-out windings should be tested, providing the spring tension is not too great.

Sometimes the cut-out points (P) fail to open when the engine slows down or stops. This is caused by the points burning together, and thus the battery will discharge back through the generator, but the "discharge" would show on the "discharge" side of the dash ammeter when all switches are "off."

Tests of the cut-out windings are explained farther on.

Test V2: To test voltage of battery when discharging with lights on only, use the 0 to 30-volt connections and scale. The voltage, if charged for a 3-cell battery, will be 6 to 6.3 volts, or 2 to 2.1 per cell. **If discharged,** it will be 5.4 volts, or 1.7 volts per cell.

If tested when the starter is on, a charged battery will drop to 5.4, or 1.7 volts per cell, but will regain its normal voltage after a short while. If it drops to 5 volts or less, or 1.6 volts per cell, it is discharged; or, if fully charged, and it drops as low as this, then the plates are sulphated or an internal short circuit exists. See also the instruction on storage battery.

On testing the voltage of the generator (V1), and the voltage of the battery (V2), when the generator is charging the battery, if any difference is found, or a drop in voltage occurs, it will be the difference between the two readings.

Test V3: To test the voltage which reaches the starting motor from the battery, to see how much drop there is in voltage at the starting motor when operating, close the starter switch for an instant. There will be some drop. If the engine is cold and stiff, it will cause the motor to draw more current. The more current that is drawn, the greater the drop.

If the starting motor should fail to start when the starting switch is depressed, then test to see if there is an open circuit in the armature of the motor, or in the brushes or the brush-holders. This test will determine if the current is reaching the motor.

If there is **an open circuit in the armature,** then the meter would indicate the voltage of the battery, because the top test-point would connect with the (+) of the battery, and the lower (TP) would connect with (−) of the battery. The armature being open, there would be a break at this point.

If the field-circuit is open, there would be no indication at all, because the field is in series with the brushes of the armature.

When a battery is supplying current to a motor and the amperage draw is heavy, there is a drop in voltage at the motor and also at the battery itself, which delivers the current.

Ammeter Tests

Ampere tests are to ascertain the quantity of current flowing. A "shunt" must be used (see page 465). Connect the shunt in the circuit as shown at tests (A1) and (A2), being sure that the positive (+) wire of the circuit is connected to the (+) connection of the meter, and the negative (−) wire of the circuit to .1 binding post of the meter.

Should the charging rate appear to be abnormally low with no apparent reason, it is a good plan to check the ammeter by connecting the test meter (A1) in series with it.

Reliable meters may become defective, as automobile service is extremely hard on a sensitive ammeter.

Test A1: To test the accuracy of the dash ammeter, use the 30-ampere shunt and connect as shown. Speed the engine up and note if the reading is the same on the dash ammeter as on the testing instrument.

A rough check on the accuracy of the ammeter may be obtained by noting the ampere readings of the various lights on the car, and then switching them on one at a time. The reading of the ammeter should correspond to the total amperage required for the lights.

With the engine running and the lamps on, the ammeter may register either "discharge" or "charge," depending on the speed of the engine, the capacity of the generator with respect to the lamps, and the condition of the battery, that is, whether it is charged or not.

Unsteady reading of the ammeter may be due to a defect in the instrument, or to loose contact, or to intermittent ground.

Tapping the ammeter should jar the hand loose if it is only stuck. If it still refuses to register, examine the connections, and if these are all right, look at the cut-out points and see if they are closed. Finally, disconnect one of the main wires from the generator terminal to see whether any current is flowing from the generator, and follow the wires thence to the ammeter, examining them at each terminal to see whether current is flowing, by touching the disconnected wire to its terminal.

Test A1: To test cut-out: Use 0 to 30 shunt and scale. At a car speed of 7 to 10 miles per hour, cut-out points (P) should close, and at 15 or 20 miles car speed, the generator should be charging the battery at 10 to 20 amperes, if lights are off (this varies on different systems). If it shows less than 9 or 10 amperes, the "regulator" or "third brush" should be regulated to bring the current up to at least 10 amperes, 15 amperes being the average.

Throttle the engine slowly, and note that the needle will drop back towards zero. When it reaches zero, note whether cut-out points (P) open, and at what car speed.

Test A2: To test the amperage required by the starting motor: Use the 300-ampere shunt and connect as shown. Test with engine idle. It is assumed that the battery shows 1,275 to 1,300 hydrometer test, and is supposed to be charged.

The average starting motor requires 150 to 200 amperes, if the engine is warm and flexible, or 250 to 300 amperes, or even more, if cold and stiff. If the engine is flexible and an excessive current discharge is shown, then there may be a short circuit in the motor or brush-holders, or possibly the starter mechanism is out of order.

Note. The actual amount of current required by a starting motor varies according to the temperature, condition and size and compression of the engine. If it is extremely cold, the oil is congealed and all parts are stiff; thus a great deal more current is required than when the engine is warm and flexible.

If an engine has been standing for a long time, or out of use, it is likely that the motor will require more current than if in daily use.

HOW THE DASH AMMETER INDICATES TROUBLES

In this instance we refer to the ammeter as usually attached to the dash (cowl) of a car.

The dash ammeter indicates when the generator "charges" the battery, and at what rate. It indicates the rate of "discharge" from the battery to the lamps. It also indicates whether or not the system is working properly. When the battery is neither "charging" nor "discharging," the pointer should indicate "0."

Ammeter troubles may be divided into two classes: those that manifest themselves when the engine is **idle** and those that show only when it is **running.** Both classes have two subdivisions, with **lamps on** and with **lamps off.**

Remember that **the ammeter should show "charge" at speeds above 8 or 10 miles per hour;** and that when the engine is at rest with lights turned off, the needle should stand at "zero," and should not show "discharge."

It shows "discharge" when lights are on and the engine is idle, or at a speed of less than 8 miles per hour. In other words, the battery is then discharging, and is not being charged.

With these points always in mind, it is possible to diagnose many troubles by noting the action of the ammeter, for if it varies from its intended purpose, or its usual action, something is wrong.

When the generator is not charging the battery, and if the battery is being used for lights, ignition, or horn, the needle will be on the "discharge" side of (0) and the amount of current being consumed will be shown in figures on the dial.

When the car is running 10 or 12 miles or more per hour, the ammeter should indicate "charge."

If on connecting an ammeter to the circuit, the needle should go to the "discharge" side, when the engine is running at sufficient speed for the generator to charge the battery, then it indicates that the terminals have been wrongly connected. Reverse the connections.

If the battery is wrongly connected, when the generator is running the ammeter will read in the opposite direction, or the cut-out points will vibrate back and forth, opening and closing the points and causing the needle to swing back and forth as it opens and closes.

On most of the third-brush regulated generators now in use, the cut-out would soon close, however, as the polarity of the generator would adapt itself to the battery polarity. In such case the needle of the ammeter would be steady, but it would read in an opposite direction to its former reading.

If the ammeter indicates zero when the generator should be charging the battery, it shows that the circuit is open, or that the generator is at fault.

If the ammeter does not indicate "charge" when the engine speeds up, but indicates "discharge" when the lights are turned on, then the generator is not delivering its proper output. Look to the "third-brush" or other regulation system, and see if it is properly adjusted; also see if the brushes seat properly; or there may be a short circuit in the lighting wiring.

If the needle is forced to the scale limit on the "discharge" side, it indicates an overload or a short circuit.

When the engine is running and lamps are burning and the ammeter hand stands at zero, it indicates that the generator is producing exactly the same amount of current that the lamps are consuming. Thus the battery is "floating on the line" and is not receiving a charge, nor is it discharging.

If the ammeter shows excessive "discharge" at low speeds, or when the engine is idle, this is caused by the cut-out contacts being held closed or "stuck." Thus current is flowing from the battery through the generator. This must be corrected at once by disconnecting the points. If the light switch is "on," then a ground or short may be in this circuit.

The ammeter will always indicate if a short circuit exists in any part of the wiring, except from the battery to the switch bus bar, and in the starting-motor circuit.

If the ammeter does not indicate "charge" with the engine speeded up, and does not indicate "discharge" with the lights on, and the engine at rest, there is an open or loose connection in the battery circuit; or the battery terminals may be loose; or the generator terminals are loose; or the ammeter may be at fault.

If the ammeter indicates "discharge" with the lights turned off, and the engine at rest, the ammeter pointer may be bent; insulation on the wires may be injured, permitting contact with frame, causing ground or short circuit, or the cut-out points may be stuck.

If the trouble seems to be in the ammeter, it is well to place a test ammeter in circuit, to check the first instrument. If the instrument registers incorrectly it should be returned to its makers for repair.

If the ammeter indicates "charge," with the engine at rest, the ammeter pointer may be bent.

When the ammeter "charge" indications are below normal, the generator output varies with the condition of the battery on some generators. This may also be due to the regulation of the generator not being properly adjusted. For instance, the third brush may need resetting, or the brushes may not be making good contact, or the commutator may be dirty or rough, or may have high mica.

When the ammeter "discharge" indications are above normal, the lamp load may be excessive or the lamps may be old; wires may be grounded or shorted.

If the ammeter pointer jerks intermittently to "discharge," limit of scale while engine is speeding up, there is a short circuit or a ground in the system or in the field-windings.

If fuses blow out repeatedly, look for a heavy ground, or the fuse may be too small for the current required, or a short circuit may exist in the system.

If larger bulbs than standard or extra lamps are used, "discharge" indications will be higher. The generator may not be capable of charging the battery sufficiently to overcome the excess load, especially if there is insufficient day driving or excessive use of lamps at night, thereby permitting the battery to discharge more rapidly. Therefore, before adding more lights or appliances to the electric system, the amount of charge that the battery receives should be considered, especially during cold weather, when the starting motor is used more and the drain on the battery is greater. If the battery receives less than 10 to 15 amperes on an average, it will be necessary to have it charged at an outside source occasionally.

INSTRUCTION No. 43

TOOLS AND EQUIPMENT FOR THE AUTOMOTIVE ELECTRICAL REPAIR SHOP:[1] When to Test on the Car and on the Bench

TOOLS FOR ELECTRICAL WORK

This subject is a broad one. The amount of repair work to be done would determine the equipment in each case. Therefore only a few of the really necessary tools are mentioned here.

Pliers: An assortment of about 5″ long-nose, short-nose, and cutting pliers.

Screwdrivers: An assortment of about five or six, from very small ones to larger ones.

Chisels: Two or three sizes, and also a center punch for locking and unlocking pole screws in generator frames.

Files: One very fine jeweler's file for contact points, and a mill file and round for cleaning wires and battery terminals.

Thickness gauge to adjust contact-breaker points, cut-out, regular points, and spark plugs.

Flat wrenches: Various sizes; these can usually be purchased in sets or with tool kits.

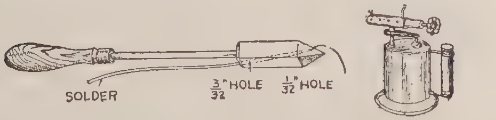

Fig. 2. Illustration at left shows a simple and handy method for soldering. The wire solder is inserted in a hole drilled in the soldering copper. A blowpipe torch is shown on the right.

Soldering irons: Three sizes, a pair each of ½ lb., 1 lb., and 2 lbs., for soldering coil terminals, wire connections in field coils, commutator wires, armature wires, terminals, cut-out and regulator points, etc.

Soldering flux for electrical work. Wire solder with flux inside is used extensively.

Blow-pipe torch: Very essential.

Tape: For taping inside of generators, etc. Where there is excessive heat, a tape called "English superfine twilled tape" is used. It is then coated with shellac and the alcohol is burned off by lighting with a match. **Friction tape** is the kind generally used for outside wire connections.

Shellac is used for armature work, connections, etc. See Index, "Shellac, how to mix and keep."

Note. When grounding a wire to the frame or to the engine, clean off all paint. Scrape thoroughly. After making the connection, coat with vaseline to keep the connection from corroding or rusting.

When soldering a wire into a lead terminal, such as a heavy storage battery connection, clean well. Add flux, and then melt the solder in the terminal by means of a torch. When hot, insert the wire and let cool; this is termed "sweating."

Fig. 3. This hook, 4″ long, is used for pulling brush springs.

Fig. 4. Socket wrench for brush mechanism and coil nuts.

A brush lifter for lifting brush springs on generators and motors is shown in Fig. 3.

A socket wrench suitable for the nuts on brush-holders, coils, etc., is shown in Fig. 4. Several sizes can be made.

A fine-pointed scratch awl to dig out copper dust and material that will short-circuit between commutator segments is another necessary tool. A tool made on the order of that in Fig. 3 would be suitable for this work.

Tools for undercutting mica are explained farther on.

Fig. 5

Fig. 7

Fig. 6

Fig. 8

Pole-piece double gauge: It often happens that it is necessary to put new field-coils in the generator or motor, owing to the fact that they become shorted or grounded. In order to do this, it is necessary that the polar diameter be exactly right—that is, the distance between the faces of the pole-pieces. This distance is measured with a pole-piece double gauge (Fig. 5); one end of the gauge being a "Go" indicator, and the other end a "No Go" indicator.

Pole-piece spreader: If the gauge does not slip into the polar diameter on one end and fails to go on the other, the dimension is wrong, Generally it is too small, and the pole-piece must be spread farther apart and the tool (Fig. 6, pole-piece spreader) is used for this work. There is no possible way for spreading the pole-pieces so as to get the proper clearance between the armature and the poles without this tool. In other words, the object of these tools is, first, to spread the pole-pieces and frame to give the right air gap between the armature and pole-pieces with tool No. 6, and then to measure these dimensions with No. 5, after the work has been done, to see that it is right and, if not, to correct it.

---

[1] This subject does not include storage-battery equipment. This is fully treated under instruction on Storage Batteries.

A pinion puller, used for pulling the generator-drive pinions off the armature shaft (Ford), is shown in Fig. 7[1].

A bearing puller, used for pulling ball bearings off the armature shaft, is shown in Fig. 8.

Lathe for Electrical Repair Work[2]

A lathe suitable for turning down armature commutators, and for making motor repairs and electrical work in general, suitable also for cutting screws and other small work, such as tools, gauges, taps, etc., and for making battery and ignition parts, is shown in the illustration below.

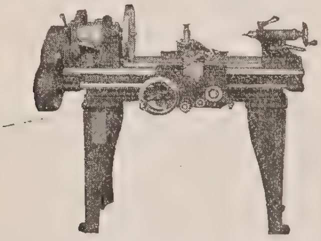

Fig. 9. This lathe has an 11″ swing, with 1¼″ swing over the bed, and is made in 3, 4, and 5-foot beds. It can also be supplied with milling attachments, and keyway cutting attachments.

Bench Lathe for Commutator Work[1]

The illustration below is that of the Onan Lathe, which can be placed on a work bench and operated from a line shaft.

With this lathe it is possible to true up and turn the commutator of any starter or generator armature. Without removing the armature from the lathe, it is possible to undercut the mica between the bars.

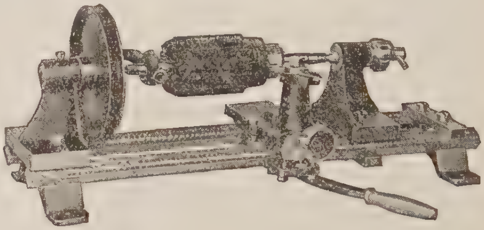

Fig. 10. The turning tool is controlled by a hand-wheel screw feed—the carriage is operated lengthwise by a drop-forged handle with suitable adjustment for every commutator. The lathe is built with 7″ swing; bed 22″ long; furnished with two Armstrong high-speed tool bits, lathe dog, suitable wrenches, etc., and is complete, ready for operating. It is driven from any available power. Shipping weight complete, 35 lbs.

The subjects of **commutator troubles, tests, and repairs,** and also **brush troubles** (fitting and seating brushes, etc.) are treated on pages 491 to 496.

INSTRUCTIONS FOR CLEANING REPAIR PARTS OF ELECTRICAL APPARATUS

The cleaning outfit should consist of three sheet-steel tanks of suitable size (preferably about 35 gallons), which are mounted in such a manner that the contents may be kept heated to the desired temperature; three stone jars of approximately 15 gallons capacity; and a sawdust box.

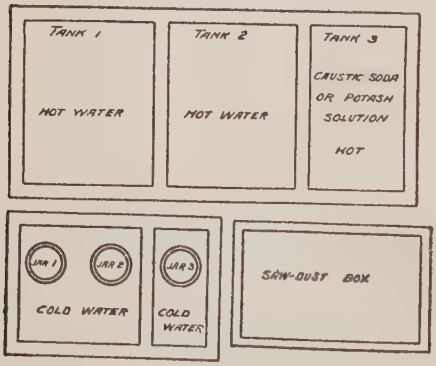

Fig. 11. Plan of arrangement of tanks and jars for cleaning.

Two of the steel tanks should be equipped with overflow pipes so that they can be kept about two-thirds full at all times. These will be spoken of as tank No. 1 and tank No. 2. They are used for clear, hot water for rinsing the apparatus after it has been cleaned. A supply of water should be available, so that this water can be kept as clear as possible.

The third tank does not need either a drain or overflow pipe, and should be used for the potash or caustic soda solution. This solution can be used for a long time without changing it by simply adding a small amount of potash or soda as the solution is found to be weakened. All three tanks are maintained at a temperature of from 180° to 212° Fahrenheit, or approximately at boiling point.

The three jars mentioned above are to be used for the acid solutions, and will be spoken of as jar No. 1, jar No. 2, and jar No. 3, respectively.

A wooden tank should be provided which is large enough to permit the three jars to be set in it, and also to carry a supply of clear, cold water. This tank should also be divided so that jars No. 1 and No. 2 are in one division, and jar No. 3 in the other. This is very important, as the work cannot be rinsed in the same cold-water bath after being immersed in these various solutions. The sketch shown in the figure will give an idea of the outfit.

Cleaning Solutions

The solutions recommended are as follows:

In tanks Nos. 1 and 2, place clear, hot water.

In tank No. 3, place a solution of potash or caustic soda, made by mixing 1 lb. of potash or caustic soda with one gallon of water.

Jar No. 1 is filled with a solution made up carefully from the following formula: four gallons of nitric acid; one gallon water; six gallons sulphuric acid. The water is placed in the jar first, the nitric acid is added slowly, and the sulphuric acid is poured in last. This order should be very strictly observed, as it is dangerous to attempt to mix up a solution of these acids in any other manner.

---

[1] Can be secured for Ford work from Service Station Equipment Co., Chicago, Ill.

[2] Illustration is that of a new 11″ screw cutting lathe, especially adapted for electrical repair shops, manufactured by The South Bend Lathe Works, South Bend, Ind.

[1] Can be secured of A. L. Dyke, Electrical Department, Granite Bldg., St. Louis, Mo.

The solution in jar No. 2 is made up from the following formula: one gallon hydrochloric acid to three gallons of water.

Jar No. 3 is filled with the following solution: ½ lb. of cyanide to one gallon of water.

Tank No. 2 should be used for parts which have been in the potash solution, and for no other purpose; tank No. 1 is for general rinsing.

Cleaning Various Metals

Steel is boiled in the potash solution until the dirt is removed. This should take only a few minutes. It is then rinsed in tank No. 2, and dried in sawdust.

Cast iron is boiled in the potash solution until the dirt is removed, rinsed in tank No. 2, dipped in the acid solution in jar No. 2, rinsed in cold water, then rinsed in tank No. 1, and dried in sawdust.

Brass is boiled in the potash solution until the dirt is removed, rinsed in tank No. 2, dipped in the acid solution in jar No. 1, rinsed thoroughly in clear, cold water, dipped in the cyanide solution, rinsed in clear, cold water, rinsed in tank No. 1, dried in sawdust. **Copper** can be cleaned in the same manner.

Polished aluminum should first be thoroughly washed in benzine or gasoline, rinsed in tank No. 1, dipped in the acid solution in jar No. 1, rinsed thoroughly in clear, cold water, rinsed in tank No. 1, and dried in sawdust.

Plain aluminum (**polished**) should be dipped in the potash solution, rinsed in tank No. 2, dipped in jar No. 1, rinsed thoroughly in clear, cold water, rinsed in tank No. 1, and dried in sawdust.

Plain aluminum (**not polished**) should be dipped in the potash solution, rinsed in tank No. 2, dipped for a few seconds in the acid solution, rinsed in tank No. 2, dipped for a few seconds in the acid solution in jar No. 1, rinsed thoroughly in clear, cold water, rinsed in tank No. 1, and dried in sawdust.

It will be noticed that when the aluminum is put in the potash solution the metal is attacked or eaten away very rapidly. Care should therefore be taken not to leave the work in this solution any longer than is absolutely necessary. In cases where the work is covered with caked grease or has hard grease deposits on it, these pieces should first be washed in benzine or gasoline. Aluminum parts should never be washed in the potash or soda solution unless they can be put through the acid immediately after. The acid dip is used to neutralize the effects of the potash solution. Parts should be held in the acid solution for only a few seconds.

Paint on aluminum should be removed with a good varnish or paint remover, unless it is a very small quantity and the work is to go through the potash solution.

For enameled work, it is recommended that it be washed with soap and water, dried thoroughly, and then polished with a cloth dampened with Three-in-One or O'Cedar oil.

The methods described above are for solid metals only, and should not be used on any plated materials. Practically all Delco clips are tinned, and should be cleaned, therefore, in benzine or gasoline. All plated parts should be cleaned in benzine or gasoline.

A HOME-MADE ELECTRICAL TEST STAND

Tests for the internal parts of a generator, motor, cut-out, etc., will be explained in what follows. These tests might be termed "bench tests," and are usually for internal troubles. They are such tests as are necessary when the troubles are such that they cannot be remedied on the car, such as testing armatures, field windings, etc. Therefore some sort of testing apparatus is necessary in such cases.

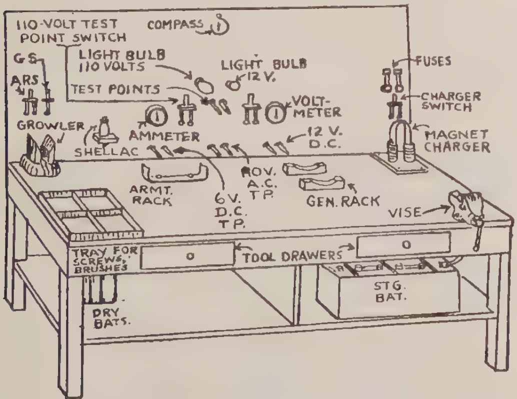

Fig. 12. Electrical test bench.

The bench (Fig. 12) can be made about 36″ high and about 5′ or 6′ long, with a lower shelf about 6″ or 7″ from the floor.

A vise, with jaws opening to about 8″, can be used to hold the generator when being driven by a motor. The vise is also handy for other work.

Note that the test leads, or cables, are of flexible wire and run through pulleys with weights (Fig. 12A), similar to pulleys and weights on a telephone switchboard, thus keeping the wires off the bench.

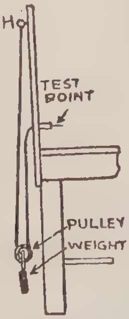

Fig. 12A

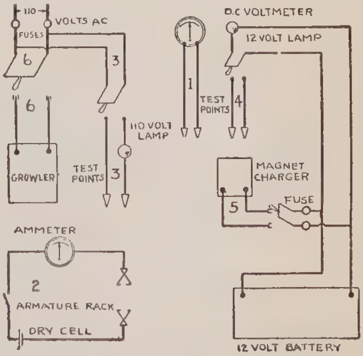

Fig. 12B

Necessary Parts and Wiring Circuits

Volt and ammeter: Model 280 Weston, combination volt and ammeter, as described on page 464, is recommended. This instrument is also fitted with a scale for cadmium tests of storage batteries (explained under the instruction on Storage Batteries).

If this represents too great an outlay of cash, then Model 301 Weston voltmeter and Model 301 Weston ammeter are recommended. These instruments are suitable for readings up to 30 amperes or 30 volts. See Index under "Weston voltmeters and ammeters."[1]

---

[1] These instruments can be furnished by A. L. Dyke, Electrical Dept., St. Louis, Mo.

The wiring of the different circuits is shown in Fig. 12B, as follows:

(1) **Voltmeter** (Model 301 Weston) with test points.

(2) **Armature rack** for testing for open and short circuits in armature. Dry cells can be used. Note that the ammeter (Model 301 Weston) is in series with the circuit.

(3) **Test-light and points** (high voltage) for use with 110-volt circuit through a double pole switch. For testing for short and open circuits. The 110-volt lamp is in series. A tungsten carbon filament lamp of about 15 watts can be used.

(4) **Battery test-light and points** (low voltage) are connected with a storage battery. Note that in (4) a low-candle-power lamp is in series, the voltage being same as battery (6 or 12 volts).

(5) **Remagnetizer** for remagnetizing magnets. Connected with the battery by a double-pole switch and with fuses in the circuit.

(6) **Growler** connected with a 110-volt alternating-current line for testing armatures for open and short circuits (explained farther on).

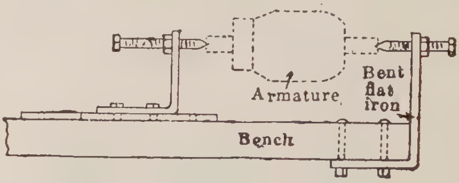

Fig. 13. Adjustable armature rack.

A method of making an adjustable armature rack is shown in Fig 13. This can be substituted for the one shown in Fig 12, as it is more serviceable, being adjustable.

NORTH EAST TEST-BOARD

The test-board shown in Fig 14 below, is that put out by the North East Electric Co., and supplied to their service stations for testing the N.E. motor-generators and ignition units. It is shown in order to give the reader an idea of its construction. In order clearly to understand it, first read the description of N.E. electric system installed on the Dodge.

TYPE 8901-B, 8901-C OR 8901-D TEST BENCH

Fig. 14. Test-board.

With this test-board it is possible to operate the motor-generator and all its parts as if connected on the car. It will, of course, be necessary to drive the motor-generator by some means, when used as a generator. The different circuits are as follows:

Starting-motor circuit: From (+) of the battery, to and through switch (C), through heavy black wires to switch (A), to terminal of board (+2), to and through the motor, to (−3), to (−) of battery.

Note that the voltmeter is connected across this circuit at switch (A) (on the left), and by the small wire at (−3) terminal. The ammeter is not in the circuit, as it is open at the cut-out points of the cut-out (upper left corner).

Cut-out voltage circuit: Start from the motor-generator, which we will assume is being driven as a generator. Start at (+2) terminal of the board, which connects with the (+) main brush of the generator, to voltmeter (switch **A** is open), above the voltmeter to the cut-out, then through the fine wire voltage winding (small dotted lines), through the smaller or lighter wire to the voltmeter, to terminal (−3) of the board, to (−) main brush of the generator.

Note that the voltmeter is connected directly across this circuit and will indicate at what voltage and speed of the generator the cut-out points will close the charging circuit.

Generator charging circuit: We will assume the cut-out points closed at a certain speed of the generator when a certain voltage was reached (see page 370, giving these details of the N.E. Dodge motor-generator and cut-out). The charging circuit would then be from (+2), to the voltmeter, above the voltmeter to the cut-out, through the closed points of the cut-out, through the cut-out series winding, to the fuse, through the ammeter, through switch (C) (switch **A** is open), to the (+) terminal of the board, to the (+) terminal of the battery, out the (−) terminal of the battery, to the (−) terminal of the board, to the (−) terminal of the generator.

Note that the voltmeter is across the circuit, and the ammeter is in series with the circuit. Thus the voltage and amperage generated at various speeds of the generator can be observed. For instance, at maximum speed, the generator should show a certain amperage and voltage and the third-brush regulation can be set accordingly.

At a certain low speed the cut-out points should open at a certain voltage when a certain amperage discharges back through the series winding of the cut-out (see page 370 for these data). All of this can be observed with the voltmeter and ammeter connected with the circuits.

The device on the left of Fig. 14 is for testing the ignition. See also, pages 228, 226, 371, 230.

HOME-MADE METHODS OF DRIVING A GENERATOR FOR TESTING

Various methods are used for driving a generator so cut-out and output of the generator can be tested.

We suggest two simplified methods, as follows:

1. By using a ½ h.p. electric motor,[1] (Fig. 15), with a speed of about 1,800 r.p.m.

Cone pulleys can be placed on the motor (Fig. 15), to drive the generator, on which there are two sizes of cone pulleys. The cone pulley on the motor, of which there are five sizes, and also the one on the generator, of two sizes, can be made in one piece of hard maple or metal, by turning them up on a lathe. A ½″ round belt is used to transmit the power.

Sizes of motor pulleys: 2″, 3″, 4¾″, 6″ and 8″.

Sizes of generator pulleys: 6″ and 8″.

---

[1] A ½ h.p., 110-volt, direct-current motor is priced at $65.00 and can be obtained of A. L. Dyke, St. Louis. The cone pulleys we do not furnish. The General Electric Co., Ft. Wayne, Ind., manufactures a type "RSA," ½ h.p. motor suitable for alternating current, and a type "SD" for direct current.

The variations of speed of the generator which can be obtained with the pulleys of the sizes as figured out are as follows:

8″ motor pulley to 6″ gen. = 2,400 r.p.m.
6″ motor pulley to 6″ gen. = 1,800 r.p.m.
4¾″ motor pulley to 6″ gen. = 1,425 r.p.m.
3″ motor pulley to 8″ gen. = 675 r.p.m.
2″ motor pulley to 8″ gen. = 450 r.p.m.

On different generators there are different sizes of shafts. Some are tapered, but most shafts on later generators are straight keyed shafts, and average about 1½″ to 2″ in length. The average diameter varies. The Delco is 11/16″, the Westinghouse ⅝″ and ¾″, the Remy ⅝″ and ¾″. Therefore bronze bushings should be provided for the generator pulley which can be removed, and in time a valuable collection will be at hand ready to use on subsequent tests.

Some sort of sliding base (V, Fig 15), with a screw (S) to adjust the tension of the ½″ round belt, should be provided. A clamp, similar to a woodworker's clamp, can be used to hold the generator to the base.

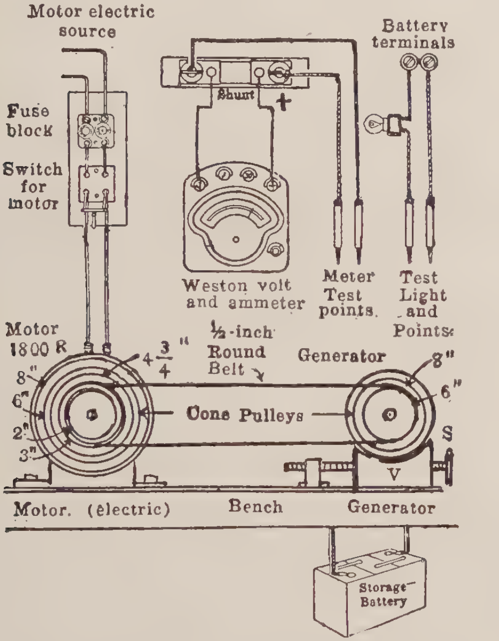

Fig. 15. Method suggested for rigging up a motor for driving a generator on a test.

To figure the speed and size of pulleys to use for other speeds than those given, see Index under "Speed of pulleys, how to figure."

2. **Another method of driving the generator** (Fig. 16) **is by means of a line shaft** (300 r.p.m.). Use a 4″ face pulley, 18″ diameter. This will give a speed to the countershaft of 1,800 r.p.m. if a 3″ diameter 2″ face pulley is used on the countershaft. Note that two pulleys are used on the countershaft, one with a 2″ face by 3″ diameter, which is tight to the shaft; the other is of the same size, but is loose, thus permitting the 2″ flat belt to shift from one to the other, to start or stop the line countershaft.

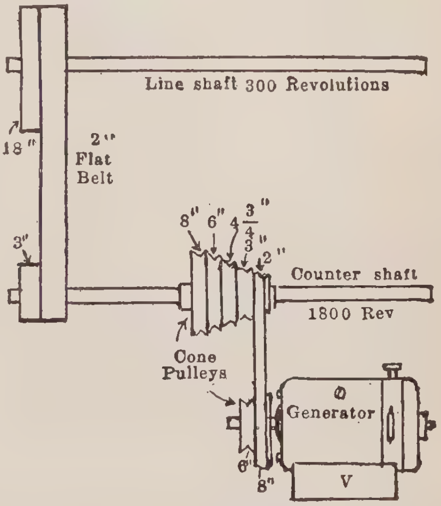

Fig. 16. One method of driving a generator from a line shaft.

As we have the same number of revolutions of the countershaft in Fig. 16, as we have of the motor in Fig 15, we can therefore use the same diameter of cone pulleys.

Other methods can be employed. These are suggestions only.

See page 507 for: "A modern electric testing stand."

HOW TO START TO MAKE ELECTRIC TESTS AND HOW TO LOCATE ELECTRICAL INFORMATION IN THIS BOOK

The greatest difficulty that the electrical repairman experiences in starting into this line of work is to know just how to start and where to obtain parts, etc. The object of these next few pages is to acquaint him with the details of making tests on the **car** and on the **bench**, and to furnish suggestions as to how and where he may obtain data and information. **Refer to the Index often.**

See **Digest of Troubles,** page 454, also pages 512 to 518, for locating other motor and generator troubles.

It will be noted that reference is frequently made to the fact that A. L. Dyke, Electrical Dept., St. Louis, Mo., is in a position to furnish testing instruments and books of data, etc., and also to do electrical repair work. This service is not so much conducted for profit as it is to assist the student in getting his initial start. The parts we purchase for filling orders are purchased of the local branches of the different manufacturers. Later on, after the student is established and actively in business, he can no doubt purchase direct.

The books and instruments that we recommend are those we know are needed. It is impossible to give all data in this one book; hence the necessity of purchasing a few others, such as a Wiring Manual and Service Manuals. See advertisements in the back of the book.

When a car owner drives to your shop and tells you that his generator fails to generate current, or that the generator fails to charge properly, or that the lights burn dim, or that the battery constantly runs down, you must, like a good physician, make careful note of the troubles and then in your own mind **analyze the symptoms** and formulate a plan for your tests and diagnosis of the case.

The first procedure is to endeavor to **make tests on the car** without removing any of the parts. These tests are given under various headings in this book. Before any tests are made, however, turn to the "Digest of Troubles" and find the probable cause, and figure out in your mind which one of the causes would most likely apply to the case. Sometimes troubles are attributed to the electric system, when in reality they are engine troubles, or ignition troubles.

Then make the tests, first one, then another, thus eliminating one cause after another, until the real cause is finally found. This is termed the "process of elimination," and is a mighty good term to memorize and keep in mind. See "Digest of Troubles." The good electrical repairman is classed as a very intelligent man, just as a good physician is, and he must study and be able to concentrate in order to do his work intelligently.

If, after making the tests, it is found that the internal parts are defective, such as a defective ignition coil, generator, cut-out, or battery, then it is time to remove the part to the bench and to make the tests.

Procedure of Tests, and Diagnosis

When starting to locate troubles in the electrical system of a car, first divide the electrical system into parts, as explained on pages 448, 455.

If the trouble is in the lighting circuit, see page 482.

The large blue print Wiring Manual is very necessary in tracing circuits.

If the trouble is in the ignition system or circuit, determine the make of the system, see Index, and study up on that system. Refer to the Index for testing for ignition troubles.

If the trouble is in the storage battery, see the instructions on Storage Battery, and the "Digest of Troubles."

For battery work, we recommend the Cadmium Test Outfit, and also a book entitled, "The Automobile Storage Battery," price $5.00.

If the trouble is in the generator or cut-out, turn to the Index and the "Digest of Troubles."

Starting Motor

If the trouble is in the starting motor, refer to the "Digest of Troubles" page 454, and the Index on "Starting motors." The troubles with a starting motor are either **electrical** or **mechanical.** See also, pages 455, 517 and 486 to 490.

Mechanical troubles with the starting motor that are most common are as follows:

1. **Worn bearings:** Many starters have plain bronze bearings which become worn from lack of oil and long service. Thus when heavy charges of current of 200 to 300 amperes pass through the starter, the armature revolving is forcibly drawn to the pole pieces, as the air gap is very slight, thus damaging the armature. Worn bearings can be replaced if you are equipped with a lathe for turning up and boring out a new bushing.

The end plate can be returned to the manufacturer or to A. L. Dyke, Electrical Dept., St. Louis, Mo., and an end plate with bushing fitted will be supplied.

2. **The starter armature shaft is sometimes bent or twisted out of true,** as a result of back-firing of the engine and of hard strains. To test, place in lathe centers and straighten with a forked bar or otherwise. This trouble is more common with starters than with generators. See also, pages 455, 486, 489, 320.

Electrical troubles, most common with the starting motor are described below. But before making any tests of the starting motor electric system, the engine should be tested first to see if it is stiff or hard to crank. The next test is of the battery.

1. **Examine battery:** See if the electrolyte is above the top of the plates. If not, the battery is probably discharged, or nearly so. If the electrolyte covers the top of the plates, then test the electrolyte with a hydrometer to see if it is charged.

If the hydrometer shows 1.200 s.g., or less, it indicates that the battery is fairly well discharged. If it shows 1.225, it is fairly well charged, but not fully charged. The hydrometer should show 1.250 to 1.300. When testing the battery with a hydrometer, the temperature of the electrolyte should be about 70°, otherwise the readings will not be correct. See Index under "Testing battery, temperature."

2. **Loose or poor connections:** These are usually at the ground connection of the battery or on the starter switch. The starting switch blades may be bent or burned and corroded. These connections as well as all internal connections should be clean and tight.

3. **Poor brush contact.** Usually the result of lack of spring tension or worn brushes. Carbon brushes have a tendency to stick in the holders, especially if gummed with carbon dust and oil. Gauze brushes are sometimes used on starters, and should seat perfectly. See Index under "Brushes, seating of."

4. **Rough commutator:** This will necessitate removing the armature and turning the commutator down on a lathe (see Index under "Commutators"). Do not undercut mica on the starting-motor commutator.

5. **Soldered armature coil terminals loose from commutator.** Resolder. Loose terminals are often the result of heat produced by excessive current; also of poor soldering in the first instance. See Index under "Commutators."

The average speed of a starting motor, fitted with a Bendix drive, on a "free running test," or no load is: 3,725 r.p.m. minimum and 4,950 r.p.m. maximum. The amperage is about 70. Under load, the speed varies 1,000 to 2,300 with 8 lb. pull on a 6″ pulley. The average amperage of starters when starting is given on page 471. This varies, however, as starters are designed in different sizes to start different sizes of engines. See page 489, giving an example of how starting motors are tested according to data given in the "Service Manuals."

Generator

The generator circuit is divided into parts as follows:

1. Generator.
2. Generator regulation system.
3. Cut-out.
4. Storage battery.
5. Wiring system connecting the above.

Generators are usually shunt-wound, and there are four different regulation methods in general use:

1. Third-brush (inherent constant current) regulated.
2. Voltage regulated; where resistance is inserted in the shunt-field winding by an electromagnetic regulation system (see Index under "Voltage regulation").
3. Current regulated; where resistance is cut into the shunt-field winding by an electromagnet (see Index under "Current regulation, electromagnetic").
4. Compound winding with a "differential" action (see Index).

The third-brush regulation is used most. The output of the generator can be **increased** by moving the third brush in the direction of the rotation of the armature, or **decreased** by moving it in the opposite direction. See Index under "Adjusting third brush."

The principle of the third-brush regulation is explained on pages 357, 361. After an approximate speed of about 1,800 r.p.m. is reached, the output begins to drop off, for the reason explained under "Armature reaction." See Index. It is important to see that the third brush always makes good contact with the commutator.

The output of the generator with the voltage or current-regulation method, using an electromagnetic principle, can be increased or decreased by decreasing or increasing the spring tension. See Index under "Adjusting regulators, electromagnetic."

A compound-wound generator, which is an inherent method of regulation, with constant current, has the two windings on fields opposing each other at high speeds of the generator, such as the "bucking-series" winding, and the "cumulative-compound" winding, explained under this subject; see Index.

With the compound-wound generator, not using a third-brush or electromagnetic principle of regulation, but depending upon the differential action of the two windings, there is no provision made for increasing or decreasing the output. Sometimes the series winding can be shortened, or lengthened, as explained on page 356.

The cut-out opens and closes the circuit between the generator and battery, the function of which is explained under this heading; see Index, generally, and also under "Testing and adjusting cut-out."

Generator Troubles

Conditions which necessitate tests of a generator are as follows:

1. When the generator fails to charge the battery.
2. When the generator output is low or excessive.
3. When the ammeter fails to indicate properly.
4. When the ammeter is not steady.

There are many other conditions but those just mentioned are the usual or most common causes for the necessity of testing. See also "Digest of Troubles."

First, test the generator on the car.

Before removing the generator, study out the internal circuits of the system by referring to your "Wiring Manual" and "Service Manual."

Then make the following tests while the generator is on the car:

1. **There is a fuse which is sometimes placed in the shunt-field circuit** of the generator. See if it is making good contact and is not blown.
2. **Examine the brushes** and see if they are making good contact.
3. **Examine the cut-out points** and see if they close at about 650 to 1,000 r.p.m. of the generator, and if they open at lower speeds. A "Service Manual," which gives all these data for all generators is advised. For cut-out troubles, see Index.
4. **See that all connections are tight** from the generator field connection of the brushes and from the generator to the cut-out, to the ground connection of the generator and the battery. The "Wiring Manual" will assist you in tracing.
5. **Examine the commutator—see whether it has thrown solder,** that is, whether the solder which binds the ends of armature windings to the commutator bars is loosened. If so, the generator must be removed and resoldered.
6. Examine the commutator and see whether it is rough or whether mica protrudes. If so, there will be sparking at the brushes. This will require removal of the generator, so that the commutator can be turned down and the mica undercut and the brushes made to fit properly. See Index under "Undercutting mica."
7. **Place your testing ammeter in the generator circuit,** as explained on page 470, at test A1, to see if the dash ammeter is reading properly. Then run the engine and check the readings.
8. **If the generator output is lower or higher at maximum speed** than the "Service Manuals" give for the type of generator being tested, then increase or decrease the output. See Index under "Regulation methods." See also "Digest of Troubles."

Generator Bench Test

Conditions which necessitate removal of the generator from the car are as follows:

1. **If no current is indicated** by the ammeter tests.
2. **If the ammeter needle is not steady.**
3. **If the generator will not produce its proper output** after adjusting the third brush or other regulation method. Failure of the third brush to seat properly is the cause of many generators not giving their proper output, or even giving none at all, or intermittently.
4. **If there is excessive sparking at the brushes,** and it cannot be remedied by proper brush adjustment.
5. **If the commutator is rough** and mica protrudes.
6. **If there is noise.**

After removal of the generator to the bench, there are four methods of testing:

1. By motoring the generator.
2. By examining the commutator.
3. By driving the generator.
4. By testing the armature and field windings.

Testing Generator by Motoring It

Connect the generator with a fully charged battery: It makes no difference which wire is connected, as most generators will automatically reverse their polarity. If, however, you know the (+) terminal of the generator, use it. The motoring test will determine if trouble is in the armature or the field.

Running the generator as a motor is a quick method of determining the general condition, and is easily and quickly tested out. See also page 491.

An ammeter with the 30-ampere shunt is connected in the line; the ammeter must be connected through the (+) pole of the meter to (+) of the circuit. See page 465 for description of the Weston meter, which we assume is being used for the tests.

The cut-out is not in the circuit in this test. If, however, the cut-out is in the generator, close the points, otherwise the generator will not motor. The generator should run in the driven direction, unless the field connections are wrong. In this case change the internal wires at the brushes.

If the generator fails to motor, the trouble is probably due to an open field circuit or to absence of brush contact.

If the generator motors, it should do so without undue sparking at the brushes or any unusual noise.

It should draw approximately from 3 to 5 amperes. On the Ford, the amperage is 4, and on a N.E. motor-generator (model G), it is about 5 amperes with the 12-volt battery. If it is over 8 amperes, then there is evidence of a short-circuited armature, providing the machine is free of mechanical defects.

The "Service Manuals" give these data for all generators.

The average speed of a generator when being motored is 400 r.p.m. with a voltage or relay type of regulation, and 350 r.p.m. with a third-brush type of regulation.

If the generator draws too much current when being motored, the trouble is very probably to be found in the armature.

If the needle of the ammeter vibrates, there is probably a short circuit.

The armature should then be removed, and placed in the stand (Fig. 13, page 476). Separate tests should then be made. See Index for "Armature tests."

Testing Generator by Examining Commutator

Eighty per cent of generator troubles are indicated by the condition of the commutator. Remove the cover (Fig. 17), and examine for the following:

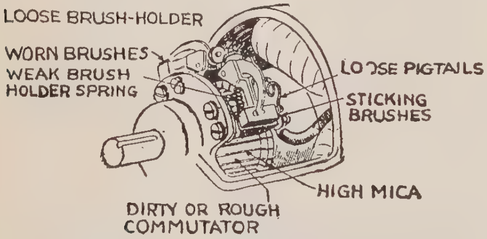

Fig. 17. Commutator and brush inspection.

1. **If the commutator is burned black** over its entire surface, it is usually due to grease, or carbon dust from the brushes. If caused by carbon dust, the commutator is probably rough, and should either be turned down on a lathe or sanded in (explained under "Commutator troubles"; see Index). It is best to turn the commutator down, but sanding will do in an emergency. Blow carbon dust out of the generator housing with air pressure.
2. **Improper brush-spring pressure,** which permits arcing, will also produce a rough commutator.
3. **If there is an open circuit in the armature,** there will in all probability be a flat place on the commutator segment or bar, the result of a heavy spark at the brush occurring on the open commutator bar when the brush makes contact with it. The cause of such an open circuit in the armature coil is usually a loose connection where it is soldered to the commutator bar. Examine all of the connections carefully.

   Sometimes troubles of this nature occur only when the armature is revolving, which causes the wire to fly loose, through centrifugal action of rotation. Hence the connections must be carefully examined.
4. **If the mica protrudes above the commutator bars,** or if the brushes or brush holders are loose, or if the brushes are worn, this indicates that there has been excessive sparking at the brushes. These parts should be examined carefully and remedied. See Index under "Commutator and brush troubles."

Testing Generator on the Bench by Driving It

Various methods are used for driving a generator so that the cut-out and output of the generator can be tested. A home-made outfit is shown on page 477. See also Index under "Electrical testing outfit."

Additional Pointers

If a generator fails to deliver its proper output, or if the cut-out fails to operate, the first step is to find out why. If the tests suggested above determine the fact that the generator armature coils, or the field coils, or the cut-out windings are defective, it does not pay to attempt to repair them, as armature winding is a trade learned only by careful study and long experience. It is best to return the part to the factory,[1] and order a new part. In many instances an allowance will be made on defective armatures toward a new one.

The electrical repairman can, however, do such work as testing, cleaning, and sanding the commutator, under-cut mica, fit or seat and adjust brushes, solder loose wires at commutator segments, etc., as explained under these different subjects.

He can also adjust and regulate the output of generators. Most generators now have the third-brush regulation. It is therefore a simple matter to increase or decrease the output by moving the third brush, after determining what make of electric system is used, and then referring to the Index of this book, or to the Service Manuals.

A Data Book or Service Manual giving the speed of different generators at which the cut-out should cut in and cut out, the amperage at various speeds, etc., is very necessary.

Bearings and Brushes

Bearings: Many generators had ball and roller bearings. Delco still uses ball and roller bearings. Most of the other generators and starters now use plain bronze bearings. You can fit new bearings if you are equipped with a lathe and can do the work accurately. It is advisable to send the end plate to the factory, and obtain a new bearing fitted into the end plate.

If the shaft is worn, then it is best to true it up on a lathe and to fit new bearing bushings and ream them out, so as to have the shaft correspond with the bore of the bearing bushing, or else to send the entire generator or motor to the factory.

Brushes: Generators usually use carbon brushes copper plated. Starting motors use a composition of graphite and carbon or some similar substance which is softer than generator brushes. Some starting motors use gauze brushes. See Index under "Brushes." It is best to obtain brushes as recommended by the manufacturer.

On page 494 we advise how to sand brushes. On some generators this is not possible, as the brush arm is too short. In this case, the brush should be placed on the generator, the generator should be "motored," and thus the high spots on the brushes will show. Scrape high spots of brushes down.

Good brush contact is very essential on both generator and starter.

---

[1] A. L. Dyke, Electrical Dept., St. Louis, Mo., is in a position to supply these parts and advise you where the nearest representative of the different electric companies is located. This service on our part is rendered not so much for the small profit, as for the benefit of our readers, in order to assist them in getting started.

Oil the generator and starting-motor bearings often. **Don't oil or grease** the commutator.

Parts to Carry in Stock

If you propose to do electrical repair work, then in addition to testing instruments and tools, you should carry parts in stock, such as:

1. Brushes.
2. Lamp bulbs.
3. Fuses (see Fig. 18).
4. Ignition coils: ignition resistance units, condensers, contact-breaker arms for Atwater-Kent, Delco, Remy, Westinghouse, and Connecticut ignition systems.
5. Ignition cable.
6. Primary and lighting wire.
7. Ignition switch keys.

Some of the parts which should be carried in stock by the electrical repairman are illustrated. **Addresses of some of the manufacturers** are: Chicago Fuse Mfg. Co., Chicago ("Union" fuses); Delco Electrical Laboratories, Dayton, Ohio; Remy Electric Co., Anderson, Ind.; Westinghouse Electric Co., Pittsburgh, Pa. (motors, generators, and ignition); Connecticut Tel. and Elect. Co., Meriden, Conn.; Atwater-Kent Co., Philadelphia, Pa. (ignition); K.W. Ignition Co., Cleveland, Ohio (magnetos, coil units).

Ignition replacement parts can be secured of Jefferson Elect. Mfg. Co., 426 So. Green St., Chicago, Ill.; New York Coil Co., 338 Pearl St., New York, N.Y.

It is advisable to find out the make of cars in your vicinity and the electric system used on the cars, in order to have appropriate parts on hand. By referring to "Specifications of leading automobiles," you will find the specific make of electric system listed with each make of car.

INSTRUCTION No. 44

DIFFERENT METHODS FOR TESTING THE ELECTRICAL PARTS OF A CAR: Lighting Tests; Armature Tests; Field Tests; Generator Tests; Starting Motor Tests; Cut-Out Tests

This instruction will deal with the subject of various methods of making tests. For instance, grounds are usually tested with the test light, although a meter can be used.

Armature and field ground tests are also usually tested with a test light, but a meter can also be used.

Armature tests for open circuits and short circuits are usually tested with a meter, using the millivolt drop test.

An ammeter of a 30-range capacity can be used for testing generator armatures for short circuits and open circuits, as explained under the F. B. test-stand tests.

The "growler" is best for testing motor armatures, owing to the very low resistance of the motor coils. Torque tests and free-running tests can also be made of the motor, but the object of a "free-running test" of a motor, or a "torque test," is to find out if the trouble is in the field or in the armature.

Likewise, the "motoring test of a generator" is for the purpose of localizing the trouble: to discover whether it is in the armature or the fields, and whether it is an open circuit, a short circuit, or a ground.

LIGHTING TROUBLES

Lighting troubles are attributed to one or more of the following causes:

1. Poor connections.
2. Open circuits or broken connections.
3. Grounds.
4. Short circuits.
5. Weak battery.

Poor connections and open circuits may exist at any point on the lighting circuit, from the battery to the lamp bulb.

Grounds and short circuits may exist at any point on the lighting circuit.

Lighting Trouble Indications

If lamps do not light up:

1. Examine the fuse block for blown fuses. **If the fuse is blown,** do not replace it immediately, but look over the wiring for an accidental ground or short circuit. If the fuse in the headlight circuit blows, turn off the headlight switch until the trouble is located and removed. In looking for grounds, any abrasion of the insulation on the wire, or a metallic contact between the wires or between the current-carrying part of the wiring devices and the metal of the car should be watched for.

   When the trouble has been located and corrected, then replace the blown fuse with another of the same capacity, making sure that it is of the proper size.

2. **If the fuse is not blown,** look for burned-out lamp bulbs, open circuits, loose contacts; or the lighting wire to the battery may be loose, or disconnected, or the battery may be run down, or discharged.

3. **In case the battery is discharged,** recharge it immediately, and if possible, give it a gassing charge. See Index under "Hydrometer test."

If lamps in one circuit do not burn:

1. The lamp may be burned out. Try another lamp in the same socket.

2. If the fuse is thought to be blown, try the same fuse in another circuit. If the fuse is blown do not replace it immediately, but look over the wiring for a ground or short circuit.

   If the trouble cannot be located immediately, turn off the switch on the damaged circuit until the trouble has been located.

   If the trouble is in a particular lamp socket, disconnect the attachment plug from this socket until the trouble can be removed, and see that the removed attachment plug does not dangle in such a way as to make a short circuit on the metal of the car.

3. There may be an open circuit or a broken connection in the wiring. Examine the places where the connections are made on that particular circuit.

4. In case the trouble is due to a short circuit on some particluar lamp socket, disconnect the attachment plug leading to this socket until the difficulty can be remedied.

If none of the lamps will burn—and no spark is obtained for ignition:

1. Terminals of the battery may be disconnected or corroded, so that they do not make good contact.
2. Ground wire, from the battery to frame of car, may be disconnected or broken.

If the ignition is all right, the trouble may be due to:

1a. The lead wire from the switch to the lights may be disconnected or broken.

1b. The lead from the generator terminal to the fuse box may be disconnected or broken, or the fuses blown, owing to a short circuit.

1c. The lamps may be burned out.

1d. The battery may be run down.

If there are no lights or dim lights, with the engine running: There is a group of troubles which can be classified under the general head of open circuits. There are seven of these which are prominent:

1. The generator terminal or brush connections may be loose, or may make poor contact. If, how-

ever, the generator is charging the battery—which is indicated by the ammeter showing "charge"—then the trouble is not in the generator.

2. The wire connections to the switch may be defective.

3. The wire connections to the lamp connector terminals may be defective.

4. Lamp-socket terminal may be loose.

5. Bulbs may be burned out.

6. Bulb bases may be out of contact with lamp sockets.

7. There may be broken wires, especially where connections are made to the lamp sockets.

If lamps go out for an instant only: When the lamps in one circuit act this way, there is probably a loose connection on the circuit so affected. It may be in any part of the system, and the first place to look is at the fuse connection.

A slight short circuit which occurs at intermittent periods would also cause this trouble, but in this instance, a higher "discharge" rate will be shown on the "ammeter."

If lamps flicker: This trouble is attributable to loose connections, usually at the lamp socket or fuse.

It can also be caused by bad contact or an intermittent ground. For instance, a contact might be just loose enough so that vibration would cause the circuit to be made and broken repeatedly.

A grounded wire would cause this trouble by alternately making and breaking the ground connection. Every time the ground is made, the light goes out because the current flows through the ground instead of through the lamp.

Obviously the trouble may be roughly located by noting whether all the lamps flicker, or only one. If all do, then the test should start at the ammeter; then at the switch; then at the circuit. If only one light flickers, then the trouble is in this individual circuit.

If lamps flicker and the ammeter is unsteady: This may be due to a loose connection in the light wires; a loose connection between battery and generator; a loose contact at lamp bulb; or, finally, to an exposed wire touching the frame intermittently, causing a short circuit.

If one lamp burns dim: Change the bulb; it may be old and blackened, or partially short-circuited in the filament. If the same lamp is still dim, test the wiring to the lamp. Examine the lamp socket. A great many of these troubles are found in poor connections in the lamp socket, or in a slight ground in this circuit.

If all lights burn dim: The usual trouble in this case is loose or slightly grounded connections, or poor or corroded connection at the battery. More likely the battery simply has not had sufficient charging. This can be determined by watching whether the lights brighten up when the engine is speeded up, at which time the generator is supplying current.

If the wiring is all right, run as much as possible with lights off, so that the dynamo will charge the battery at a higher rate. Or it may be necessary to set the charging rate of the generator higher.

If the battery continues to run down, examine the cut-out. If the cut-out is in good order, then test battery with switch off, for a "ground" or slight "short circuit" in the sockets, or switch.

If there is no ground, then test the battery electrolyte, and also each cell separately, as directed in the instructions given under "Storage Battery."

Lamps may also be old and blackened, in which case, try new bulbs.

If the lamps are bright with the engine speeded up, and dim when the engine slows down or is idle:

In this case the battery is discharged, because, when the engine is speeded up, the generator current is used, and if the lights brighten up, then it is clear that if the engine slows down and the battery supplies current and the lights are dim, the battery itself is weak. Loose or poor contact of the battery terminals might also cause this trouble, or probably the **battery terminal is sulphated.**

If possible, have the battery charged at once from an outside source. If this cannot be done, endeavor to run with fewer lamps than normal turned on for a few days, or until the battery voltage picks up again.

If the lights grow dim when the engine is speeded up, the wires are probably reversed at the generator.

If lamps burn very dimly when the starting pedal is used: The battery is weak, and probably almost discharged; or the battery is injured in one or more cells, probably due to lack of water; or battery terminals or ground wire is not tight.

If lamps will not light, but the starter cranks the engine: Lamps are burned out, or the filament is broken; or the system is short-circuited, or there is an open circuit at the fuse or the switch or the wiring.

If lamps seem to burn brightly, but fail to illuminate the road sufficiently: Lamps are out of focus. The rays of light are directed too far upward. (See "Focusing of lamps and reflectors.")

If lamps are too bright: The regulation of the generator is evidently set for a higher voltage. Use lamps of higher voltage.

If lamps burn out often: This is due either to a poor grade of lamps, or to an improper voltage of lamps; also to **sulphated battery terminals,** or to loose battery connections.

If fuses blow repeatedly: Lamps are defective—probably with short circuits. First try new bulbs. The fuse may not be of large enough capacity.

TESTING THE LIGHTING CIRCUIT FOR OPEN CIRCUITS, GROUNDS, AND SHORT CIRCUITS WITH A TEST LIGHT

In this example we shall use a test lamp and test points from a 110-volt lighting circuit of either direct or alternating current. A voltmeter could be used.

A point to remember, when testing any circuit, is that a **complete circuit is necessary** in order to have the electric current do its work.

When using a test light, it is advisable occasionally to bring both test points together or to touch one with the other, to make sure that the test light is still in working order, as very often the filament of a lamp breaks, owing to the rough nature of test work. When this happens, one is led to erroneous conclusions.

It is a good plan to inclose the test lamp in a wire cage to prevent excess vibration to the lamp bulb and also to avoid injury to the small glass tip on the end of the lamp bulb.

Wiring-System Troubles

Wiring troubles are:

1. All lights out; none burn.
2. Only one branch of lights burns.

Cause of 1: Fuses blown; battery discharged or disconnected; poor connection at battery terminal or ground wire; open circuit; short circuit. Test the battery; examine connections.

Causes of 2: Open circuit; short circuit or ground in this branch. Test as suggested below. May be due to burned-out lamp bulbs or poor contact at lamp sockets.

A single-unit Delco electric system, using a single-wire grounded return wiring circuit is shown in Fig. 1 as an example. The tests however will apply to many of the other systems. The idea here is to point out how to make the tests for the different external circuits.

To Test for Grounds

See test No. 4; place one of the test points (T) on the frame of the car and the other test point (T1) on the negative (—) terminal of the battery (A).

If the test lamp lights, then a ground is indicated, and will likely be on the switch or in the motor windings (if all the switch buttons are pushed in).

Note. **If the battery box becomes badly acid soaked, it may cause the lamp to light,** owing to grounding through the box. Disconnect the (+) terminal of the battery from the wiring system, and test as before. If the lamp lights now, the battery **box should be insulated** from the frame of the car with a piece of dry wood and the battery should be cleaned and dried, and the battery box should be painted. See Index under "Battery box acid-soaked."

4. Now with one of the points still grounded to the frame of the car, touch with the other point different terminals of the combination switch.

If the lamp lights, then a ground is indicated. It should be found and removed.

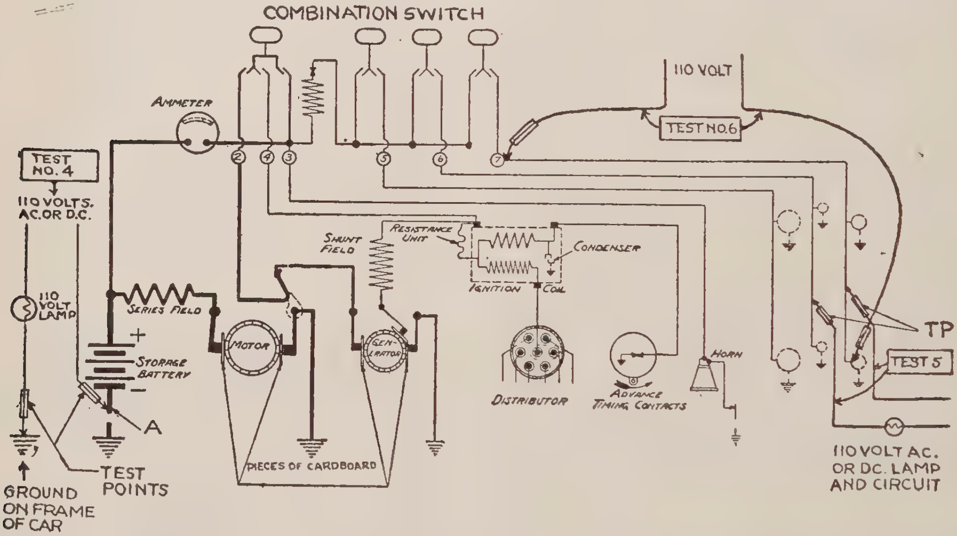

Fig. 1. Diagram explaining how to use a test light for testing for open circuits, grounds, and short circuits in the lighting circuit of a car or wiring system.

Most of the troubles in the wiring system are grounds, short circuits, and open circuits.

It will be observed that certain portions of this circuit are intentionally grounded to the frame of the car. The battery terminal, the lamp return wires, one motor and one generator brush, one of the timer contacts, one terminal of the horn push-button, and one terminal of the condenser in the coil are grounded.

When Testing for Grounds

1. Remove these grounded connections by disconnecting the battery terminal (negative [—] in this instance) from the battery which is grounded to the frame of the car, and remove all lamp bulbs.

2. Place a piece of cardboard between the commutator and the brushes of the motor and the generator (third brush also). See Fig. 1.

3. Disconnect the lead wire from the horn button and distributor and raise the base of the ignition coil so that it is insulated from the top cover of the motor-generator.

To Test for Short Circuits

For testing for short circuits between two wires which are supposed to be insulated from each other —see test No. 5; place one test point (TP) on one wire and the other point on the other wire.

If the lamp lights, a short circuit is indicated between the two wires.

If the lamp does not light, then this portion of the circuit is in proper condition.

To Test for a Broken Wire

To test for a broken wire—see test No. 6; place the test point at each end of the wire as shown.

If the lamp lights, the circuit is complete.

If the lamp does not light, then there is a break somewhere between the two points. By gradually moving the test points toward one another, the break can be definitely located.

If Lights Burn Out Often

This is likely due to using a lower-voltage lamp than is used on the generator circuit. Test the voltage at the lamp socket with the voltmeter when the generator is running at normal speed, and use lamp bulbs accordingly.

TESTING THE LIGHTING, HORN, AND IGNITION CIRCUITS WITH A METER

Lights

Causes: If all the lights do not operate, the trouble may be due to the lighting system being short-circuited, open-circuited, or grounded.

If individual lights do not operate, the branch systems may have any of the defects mentioned, and, in addition, that of burned-out lights.

Testing[1]

Short circuit: To test for a short circuit in the general lighting system, insert the 300-ampere range shunt in the circuit. Connect the instrument to the shunt. An indication will be obtained if a short circuit exists. (An indication may also show a ground.)

If some of the lights only do not operate, connect the instrument as just described and close the switch for the branch containing those lights, for instance, between switch 7, Fig 1, and the light circuit. An indication will be obtained if the branch contains a short circuit or ground. If a short circuit is indicated, the wiring and light sockets should be carefully examined.

Note. If the indication obtained is less than 30 amperes, the 30-ampere range shunt may replace the 300-ampere range shunt.

If any lights are burned out, measure the voltage at the socket, using the 30-volt range. This should be done for various engine speeds.

If a voltage is indicated which is higher than is proper for the particular system being considered, examine the generator regulator system to locate the trouble.

Open circuit: If all lights do not operate, and the instrument does not show a short circuit or ground, the general lighting system is open-circuited. This is probably due to a disconnected wire.

If some lights only do not operate and no short circuits or grounds are indicated, the branch systems which contain these lights are open-circuited. This may be in the wiring, or because the lights are burned out.

Grounds: Disconnect all wires from the battery and all intentional ground connections. Then proceed as described under "Short Circuits."

Horn

The causes for the horn failing to operate may be similar to those affecting the operation of the lights.

Open circuit: Connect the 30-ampere range shunt and instrument in the horn circuit, between the switch terminal 3 (Fig. 1) and the horn circuit. Close the horn switch. If no indication is obtained, the horn circuit is open-circuited. By inspection, the place at which trouble exists can readily be found.

Short circuit: If a test for an open circuit does give an indication, the horn circuit is short-circuited or grounded.

Note. If the indication is less than 3 amperes, the 3-ampere shunt may replace the 30-ampere shunt on the ammeter.

Ignition Troubles

Causes of trouble: Ignition troubles may be caused by loose connections, open circuits, grounded wires or spark plugs, short-circuited wires or spark plugs, improper adjustment of spark gap of plugs, incorrect order of cylinder firing, broken-down or short-circuited spark coil, and broken-down or grounded condenser.

If a magneto is supplied, trouble may be in the magneto.

Ignition troubles and tests are treated under the ignition instructions. See Index.

A visual inspection and the application of tests already described will undoubtedly enable one to locate the fault.

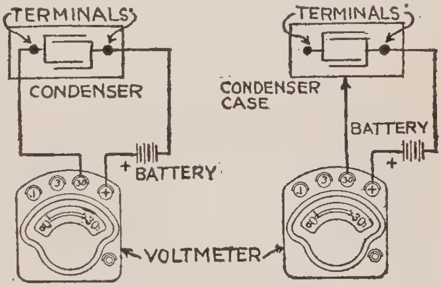

Fig. 2

Fig. 3

Condenser broken down: Connect the negative (−) binding post of the battery to one terminal of the condenser (Fig. 2). Connect the positive (+) terminal of a battery to the (+) binding post of the instrument. Then, finally, complete the circuit from the 30-volt binding post to the other condenser terminal.

If the condenser is good, no indication will be obtained. **If it is broken down,** an indication will be obtained.

Condenser grounded: Remove one connection from a condenser terminal and touch it to the condenser case (Fig. 3). **If an indication is obtained,** that section of the condenser is grounded. Replace the connection to the condenser terminal and repeat, removing the connection from the other terminal and touching it to the case. See also Index, under "Condenser tests."

General Wiring Troubles

Causes of trouble: Troubles in the general wiring of an automobile may be due to short circuits, grounds, open circuits, and poor connections. These faults can result from oil and water-soaked insulation, from damaged insulation caused by rubbing of the wires against the metallic parts of the automobile, and from vibration of the automobile when in service.

These faults can be located by visual inspection and by the application of the various tests already described.

It is well to consult the manufacturer's wiring diagrams before attempting to make any changes in the wiring.

---

[1] The Weston "model 280" instrument is used as an example in these tests. See page 464.

TESTS OF A STARTING MOTOR WITH A METER (ALSO APPLICABLE TO THE GENERATOR EXCEPT THE OPEN-CIRCUIT FIELD TEST)[1]

The subject of starting-motor troubles is also treated on pages 455, 517, 518. The purpose here is to explain first the common troubles of a starting motor and then how to make the tests.

Starting-Motor Troubles

Starting-motor troubles can be divided under two headings:

1. Failure to operate.
2. Operates slowly and without sufficient power to crank the engine.

Causes of 1: Battery weak; open or short circuits, or grounds may exist in wiring from battery to starter switch; sticking of starting switch (common); mechanical troubles, such as a stuck Bendix drive gear, worn bearings, waste or foreign substance between armature and pole pieces; trouble with starter mechanism.

Test by examining each carefully. If none of these causes exist, then the trouble is an internal one of the motor, and may be due to an open circuit in the motor armature or field. Tests are shown elsewhere.

The trouble may also be due to a dirty commutator, to grounded brushes, or to the fact that the brushes are not making good contact. Tests are shown elsewhere.

Causes of 2: Battery discharged—test battery; poor contact at battery terminal or ground wire from battery to frame; poor brush contact; dirty commutator. Test. See also "Digest of Troubles."

The first test, however, which should be made, before making other tests, is to **test the engine,** to see if it cranks easily when cranked by hand. If the engine is stiff, it is probably using more than the normal amount of current, thus rapidly discharging the battery; or the engine may not start easily owing to carburetion or ignition trouble.

The second test should be that of the **battery** (see Index under "Testing the storage battery").

Failure of the engine to start when the starting motor is working satisfactorily: This may be due to failure of gasoline or spark. Test out as follows:

(1) **Ignition switch:** Examine to see if "on."

(2) **See that there is gasoline in the carburetor,** and that it reaches the engine, by priming. If there is no gasoline in the carburetor, which can be determined by depressing or raising the float to see if gasoline drips, then it is useless to waste current trying to start the engine with the starting motor. The gasoline may be used up, it may not be turned on, or the gasoline feed pipe or valve may be stopped up. If the system involves gravity feed, the gasoline may not flow into the carburetor on steep hills.

(3) **If there is gasoline in the carburetor,** take out one of the spark plugs and lay it on the engine with the sparking point in the air while the engine is turned over by hand or by the starting motor. Also examine the spark plug points—they may be too far apart. $\frac{1}{64}''$ to $\frac{1}{32}''$ apart is about right. If a spark passes, the trouble is not in the electric system, but is probably caused by cold gasoline or the need of priming.

(4) **If there is no spark,** then see "Digest of Troubles" and Index, and follow the diagnosis.

Before an engine will start, there must be gasoline and a spark.

If sometimes the gears mesh and the motor runs satisfactorily, and at other times it is impossible to mesh the gears, the motor refusing to turn when the contacts are closed, it indicates the possibility of an open circuit in the switch or starting motor.

If the engine does not pick up immediately after two or three trials, even though the motor turns the engine over, the trouble is in either the gasoline supply; the spark plugs; the carburetor; or the ignition system.

If the starting motor continues to run after the switch lever is released, see that the return spring on the switch, or switch lever, is strong enough to return the parts positively and fully to the "off" position.

If the starting motor cranks the engine very slowly: Battery is almost discharged; battery may be sulphated; engine may be stiff; brushes may be loose or may make poor contact.

If the starting motor does not rotate at all: Battery may be discharged; starting switch may not be making good contact; the motor brush may not make contact with the commutator; the battery terminals may not make good contact; switch contact may be poor.

Owing to the high volume of current carried through starting motor brushes, if they are worn or not properly adjusted, the commutator may become pitted and cause excessive wear—result: failure of starting motor to operate properly or excessive sparking and weak motor. Remedy: Take the armature out and true up the commutator on a lathe.

If the starting motor rotates but does not crank the engine: Roller clutch does not work properly (Delco system), or the Bendix drive is out of order; gears may be improperly meshed; if a Bendix automatic, spring may be broken. See pages 320, 456.

If the starting motor cranks the engine a few revolutions and then stops: Battery may be weak—almost discharged; a loose switch contact may exist.

If the starting motor cranks the engine and the engine does not start: These symptoms indicate that trouble is not in the starting system.

If the battery is all right proceed to examine the connections, beginning with the battery. The current may be shorted, because of electrolyte spilled over the top of it; or the terminals may be sulphated, in which case enough resistance will be offered to the current to prevent proper operation.

Scrape off the sulphate, wash surrounding metal parts in carbonate of soda or some other alkali.

Clean the battery terminals inside with a round file; **clean the wire terminal** with a flat file; replace the wire, and draw connections tight.

Next examine the ground connection of the battery to the frame. This should be cleaned and tightened, if not soldered. Looseness here is a frequent cause of open circuit. Then examine the connections from battery to starting motor switch; thence the brushes to the commutator. Good battery and ground connections are very important.

See "Digest of Troubles" for other starting-motor troubles, both "electrical" and "mechanical."

Starting-Motor Troubles in Relation to Testing with a Meter

The following tests are made with a Weston "model 280" instrument.

Causes: If the starting motor does not operate, the fault may arise from several causes, acting separately or collectively. The more important causes are fully discussed in the following text:

The battery: The battery is generally the most abused part of the starting and lighting system, and consequently may easily become discharged. In this condition it is not capable of supplying sufficient current to operate the starting motor. The hydrometer test should be applied, and if this condition exists, the battery should be investigated. See Index for "Storage battery tests."

Wiring and starting switch: Open circuits, short circuits, or grounds may exist in the wiring from the battery to the motor, including the starting switch. A common cause is sticking of the starting switch.

Defective motor: The motor may not operate because of internal troubles. These may be an open-circuited or short-circuited armature or field, dirty commutator, brushes not bearing on the commutator, or grounded brush holders, armature, and field.

Mechanical troubles are not included in these tests. See "Digest of Troubles."

Testing for Trouble: Motor Will not Operate

To locate trouble: If the battery is in good condition and the starting motor does not operate, connect the 30-volt range of the instrument to the terminals of the motor as directed in test V3, page 470. Press down the starting switch. Quickly observe the indication of the instrument.

Caution: Do not hold the starting switch down any longer than absolutely necessary to obtain a reading, as the battery is under a heavy strain which may damage it.

Open circuit in wiring or starting switch: If no indication is obtained, an open circuit exists either in the wiring from the battery to the motor or in the starting switch. A visual inspection will locate the cause.

Short circuits and grounds in wiring or starting switch: If an indication is obtained when the voltmeter is connected to the motor terminals, but the indication is much less than the normal voltage of the battery (test battery as directed in test V2, page 470), the trouble may be due to loose connections at the battery, starting switch, or motor; or to grounded or partially short-circuited wiring. A visual inspection will locate these causes.

Short circuits and grounds in motor: If no troubles are found to exist in the wiring, the cause must be in the motor. The faults as indicated by the instrument would be short-circuited or grounded armature and field, or grounded brush-holders. See under "Short Circuits" and "Grounds" for details of tests.

Open circuits in motor: If an indication approximately equal to the battery voltage is obtained with the voltmeter connected to the motor terminals, the motor is open-circuited. **An open circuit may exist in the armature or field,** or it may be due to the commutator being dirty or the brushes not bearing on the commutator. A visual inspection will eliminate the last two faults. See under "Open Circuits" for details of tests on other faults.

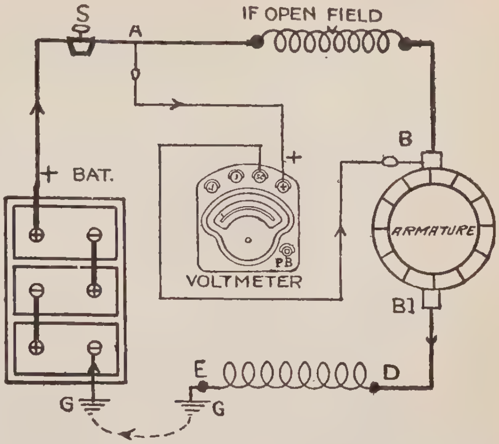

Fig. 4. Test for an open circuit in the motor field which would cause the motor not to operate. Use 30-volt terminal and scale.

To test for an open circuit in the motor field: See Fig. 4. Connect meter with the 30-volt terminal. Place voltmeter connections on one end of the field at (**A**) and the other at brush (**B**). Press starting switch (**S**).

If an indication shows on the meter that is approximately equal to the battery voltage, then there is probably an open circuit in the field, because the circuit would then be from (**A**), through the meter to (**B**), through the armature, to (**B**1), through the other field, to ground (**G**), to (−) of the battery.

If no indication is obtained, then the field is good and the motor should operate if the battery is strong. If it does not operate, then the armature may be open, and this is discovered by another test. If the field is good, there would be (approximately) no reading, because the meter would be connected on one side of the line. Therefore this test would not tell definitely if the armature is open, but it would be sufficient reason to test for an open armature.

This motor-field test is not applicable to the generator-field test.

Testing for Trouble: Motor Operates, but Slowly

If the motor will turn over, but too slowly to start the engine, any one or more of the troubles already mentioned may exist, except the open circuit in fields. In other words, an open circuit could be in one or two armature coils, or a short in one or two armature coils, and the motor would operate to a certain extent. Therefore tests of armature and field troubles will be given, which are also applicable to the generator, except the meter test of the open-circuit field of a generator, which is given on page 502.

Testing for open circuits in the armature: Connect the 30-volt range of the meter to the brushes, as shown in Fig. 5. Be sure that the brushes are bearing on the commutator. Press the starting switch.

If an indication shows on the meter and it is (approximately) equal to the battery voltage, then the armature is probably open. The current would then flow through the meter from the battery around the armature. All of the armature coils may not be open; turn the armature slowly and observe.

To test each individual armature coil to localize or find the open-circuited coil, is then the next procedure, if the armature is suspected of being open.

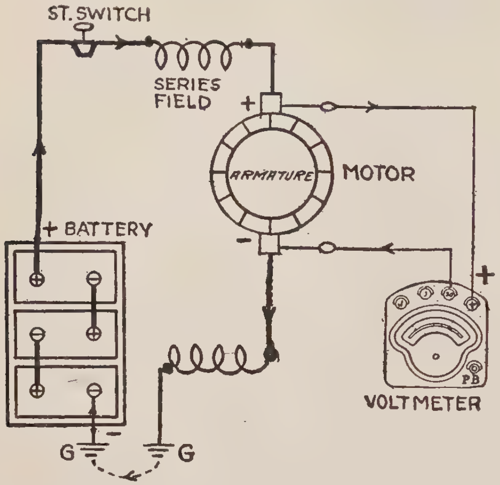

Fig. 5. Testing for open circuit in armature. Use the 30-volt terminal and scale.

Proceed as follows: Disconnect the fields from the armature, as in Fig. 6. Connect the brushes to a source of current, such as a single cell, and have a controlling **resistor**[1] in series to increase or decrease the current flow (see **R**, Fig. 6). Using the 3-volt range of voltmeter, measure between adjacent segments of the commutator.

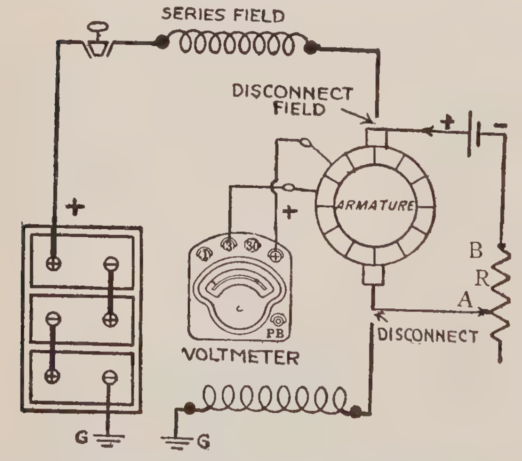

Fig. 6. Testing for open-circuited armature coils. Use the 3-volt terminal and scale. When testing for short circuits in armature coils, use the .1-volt terminals and scale. This test is what is termed a **"comparative test,"** that is, the test points of the meter are placed on two adjacent bars all the way around the commutator, and the readings on each pair should be the same. Note resistor.

If an open-circuited coil is across the ends of the meter test-points, then **an indication will be obtained** which is relatively large as compared to that obtained from a good coil (see page 498 for the reason).

It is absolutely necessary that good contact should be had at the commutator segments in order to obtain reliable results.

Note. This method can also be used when testing the generator armature for open circuits.

Testing the armature for short circuits: Disconnect the field from the armature. Connect for test to determine open circuits in the armature (Fig. 6), and try the armature for open circuits as already described. Now change the connection from the 3-volt range to the .1-volt range and measure between commutator segments.

If a short circuit exists in any of the armature coils, **the indication obtained,** when the voltmeter test-points are connected to the ends of that coil, **will be very much less** than the indication obtained from a good coil (see page 498 for the reason).

Note. This is one of the special cases when the .1-volt range should be used.

If the indication is too large, decrease the current supplied through the brushes by increasing the controlling resistance.[1]

This method is applicable to the generator.

Caution: Good contact must be had at the commutator segments in order to get reliable results.

Testing fields for short circuits: Connect one cell with a regulating resistor (**R**) in series to the ends of the entire field, as in Fig. 7. (The field is usually made in two or more sections.)

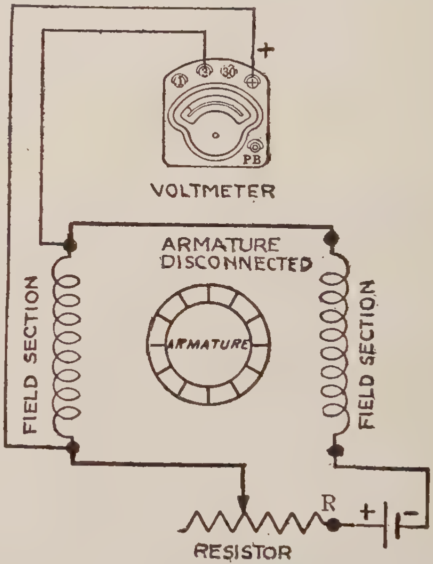

Fig. 7. Testing the fields for short-circuits. Use the 3-volt range to start with.

Using the 3-volt range, measure the voltage across one field section. Transfer the voltmeter leads to the other section in turn.

If on one of the sections **no indication is obtained,** that section is short-circuited, because there is no **resistance offered by the field which is short-circuited.** If it were not short-circuited, then the reading would be that of the voltage drop, due to the resistance offered to the flow of current passing through the coil winding. The greater the number of turns and the smaller the size of wire, the greater is the resistance. Therefore if a short circuit exists, there would be less resistance, depending upon the number of turns short-circuited.

---

[1] **The purpose of the resistor** is to furnish enough resistance in the circuit to cause sufficient voltage drop to obtain a satisfactory reading. The amount of resistance cut into the circuit can be varied with the resistor shown in Fig. 6; for instance, (R) is the resistance. By moving (A) down, more resistance is cut into the circuit; by moving (A) up, resistance (R) is cut out of the circuit. See page 467 for explanation, and for information as to where resistor can be obtained.

If on one section the indication is very much less than on the other section, a short circuit very likely exists in that section, because these tests are intended to compare one coil with another, and, if good, they should have approximately the same readings.

Note. If the indications obtained are less than .1 volt, the connection may be changed from the 3-volt range to the .1-volt range. This is the second special case where the .1-volt range can be used.

This method is applicable to the generator.

Testing the armature for grounds: Disconnect all intentional ground connections to the motor. Also disconnect the field from the armature. Lift the brushes off the commutator.

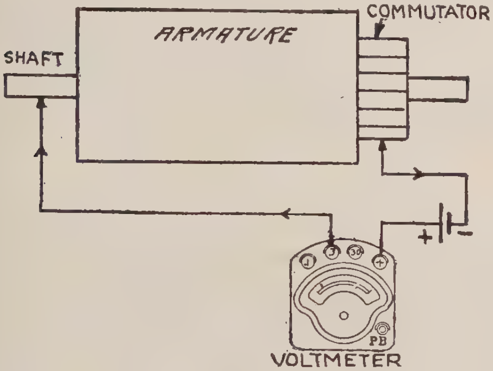

Fig. 8. Connections for testing for a ground in an armature. Use the 3-volt terminals and scale.

Connect the negative (−) terminal of a cell (Fig. 8) to a commutator segment, and the positive (+) terminal to the (+) binding post of the instrument. Complete the circuit from the 3-volt binding post to the armature shaft or motor frame.

If an indication is obtained, the armature is grounded. The cause of the ground is very likely due to damaged insulation on the armature conductors. The armature should be carefully examined for this.

On one-wire systems of the two-unit type, a grounded coil will result in slow cranking and a materially reduced charging rate.

In some starting and lighting outfits using motor-generators, two windings are placed on a single armature, each being brought out to a separate commutator. One winding is for the motor and the other for the generator. A ground may develop between these windings.

To test for such a ground the terminal of the instrument which was attached to the shaft or frame of the car should be transferred to the second commutator and the general directions followed. See also test-light test, page 497, Fig. 28.

Testing the fields for grounds: Transfer the connection from the commutator segment to one end of the field. **If an indication is obtained,** the field is grounded.

When the system is of the single-unit type, such as a motor-generator, both motor and generator fields are wound on the same field frame. It is possible for these windings to develop a ground to one another.

The method of testing for such a ground is to interpose the instrument and a cell between one end of each winding. If a ground exists an indication will be obtained.

Caution: Be certain that the ends of the field coil are not touching the motor frame.

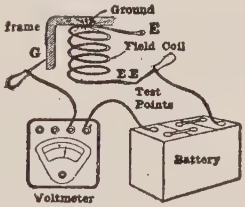

Fig. 9

When testing the field for a ground, be sure both field coil ends (E) and (EE) are disconnected from all terminals. Use the 30-volt connection as shown in Fig. 9. Place one test-point on (EE) and the other on the frame at (G). If deflection is shown, the coil is grounded and a new one must be supplied.

Testing grounded brush-holders: This test is made in the same manner as the test for a grounded armature, except that the connections should be made between the shaft of the armature or frame of the car and each brush-holder. Insert a piece of cardboard between the brushes and the commutator before making this test. If an indication is obtained, the brush-holder is grounded.

These tests are applicable to the generator.

EXAMPLE OF HOW A STARTING MOTOR IS TESTED ACCORDING TO DATA GIVEN IN THE SERVICE MANUALS[1]

In order to make certain facts clear to the reader, which are usually found in Service Manuals, we shall use some data from the Remy Service Manual on the test of a starting motor, model "118-A," as follows:

Speed, Torque, Current Data Table

Starting Motor. Model 118-A, with Bendix drive.

Torque (Pull with 6″ Pulley)	R.P.M.	Amperes	Volts
0 lbs.	3750–4250	32–40	6.0
6 lbs.	1500–1540	88–98	5.7–5.8
9 lbs.	1200–1400	110–120	5.5–5.7
12 lbs.	1020–1150	130–145	5.4–5.5
16 lbs.	800–1000	158–175	5.3–5.4

Torque of an armature is the momentum tending to turn it. In a generator, it is the momentum which must be applied to the armature to turn it in order to produce current. In a motor, it is the turning momentum which the armature gives to the pulley or gear. The torque is greatest when starting, and is in proportion to the load.

Observe that the **data given above are for a torque test of a starting motor.** Therefore we shall use a simplified torque test apparatus, consisting of parts shown in Fig. 10.

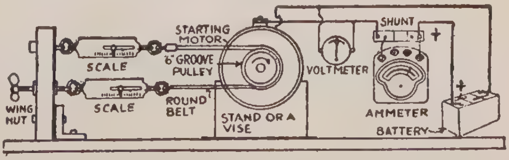

Fig. 10. Simplified illustration showing how a torque test of a starting motor is made.

---

[1] See advertisements in the back of book for Service Manuals.

The starting motor is placed in the stand (Fig 10) with a 6″ pulley on it, and is first given a "free running test" and then connected with an adjustable belt and two spring scales for making the "torque test."

The starting motor is then connected with a fully charged battery known to be in good condition (a 6-volt battery in this instance), and an amperemeter with a 300-ampere shunt is connected in the circuit as shown. A voltmeter is placed across line.

19A. Speed Indicator.

A speed indicator is used to indicate the speed. On modern test stands, as shown on page 507, a tachometer indicates the speed, but in this instance a hand-type speed indicator (Fig. 10A) is used. The point of the speed indicator is placed in the end of the motor armature shaft, and the number of revolutions per minute is counted.

Motor Free Running Test

Note on the first line of the table, on page 489, that the torque is given as 0 lbs. at 3,750 to 4,250 r.p.m., and 32 to 40 amperes at 6 volts.

Procedure of test: The motor is placed on the stand with belt detached, that is, the motor is permitted to run "free." According to the second column of the table, the motor should develop 3,750 to 4,250 r.p.m.; according to the third column of the table, the ammeter should indicate 32 to 40 amperes under these conditions; according to the fourth column of the table, the voltmeter should indicate 6 volts.

Motor Torque Test

Note on the second line of the table (page 489), that the torque is given as 6 lbs. at 1,500 to 1,540 r.p.m., and at 88 to 98 amperes at 5.7 to 5.8 volts.

Procedure of test: The belt is now attached, the motor started, and the wing nut tightened until the **difference** between the readings of the two scales is 6 lbs. (that is, a pull of 6 lbs. is exerted by the motor). The speed should then be 1,500 to 1,540 r.p.m.; the ammeter should indicate 88 to 98 amperes, and the voltmeter should indicate 5.7 to 5.8 volts. The test should be continued, using the various values of torque as given in the table. Note that the "value of the torque" refers to the **difference** between the readings of the two scales.

An Explanation of Difference in Scale Readings

Suppose that the upper scale in Fig. 10 reads 26 lbs., and that the lower one reads 20 lbs. It seems at first that the motor is exerting a pull of 26 lbs. on the top scale; note, however, that the bottom scale is helping the motor by pulling with a force of 20 lbs., and that therefore the motor itself is only pulling 6 lbs., or the difference between 26 lbs. and 20 lbs.

Stalling or Locked Torque Test

Procedure of test: Tighten the wing nut until the motor comes to a dead stop: this is termed "stalling" or "locked." The difference in scale readings at this time gives the pull exerted by the motor. This pull should be very high, as it is the force which, when the motor first starts a cold engine, breaks the oil film. The amperage will also be very high.

Therefore, note that with a series-wound motor, the greater the load, the greater the amperage consumption and the less the speed. Also note that the greater the load, the greater the voltage drop.

Such data as these are given in the Service Manuals referred to in the advertisement in the back of this book.

EXAMPLE OF HOW A GENERATOR IS TESTED ACCORDING TO DATA GIVEN IN THE SERVICE MANUALS

The Remy generator (relay regulated type) model "16-A" is used as an example.

Speed, Current Data Table

Generator without ignition. Model 16-A, using relay regulator regulation.

Amperes	R.P.M.	Volt
0.	370	6.0
7.	490	6.5
14.2	2200	6.9

On **"battery test,"** field draws 3 to 3.5 amperes at 5.9 volts.

"Generator motoring," draws 4 to 4.5 amperes, 5.8 volts and runs at 430 R.P.M.

Note that in the table there are given **three methods of testing:**

1. **By driving the generator** on the test stand and connecting it to the battery through the cut-out, as if on the car (Fig. 11).
2. **By making a "battery test" of the amount of current drawn by the shunt-field windings,** by connecting a battery across the shunt-field circuit with armature disconnected (Fig. 12).
3. **By "motoring the generator,"** that is, by running the generator by the battery free, without a load, i.e., with no tight bearings or binding at any point (Fig. 13).

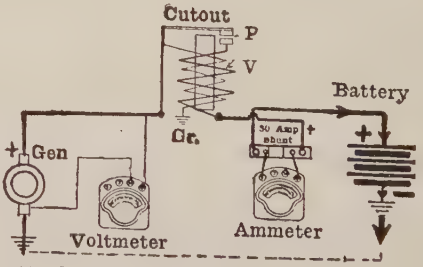

Fig. 11. Testing a generator by driving the generator.

Method 1: By driving the generator at a speed of 370 r.p.m., "0," or zero amperage, would be indicated (see table); but 6 volts is the voltage that should be indicated. The cut-out points (P) (Fig. 11) would be open, as the speed is not great enough to produce pressure sufficient to close contact-points (P). At 490 r.p.m., 7 amperes and 6.5 (6½) volts should be indicated. The cut-out points (P) should close, and the generator would charge the battery. At 2,200 r.p.m., 14.2 amperes (maximum) and 6.9 volts would be indicated. **The ampere-meter** is placed in series with the circuit indicated above, as in Fig. 11. **A voltmeter is placed across the circuit,** to indicate the voltage.

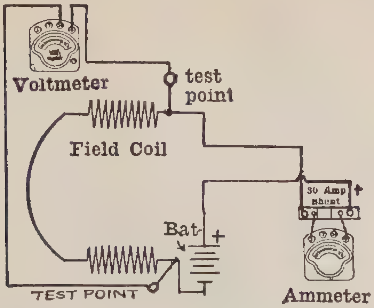

Fig. 12. Testing a generator by observing the amount of current taken by the shunt-field winding.

Method 2: By connecting a battery to the shunt-field winding terminals (Fig. 12) **with an ammeter in series with the circuit,** the ammeter should show 3 to 3.5 amperes. **With a voltmeter across the circuit,** as shown in Fig. 12, it should indicate 5.9 volts.

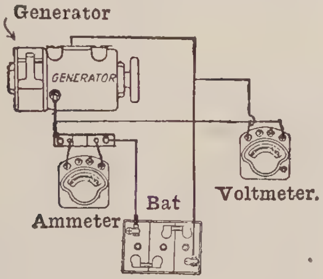

Fig. 13. Testing a generator by "motoring" it.

Method 3: By connecting this shunt-wound generator to a fully charged battery (Fig. 13) **with** the armature and all brush connections complete, and **with an ammeter in series** with the circuit and **a voltmeter across the circuit,** the generator running as a motor (termed "motoring-generator") should draw 4.0 to 4.5 amperes, and the voltmeter should indicate 5.8 volts; the generator operating as a motor should run at a speed of 430 r.p.m.

Generator Trouble Indications when "Motoring" a Generator on the Test Stand (Ford Generator as an Example)

The following tests and determinations may be made with an ammeter in the circuit and a generator connected with the 6-volt battery. Preferably one which has been in use is used, and the connections are made as shown in Fig. 14.

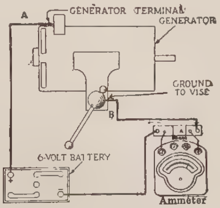

Fig. 14. Connections for motoring generator.

1. **The correct reading** is from 2 to 4 amperes, the generator running at a slow, steady speed, with no arcing at the brushes.

2. **A heavy discharge,** with the hands going beyond the limit of the instrument, indicates trouble in the head, such as the third brush not seated, fields open probably at the third brush or ground connection, the third or positive brush-holder or pigtail shorted. To prove an open field, raise the third brush and connect (A) to it. If open, no reading will be shown on the ammeter.

3. **No reading on the ammeter** indicates a dirty commutator or the brushes not seated upon it, because of the brushes sticking in the holders, or being worn too short to make proper contact, or sprung out of shape so one or both press against holder.

4. **The ammeter fluctuating between 18 and 20 amperes,** indicates short circuits in the armature.

5. **The ammeter reading 6,** with a higher r.p.m., indicates a shorted field.

6. **If the ammeter is normal,** but there is a decided flash at one point on the commutator, an open armature is indicated. Turn the armature over by hand, one segment at a time; if there is a point where the armature will not start to rotate, that coil is open.

COMMUTATOR TROUBLES AND TESTS

Commutator troubles can be classed under three headings: (1) those due to defective manufacture; (2) those due to surface wear or deterioration in service; (3) those due to a dirty or burned commutator.

Defective commutators may be grounded, may have a short circuit between the segments, or may have loose segments or high mica, or loose brush-holder springs.

Sparking at the brushes will be caused by any of the causes mentioned above, or by loose pigtails, or by loose connections of wires to the brushes, by sticking brushes, by overloading of the generator, and by short circuits in the armature windings.

If the commutator is dirty, and if grease and carbon dust have accumulated between the commutator segments, to such an extent that the bars are shorted, excessive sparking will be the result, and no current, or very weak current, will be allowed to pass.

Examine the Commutator

First, **examine the commutator** to see if it is dirty, and if it consequently prevents proper contact between the brushes and the commutator bars. If it is all blackened and covered with grease, no current, or a very small current only, will be allowed to pass.

Cleaning Commutator

If the trouble is due to grease and dirt only, it can easily be cleaned. Start the generator, and while it is running, hold a piece of cloth dampened with gasoline against the commutator bars to remove the grease.

Next, use a finely pointed tool and clean out any dirt or grease that may have accumulated between the commutator bars.

Sanding the Commutator

If the commutator is dirty, caused by excessive sparking, it will be necessary to sand it by the use of a very fine piece of sandpaper, not coarser than No. 00, held against the commutator (rough side down) while the generator is running. Never use emery cloth.

The strips of sandpaper should be a little wider than the brush (Fig. 15) and wrapped around the

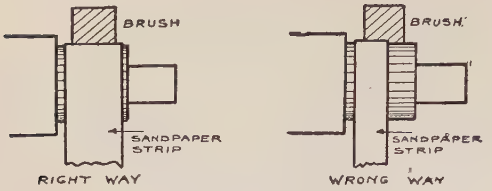

Fig. 15. Right and wrong way to sand a commutator.

commutator so as to make contact with at least half of its circumference. Fig. 15 shows the correct method on the left and the incorrect method on the right.

Worn Commutator Bars

The next source of trouble may be a very badly worn commutator, which would allow the mica between the bars to become flush with the surface of the bars. The mica should be kept slightly below the surface of the bar (which is done by undercutting the mica as explained farther on).

Mica Protruding

If the mica insulation between the commutator bars becomes flush with the bars, the brushes cannot make good contact, and this causes arcing or sparking, which burns away the bars until they are below the level of the mica which then protrudes. This not only prevents the brushes from making good contact, but the bars are pitted and become very rough. Fig. 16A shows the appearance of a commutator with protruding mica.

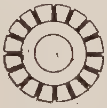

Fig. 16

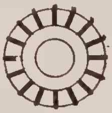

Fig. 16A

Fig. 16. Mica correctly undercut.
Fig. 16A. High mica before cutting.

This trouble is more common on generators. On starting motors, where brushes do not make contact, the commutator becomes rough and causes arcing. The mica is not undercut on a motor commutator, but if rough, it is put in the lathe and turned down with a very sharp lathe tool to take a very fine cut off the surface of the commutator.

Dressing Commutator Down and Undercutting the Mica

To remedy protruding mica: Remove the armature and very carefully true or dress it up on a lathe, as in Fig. 17. Then cut out the mica between the bars with a hack-saw blade, the sides of its teeth having been ground off so that it will cut a groove slightly wider than the mica insulation, as in Figs. 18A and 19. This will leave a rectangular groove free from mica; the depth should be about 1/32″. It is important that these spaces be free and clear of all foreign matter.

The edges of the slots should then be slightly beveled, using a three-cornered file (Fig. 18) in order to prevent any burrs remaining, which would cause excessive brush wear.

When properly finished, the commutator will have the appearance shown in the illustration (Figs. 16 and 19).

Note. The mica can also be cut by placing a special tool in the lathe and moving it laterally as a planer (Fig. 17).

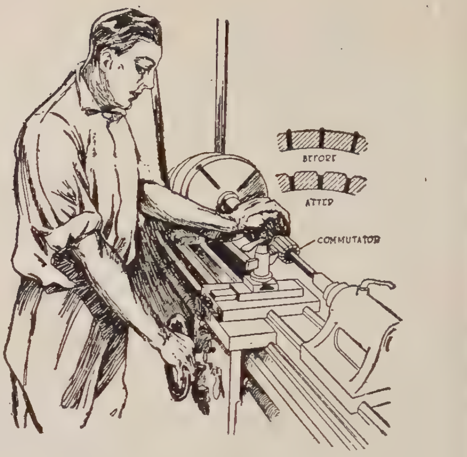

Fig. 17. Dressing down a commutator on a lathe when it is very rough, or when mica protrudes above the commutator bars.

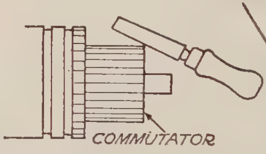
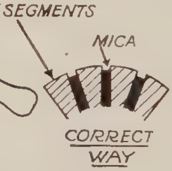


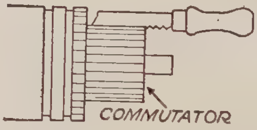
STARTING GROOVE IN MICA WITH 3-CORNERED FILE.

Fig. 18



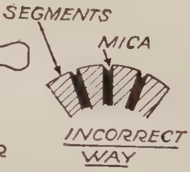
MICA MUST BE CUT AWAY CLEAN BETWEEN SEGMENTS

Fig. 19



SLOTTING MICA WITH PIECE OF HACKSAW BLADE.

Fig. 18A



MICA MUST NOT BE LEFT WITH A THIN EDGE NEXT TO SEGMENTS

Fig. 19A

The blackened and burned appearance of the commutator is not always caused by high mica. The same effect may be caused by having brushes of improper size or material, by an insufficient spring tension on the brushes, by an overload on the generator, and by an open or short circuit in the generator windings; or, where there are two windings on one armature with two commutators, by a short circuit between the motor and generator windings.

Commutator and Other Noises

Protruding mica and improperly seated brushes produce a noise which can easily be detected.

Noises are sometimes due to bent armature shafts, broken balls, or worn bearings. If an improperly seated brush causes the noise, it can sometimes be eliminated by setting the brush to one side with a small stick. Do not use a screwdriver.

Do Not Use Grease on the Commutator

It is unnecessary to lubricate either a generator or a motor commutator, as the grease or oil mixes with the carbon dust from the brushes. This will soon soak into the mica insulation and form a path between the bars, thus short-circuiting the commutator bars, and, consequently, the armature coils connected with them. This is common on old generators where the bearings wear and permit oil to pass into and on the commutator.

Loose Commutator Connections

One can tell if the generator is generating its proper output by observing the dash ammeter. One should learn just what the maximum output should be. If it generates a very low amperage, say about 2 amperes, and then at times none at all, the trouble may be due to a loose connection and sometimes that loose connection is at the point where the end of the armature coil is soldered to the segment of the commutator, which, although apparently securely soldered, may be loose. Furthermore, it may not be loose when stationary, but when it is revolving, the connection is thrown loose by centrifugal force.

One method of testing is to use a test light and test points. Place one test point on the commutator segment connected with the suspected loose armature coil and the other on the segment 180° apart, or on the extreme opposite side of the commutator, which is the other end. On passing the current through the armature coil in this manner, there will probably be a slight spark or arc at the point where loose. Test all segments in like manner, and resolder any that are loose.

Another Commutator Trouble

High segments in a commutator, the result of the commutator having been turned or dressed down eccentrically with the armature shaft (out of round), will cause the generator to produce weak current or none at all, especially at high speeds, owing to the brushes not making good contact.

The test for these two conditions is to press on each of the commutator segments at both ends with some blunt instrument. If there is the slightest movement at either end of a segment it is loose, and a new commutator will have to be installed.

To determine whether or not the commutator is running true with the armature shaft center, whittle a piece of crayon to a point and, with the generator running, bring it slowly up against the surface of the commutator. If it is out of round with the armature center the chalk will mark the high spot and leave the low side unmarked, provided the test is carefully made.

If the commutator is out of true, re-turning, using the correct size of ball bearings as supports, will be necessary.

Besides the foregoing a few other causes will give rise to the same effect. Among these are weak brush springs, sticking brush-holders or brushes, connections which are not tight enough and which, vibrating at certain critical engine speeds, introduce a resistance into the exterior line.

It may also be possible that the **armature windings are not secure in the slots,** and that, at high speeds, one of the coils moves a trifle and, coming in contact with the iron of the armature coil, forms a ground. As the armature slows down, the natural spring of the coil brings it back to a normal position in slot and causes the armature to show "clear" when tested.

Testing for a Dirty or Rough Commutator with a Voltmeter

Connect the voltmeter terminals so that the voltmeter will read 0 to 30 volts as shown in Fig. 20. (The construction of this Weston voltmeter is shown on page 468.)

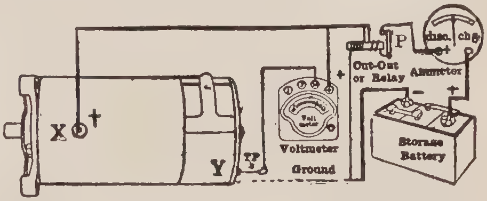


Fig. 20. Testing for a dirty or rough commutator with a voltmeter.

The positive (+) terminal of the voltmeter is connected to the positive (+) wire of the generator. The other terminal from the voltmeter which has a test point (TP) at its end, makes contact with the frame of the generator at (Y) (this being a grounded or return-wire system).

Then speed the engine up to a speed corresponding to a car speed of 10 to 15 miles per hour. **The voltmeter should show slightly over 6 volts** and the cut-out (V) should be closed, showing "charge" on the dash ammeter or indicator.

If the voltmeter does not show slightly more than 6 volts, this indicates a **dirty or rough commutator,** or else an **open circuit** in the shunt field. Press down lightly on the brushes while the generator is running, and if this causes the voltmeter to indicate and the cut-out to close, the trouble is due to **bad brush contact,** which can be remedied as just mentioned.

If the voltmeter cannot be made to indicate and the cut-out point (P) fails to close by cleaning the commutator and pressing on the brushes, the trouble is probably an open circuit in the shunt-field winding, which will have to be repaired locally or sent to the factory.

If the voltmeter does show 6 volts or more, by pressing down on the brushes, or by cleaning the commutator and brushes, but the cut-out will not close, it means that the cut-out is not in proper adjustment, and a new one should be provided if it is defective internally. The trouble may be due to loose connections on the cut-out, or to disarrangement of the contact-points, which can be examined and tested. See Index under "Testing cut-outs."

If the commutator is dirty then clean it. The probabilities are that the mica is protruding. This can be remedied as explained in preceding paragraphs.

BRUSH TROUBLES AND TESTS

Brush troubles are very common. Some of the troubles are: brushes sticking on their holders, brush springs not pressing on brushes with proper tension, loose brush-holders, loose connections to brushes, improperly seated brushes.

Brush and Brush Rigging

The open circuit is often caused by one of the brushes sticking in the brush-holder, from dirt. The remedy is obvious, that is, to clean the brush thoroughly and see that it moves easily in the brush-holder under the regular action of the spring.

No Spring Pressure

The brush spring may not have sufficient tension to hold the brush in contact with the commutator with sufficient force to give a good contact. This not only will show a partial or full open circuit, due to insufficient contact pressure, but it will be the cause of serious sparking between the commutator and the brush, and will soon burn and blacken the commutator so badly that a full open circuit will result, and no current will be generated at all.

A new spring with sufficient tension is the best way of repairing this trouble. The tension should be strong enough so that when the brush is pulled off the commutator by means of the pigtail, and then released, the spring pressure snaps it back freely on the commutator. **Too much spring pressure** has the effect of rapidly wearing out both commutator and brush, but is better than too little spring pressure.

The **approximate average brush-spring tension** on starting motors is 1 to 1¼ lbs., and from 12 to 18 oz. on generators.

Brushes Too Short

If the brushes are allowed to go too long without replacement, and are worn so short that the spring pressure is reduced very considerably, the same troubles will result. Be sure in replacing brushes to use only those of such a make as are recommended by the manufacturer; otherwise you are likely to have repeated troubles with both brush and commutator.

Broken Brush Connection

An open circuit will be caused by a poor or broken brush lead, or pigtail connection. In general, see that the brushes move smoothly in the brush-holders and that the springs press firmly and squarely on the top of the brush.

Fitting Brushes

The brush must always make good contact with the commutator; it should have sufficient spring tension to press the brush to the commutator, yet move freely.

Seating Brushes

When fitting new "generator" brushes, it may happen that they do not always fit the commutator perfectly, that is, they are not rounded to the curvature of the commutator surface.

This can be remedied by placing the rough side of a strip of No. 00 sandpaper under the brush, when it is in its brush-holder (each brush separately), and working the strip back and forth, holding the ends close together as in Fig. 21, so that it will conform with the curvature of the commutator. The entire surface of the brush must be treated, otherwise it will be uneven. The "pigtails," or brush connections must also be kept tightened.

When fitting "motor" brushes, the same method is applicable, but something harder than sandpaper must be used. A strip of carborundum cloth can be used on the "motor brushes," but sand-cloth should be used on the "motor commutator." It is seldom necessary to cut mica down on the motor commutator.

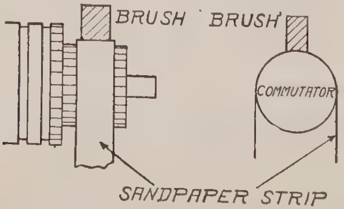

Fig. 21. Correct method of seating brushes. Place the sanded side of the sandpaper up. With the sandpaper held as shown above, a true arc is made on the brush for the entire length of contact on the commutator.

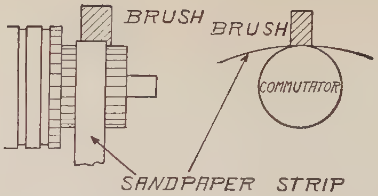

Fig. 22. Incorrect method. Note that only part of the brush is being seated. If held in position as above, the ends of the brushes are worn off, through the upward pull of the sandpaper; also the brush is subject to being pulled off the commutator while it is being sanded.

The motor brushes should be "sanded in," to avoid brush squeak which occurs sometimes as a result of a rough or irregular commutator surface, or grooves in the brushes. For this reason, if the motor commutator is rough, it is desirable to smooth it up, and then "sand in" the brushes at the same time that the mica on the generator commutator is undercut. If it is excessively rough, turn the commutator down in a lathe, being careful not to remove any more copper than is absolutely necessary.

On most of the Delco machines it will be found possible to "sand in" the upper and lower brushes by this method separately; but in a number of cases, on account of the construction of the machine, it is advisable to "sand in" both motor brushes, as well as both generator brushes, at the same time.

Spotting in Brushes

On some generators **it is not possible to "sand in" the brushes** in the manner explained above, **because the brush arm is too short.** In this case, the brush should be placed in a brush-holder and let down firmly on the commutator. Then "motor" the generator by running it from the battery as a motor. Then disconnect battery and remove brushes, leaving the "high spots." These can be scraped down.

Seating the Delco Flexible Brush

The design of the flexible generator brush arms and the third brush carrying a thermostat, used on many Delco four-pole round types of motor-generators and generators is shown in Fig. 23 (a later design is shown in Figs. 23B and 23C). Instead of the brush arm being rigid, it is made quite flexible by the use of a thin piece of phosphor bronze between the body of the brush arm and the carbon brush. Damage to the commutator is prevented, in case of brush breakage, by the insulating safety plate on the end of the brush arm, this plate being loosely mounted by the special heads of the screws securing the brush to the brush arm.

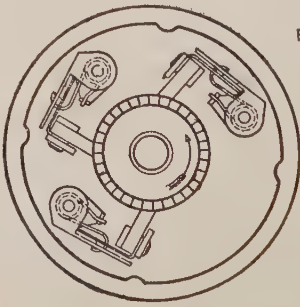

Fig. 23

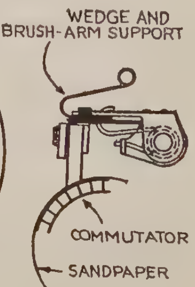

Fig. 23A

Fig. 23. Front, or commutator end view of Delco generator showing the flexible brush arms.

Fig. 23A. A side view showing brush seated on commutator. This model is now replaced by those shown on the next page.

It is very important to have this type of brush fully seated on the commutator. The brush cannot be properly sanded in by the usual methods of sanding brushes. It is necessary to place wedges between the brush arm body and the phosphor bronze, as shown in Fig. 23A, to prevent the flexible action of the brush arm during sanding. These wedges should be just thick enough to fit in place without falling out, approximately .075″. A strip of fine sandpaper or sand-cloth may then be used to seat properly one brush at a time.

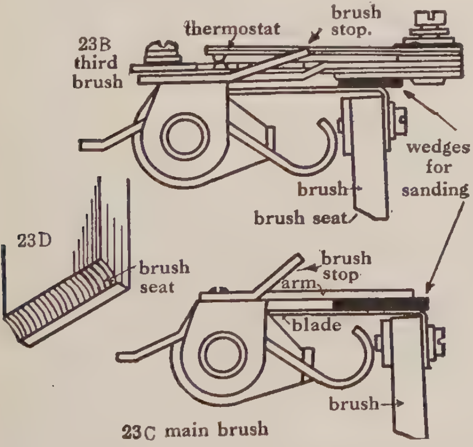
Another very successful method is to remove the end housing carrying the brush arms, so that a strip of fine sandpaper may be wrapped snugly once or twice around the commutator, gluing the overlapping edges of the sandpaper to secure it. The end housing may then be replaced and all three brushes properly sanded at the same time. This operation should cause the brushes to have a full seat on the commutator.

Remove the wedges in the brush arms and the sandpaper after the operation is completed.

The Delco Later Design of Flexible Brush Arms with Stops

A later design of Delco flexible brush arm with stops is shown in Figs. 23B and 23C.

The brush should always be assembled on the inside of the arm as shown.



Figs. 23B, 23C. Later design of Delco flexible brush arms with stops.

Fig. 23D. Showing how the brush should be seated.

Always replace all three brushes whenever inspection shows that the grounded brush has worn so short that its brush stop, coming into action, may soon keep the brush from contact with the commutator. This is the brush (on the Cadillac using No. 162 Delco motor-generator) which is on the right side of the commutator viewed from the front of the car.

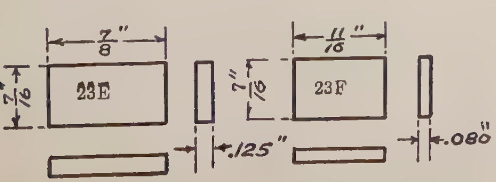


Fig. 23E. Dimensions of wedge for the third-brush arm.

Fig. 23F. Dimensions of wedge for the main-brush arms.

It is very important to have this type of brush seated on the commutator, at least to the extent shown in Fig. 23D. The brush cannot be properly "sanded in" by the usual method of sanding brushes.

It is necessary to place wedges between the brush arm body and the bronze blade to which is attached the brush. Two sizes of wedges are necessary, one size for the main-brush arms, and the other for the third-brush arm, owing to the difference in space between the body of the arm and the bronze blade.

These wedges are shown in Figs. 23E and 23F. Figs 23B and 23C show their application to the brush arms. These wedges prevent the flexible action of the brush arms during the sanding operation, keeping them rigid, and giving a seat more nearly over the entire brush.

These wedges should be just thick enough to fit in place without falling out, approximately .080″ for the main-brush arms (23F), and .125″ for the third-brush arm (23E). It will be found that the distance between the body of the arm and the bronze blade varies in some assemblies. It will be necessary in these cases to make the thickness of the wedges a little less by filing, or a little more than specified above by wrapping a couple of turns of paper around the wedges.

To sand the brushes after the wedges are properly fitted to the brush arms, wrap a 1″ strip of sandpaper, or sand cloth, snugly once or twice around the commutator, glueing the overlapping end to secure it. A drop or two of glue should be put on the commutator previous to putting on the sandpaper to hold the paper in place and prevent it from slipping during the sanding operation. The sandpaper should be wrapped around the commutator in a counter-clockwise direction, looking at the armature from the generator-commutator end.

After the glue has dried a few minutes, place the end housing carrying the generator brushes on the armature shaft and lower the brushes down on the sandpaper which is around the commutator. To prevent chipping of the edges, do not snap the brushes down on the commutator. Hold the armature in a vertical position with the housing at the top and revolve the housing in a counter-clockwise direction. This will sand all three brushes at the same time. When proper seating is accomplished, raise the brushes, remove the housing from the armature shaft and the sandpaper from the commutator. Avoid waste of brush material by being careful with this operation. Remove all glue from the commutator by sanding and remove the wedges from each of the brush arms.

To determine the seating of the brushes, mount the housing on the armature again as was done in sanding; revolve the housing several times with the brushes on the commutator. Then remove the housing as after the sanding operation, and inspect each brush seat, which is shown by a polished surface.

If at least a 75 per cent brush seat is not obtained, the wedges should be inserted again and the brushes reseated until a good seat is obtained. It may be necessary to make the wedges slightly thinner, or thicker, according to whether the seat is on the heel or toe of the brush.

It is very important that good brush seats be obtained before installing the generator on the car. If good seats are not obtained, a change in the charging rate will result as soon as the brushes become thoroughly seated.

Setting Motor Brushes

Motor brushes should be set at the position of **least sparking** when the machine is carrying **full load.** This position will be located a short distance back (in the direction opposite to rotation, instead of with direction, as on a generator) from the neutral plane.

To set motor brushes in the correct position, place the machine on a block test and apply a load approximately equal to that which it is normally required to carry. (This load will be about 40 lbs., on a pulley of 6″ diameter, or 10 ft. lbs. for starting motors.)

The speed of a motor is greatest when the brushes are at the neutral plane, and decreases as they are moved away from that position. The voltage of a generator and speed of a motor can be changed considerably by moving the brushes, providing the machine is not too heavily loaded so that it will not spark badly.

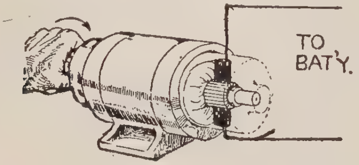

Fig. 24

In the absence of a torque-testing device, **a good method for setting brushes on a starting motor** is to place the motor on a "free running" test, no load (connected with battery), and to hold the shaft by hand, with a rag (Fig. 24), so as to offer more or less resistance; then shift the brushes to a point where they do not spark.

Setting Generator Brushes

If the generator will not come up to voltage, and the trouble is not due to improperly seated brushes, and the third brush is properly adjusted, set the brushes on "neutral" and then shift to the best position. See page 360, relative to neutral position.

Note. Use only brushes recommended by the manufacturer.

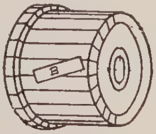

Fig. 25. Showing incorrect setting of brush on commutator.

Brushes should be set parallel to the commutator segments. Improperly seated brushes will act like a cut-out which is not working properly.

Brush Care

Once or twice a season the springs holding the brushes against the commutator should be raised and the brushes examined, to see that they operate freely in their holders. Oil or dirt should be removed with a stiff bristle brush and gasoline.

To Clean the Brushes

It is not necessary to remove them from the holders. Lift the brushes and wipe off the surface with a piece of cloth dampened with gasoline.

If the brush surface is apparently rough, then use sandpaper to fit them to the commutator, as shown in Fig. 21.

No lubricant is to be used on commutators, as the brushes are usually self-lubricating. Application of vaseline or grease is harmful, as all forms of grease possess insulating qualities to a greater or less extent.

Miscellaneous Brush Troubles

When spring tension fails, the brushes are worn too short, the tension is not adjusted or has been thrown out, through heat, or the springs themselves may be broken.

When the brushes stick, it may be due to binding or to dirt and grease. A little gasoline may tend to loosen them. When the brushes do not fit the brush-holders it is a matter of manufacture.

Overheating of brush-holders is caused by the sparking due to ill-fitting brushes or to the absence of brush lead connection and to lack of sufficient pressure on the brush.

Sparking at the brushes: If there is any sparking, or if the commutator becomes dull, it may be that the brush-holder springs are too loose, or there is excessive vibration, which may be due to a bent shaft, an unbalanced gear pinion, or to defective mounting. Brushes should be kept in perfect contact with the commutator, and it is advisable to use only the kind recommended by the manufacturer.

It may be found that where the generator is also used as a starting motor (on motor-generators), **sparking will in time develop at the commutator.** This is due to the arcing of the heavy starting current at the trailing edges of the brushes, and the trouble may be eliminated by filing down their contact surfaces.

Carbon dust (providing carbon brushes are used) may be worn from brushes by the commutator and deposited in the lower part of the generator. **This ought to be blown out with air,** otherwise it might cause a ground.

ARMATURE TROUBLES AND TESTS

In the preceding pages, the subject of **"commutators and brushes"** was treated. This is usually the first place to look for generator troubles.

Other troubles are:

Evidence of trouble: In all probability, trouble in the generator will be clearly shown by failure to generate a terminal voltage. The first warning of such a trouble would be the absence of an indication on the ammeter or indicator on the dash of the automobile, provided one is furnished with the automobile.

Causes: The causes of failure to generate a voltage may be due to (1) open circuits, short circuits and grounds in the field or armature of the generator; (2) the commutator may be dirty, or the brushes may not bear on the commutator, or the commutator may be worn; (3) the brushes may be grounded.

Locating Armature Troubles

Armature windings may be burned out or grounded. When burned out, the trouble may be due to a current overload, caused by improper regulation, a soaked winding, or a steady and prolonged return flow from the battery, due to failure of the cut-out contact points to open. A grounded armature winding is due to defective insulation.

Armature troubles are sometimes found in the attaching leads at the commutator segments. The solder attaching them may be thrown off in revolving. They can be soldered back to the segment by an electrician.

Dim lamps, low voltage, and undercharged battery might be the result of armature trouble. One of the armature coils might be short-circuited, or burned out, or a connection might be loose or broken.

Any defect in the armature will be indicated by an uneven torque, if it is operated as a motor. In the case of the generator, this may be very easily tested by disconnecting the driving mechanism, holding the cut-out points closed, and allowing the generator to operate as a motor. If everything is all right the armature will rotate evenly and in the same direction as when it operates as a generator.

Whether the torque is even or not may be determined by holding the end of the armature shaft in the hand, and noting whether the pull is steady in a manner similar to that described in Fig 24. An uneven pull means that one or more of the coils is not working; it is just like an engine with a missing cylinder. See also Index under "Motoring generator."

If an armature coil is burned out or there is a broken connection, the armature will invariably stop at a certain point; if this is the case, the commutator segments between the two ends of the coil will also be burned. Sometimes the broken connection occurs at the junction between the commutator bar and the coil, in which case the remedy is to resolder. All other armature defects should be left for the factory to remedy.

No current in the generator may be due to an open fuse in the field circuit, the third brush not being properly seated, or to the main brushes not making good contact, or to a broken connection, to a short circuit, or to broken driving mechanism. The last trouble should be looked for first. This simply means that the generator driving shaft should be tested to determine whether it is solidly connected to the engine or not. It is possible that one of the driving keys has sheared off, or that the driving gear, chain, or belt, as the case may be, has failed. See also "Digest of Troubles," page 454.

Loss of Residual Magnetism

The magnetism that remains in the steel or iron field poles and frame after the field current is cut off is called **"residual magnetism"** (see also Index). Sometimes the generator loses its residual magnetism.

When a **repaired generator** has been installed, and possibly with the **field coils reversed,** the residual magnetism left in the field poles would not correspond with the magnetism in the field coils; or when the generator has been in operation for some time with the field fuse out of the clips; or if the generator has been operated with the **battery disconnected,** and the generator terminal grounded, according to the usual instructions, it may be necessary to **excite the field** before the generator will show charge. This is accomplished by momentarily closing the cut-out points so that the battery will discharge through the generator, thus exciting the fields.

On some generators, the field can be excited by momentarily connecting the lower fuse clip to a metal part of the generator. Best results will be obtained with the engine running slightly above an idling speed, and if the operation is continued for several minutes after charging begins.

Submerged Motor-Generator

The generator must be kept free from excessive moisture. Ordinary moisture will not affect it, but it should not be allowed to become thoroughly wet, such as would be the case if the generator were to become submerged under water. This is likely to happen while fording a stream. If the generator is wet, it should not be operated until it is thoroughly dried out. This can be done by removing it from the car and baking 24 hours in an oven whose temperature does not exceed 220° Fahr. A higher temperature in the baking oven would damage the insulation.

Testing Armatures for Grounds and Short Circuits with Test-Light

There are several methods for testing armatures. They can be tested with test-lights and test-points, with a meter, or with a growler.

In this example we shall make use of **the high-voltage test-light** and employ the Delco motor-generator armature, in which there are two commutators and two windings on armature. These tests will also apply to other armatures, or where there is but one winding and one commutator, with the exception of the test in Fig. 28, which is a short-circuit test between two windings on the Delco armature.

When making tests for grounds in armature windings, or short circuits between them, or short circuits between generator and motor armature winding, raise the brushes and insulate them from the commutator with pieces of cardboard.

A grounded generator armature coil will result in slow cranking and materially reduce the charging rate. (Note that the motor and generator winding is on one armature in this Delco armature, which is used as an example).

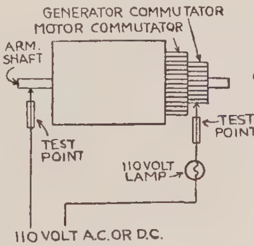

Fig. 26

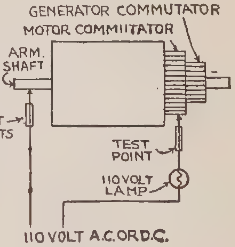

Fig. 27

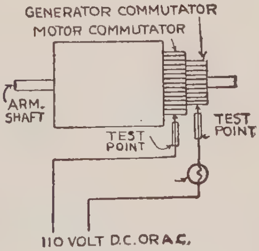

Fig. 28

Figs. 26, 27, 28. Tests with a test-light for grounds in armature. Delco motor-generator armature with two commutators used as an example. Tests apply to any other type of motor or generator armature.

To test whether the armature coil is grounded with the armature core or shaft, see Fig. 26. If the lamp lights, a ground is indicated.

A grounded motor armature coil will cause an excessive amount of current to be drawn from the battery while cranking, or prevent cranking entirely.

To test whether motor armature coil is grounded, see Fig. 27. Place the test-point on the motor commutator instead of on the generator commutator. If the lamp lights, a ground is indicated.

Short circuits between motor and generator armature coils will decrease the speed of cranking and also cause the armature to continue to run after the engine is shut down.

To test, see Fig. 28. If the lamp lights, a short circuit between motor and generator armature coil exists.

Note. The word **"cranking"** refers to the starting motor cranking the engine.

Meaning of Open and Shorted Armature Coils

The diagrams **A, B,** and **C,** Fig. 29, will explain **what is meant by an open and short-circuited armature coil. A** shows diagram of commutator with brushes which make contact with segments and carry the current during the test. It will be seen that the current **divides equally** from the upper brush, passing down each side of the armature coils, or winding circuits, and out at the lower brush, and **if in good condition, the voltage between two commutator segments will be the same.**

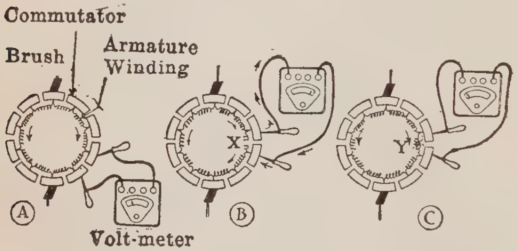

Fig. 29. Diagrams explaining open and short-circuited armature coils.

If an open circuit is in one of the coils, as at (**X**) in diagram **B,** there will be an interruption of current flow on that side, and if test-points of a voltmeter are placed on the two segments shown there will be a big **increase** of the needle, since the meter will carry all of the current flowing down that side. If points are placed on other adjacent segments on that side, there will be nearly a zero reading.

If a coil is short-circuited, as at (**Y**) in diagram **C,** the voltmeter, if placed on the segments shown, will be **nearly zero,** the short circuit having the effect of a shunt across the meter.

Armature Tests with the Volt-Ammeter for Open-Circuited and Short-Circuited Armature Coils[1]

Before proceeding, turn to pages 464, 468, and study the construction of the Weston model "280" volt-ammeter, which is used in the following test.

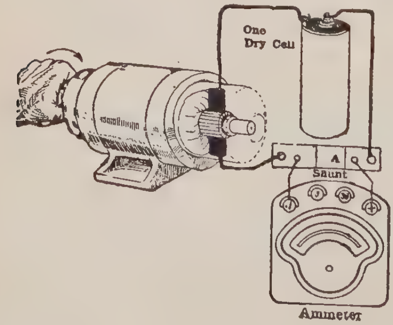

Fig. 30. Testing armature coils with one dry cell and an ammeter.

Open or short-circuited generator armature coils: When testing for open or short circuits in a generator armature, the generator brushes should be left on contact with the commutator; but disconnect the storage battery from the system. Then disconnect the shunt-field from the brushes and connect up two or three dry cells. Use an ammeter having about a 30-ampere scale and also a 30-ampere shunt and connect to the brushes, as shown in Fig. 30.

To test, turn the armature slowly by hand. If the commutator is in good order and the brushes are making good contact, the ampere reading should be the same in all armature coils when the brushes make contact with the different coils through the commutator segments, but if a very noticeable change in the ammeter reading takes place while turning, this will indicate an open or short-circuited armature coil.

It will be observed that this is what would be termed a **"comparative test,"** or where one armature coil is compared with another.

To tell if the generator armature coil is open-circuited or short-circuited, proceed as follows:

To test for open-circuited coil, connect the brushes on the commutator to a dry cell as in Fig. 31, so that about 10 amperes will flow through the brushes. The field winding should be entirely disconnected. Then connect test-points to the 3-volt scale of the meter and measure the voltage across two adjacent commutator segments. The readings should be the same all around the commutator, as the test is made on all commutator segments. But if there is a **material increase in the reading on any two segments,** then there is an open-circuited coil. This test is termed a "comparative test," that is, each armature coil is compared with the others.

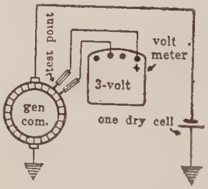

Fig. 31

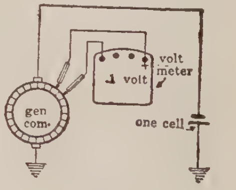

Fig. 32

If there are no open-circuited armature coils, but the test shown in Fig. 31 shows there is some armature trouble, then test for a short-circuited coil. This, however, should only be done after making the test as in Fig. 31, as we shall now use the .1-volt scale of meter, and if there was an open-circuited coil, the voltmeter might be burned out if this test was made first.

To test for a short-circuited armature coil, see Fig. 32. Connect test-points on the meter with the one-tenth volt (0.1) terminal and the (+) terminal. The voltage drop between each two adjacent commutator bars is then tested, and this test is termed a "millivolt drop test." Turn the armature slowly by hand, and test each adjacent commutator segment as shown in Fig. 32. If on testing any of these coils, **the reading drops nearly to zero,** it will indicate that one or more of the armature coils are short-circuited. The reason is stated above. See illustration **C** at **Y** (Fig. 29).

In making these tests, **care should be taken to keep the points on adjacent bars,** otherwise the voltage drop may be sufficient to injure the voltmeter.

---

[1] It is advisable to use a small amount of resistance in the circuit, as explained on page 488.

Example of a Millivolt Test of an Armature

By referring to page 465, an explanation of what is meant by a millivolt drop will be found. Also read matter in connection with Fig. 29, explaining why the voltmeter will read less when there is a short circuit than when there is an open circuit in the armature.

This explanation is one of a test used in many service stations where there are many armatures to test.

Procedure: Sand off the commutator with fine sandpaper, and solder on two segments of the commutator 180° apart, two small wires, each about 3 ft. long, No. 18 or 20 gauge (see Fig. 33). Place a 6-volt storage battery and light in series with these connections. In soldering on these wires, it is not necessary to smear the solder all over the commutator. Just enough to make the wires give a good contact will suffice. The solder will not injure the commutator, for it can be removed easily with a knife and a little sandpaper.

Use a voltmeter which will read in millivolts. A millivolt is a one-thousandth part of a volt.

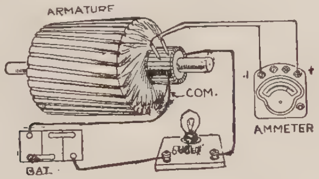

Fig. 33. A millivolt test of armature coils.

Place one of the meter contacts on the segment connected to one of the current wires, and the other contact on an adjacent segment, one immediately adjoining. If the reading of the milli-voltmeter is reversed, reverse the contacts and the reading then will be positive.

The reading the meter gives is the **millivolt drop** through the armature coils connecting these segments together. If the armature is a new one and everything is in good condition, these readings between every adjacent pair of segments will be the same. But if one coil is shorted out, or one turn of the coil is shorted out, this method will tell.

As an example, take an armature with twelve commutator segments connected up according to these instructions. The readings between every adjacent pair of segments are taken and are:

Between Segments	Millivolt Drop
1-2	2.54
2-3	2.50
3-4	2.51
4-5	0.31
5-6	0.01
6-7	2.50
7-8	2.52
8-9	2.54
9-10	2.51
10-11	2.53
11-12	2.50
12-1	2.52

It is seen that the average reading is about 2.52, which is the general result that should be expected for all pairs of segments.

Between 4 and 5 the reading decreases to 0.31. Upon examination of the armature coil we find that there are eight turns per coil. This immediately explains that seven turns of this coil are shorted out and the current is flowing through but one turn, giving an eighth of the drop in the other coil.

Between segments 5 and 6, the reading is just a flutter of the needle. This explains that the whole coil connecting these two segments is burned out and the connections probably have fused together, so that the current flows from one segment to the other commutator segment almost directly.

Note. The needle of the Weston "280" instrument (page 464) will deflect from 0 to right of scale, if 100 millivolts (1/10th of a volt) pass through the coil of the meter, if connections are made with the 100-millivolt terminal marked .1. The scale, however, is not calibrated for millivolts. Therefore in using this instrument a reading of an **armature coil should be made which is known to be good,** and the reading noted. The other armature coils should then read or compare with it.

The light in this example, just given, takes the place of the resistance unit (see Fig. 6, page 488, and explanation, page 488). It puts resistance into the circuit in order to prevent too much current from flowing through the meter.

A GROWLER FOR TESTING ARMATURES

This device (Figs. 34 and 34A) consists of **two laminated cores** (C) around which are wrapped two coils of wire (W). The upper ends of these cores (C) are shaped so that an armature can be placed between them.

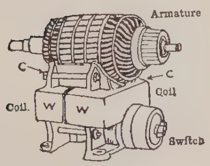

Fig. 34

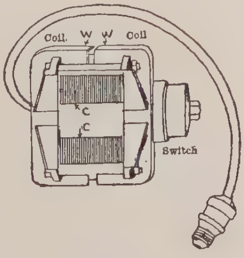

Fig. 34A

Fig. 34. View of growler with armature in place to be tested.

Fig. 34A. Top view of growler.

The principle of this device is very similar to the action of a high-tension coil. See Index under "Principle of a high-tension coil."

By referring to the action of a high-tension coil, it will be seen that when current is passed through the primary winding of the high-tension coil, magnetic-lines-of-force are produced around the wire, and these magnetic whirls cut the secondary winding and thus produce an induced current in the secondary winding.

The principle of the growler is very much the same. The iron cores (C) of the growler would represent the iron core of the spark coil, and they collect magnetic-lines-of-force. The winding (W) around these cores would represent the primary winding of a spark coil. When current is passed through the winding of the coils (W), the action that takes place is the same as sending current through the primary winding of a spark coil.

The current in the primary circuit induces a current in the secondary circuit of the armature coils, and it is by means of these secondary, or induced currents in the armature coils that open and short circuits are located.

The rapid alternations of the current through the coils on the laminated core of the "growler" cause rapid magnetic reversals, and set up a vibration in the core which produces a decided hum or growl, thus giving use to the popular name of "growler" for this device.

When the armature is placed in between the cores (C), the armature winding represents practically the same as the secondary winding on a spark coil. Consequently, if the armature under test is free from short circuits, its coils act simply as an open-circuited secondary winding on a spark coil, and no current is generated in them.

Whenever a short circuit does exist in the armature coils, the circuit thus formed operates as a closed secondary winding, and a heavy secondary current is set up in them, and thus it makes the presence of the short circuit known, as explained later.

The North-East growler (Figs. 34 and 34A) **for testing armatures** is so constructed that it may, without any change in the instrument, be operated either from a 110-volt or 220-volt circuit (Figs. 35 and 35A), and it can test any ordinary armature from 2″ to 4″ in diameter. **It must, however, be supplied with alternating current**—never with direct current—because its operation depends essentially upon the fluctuating character of the magnetic field produced by the alternating current. The growler is designed especially for operation on a 60-cycle circuit, but it can be used with reasonably good results on circuits of other frequencies.

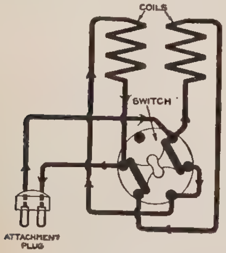

Fig. 35

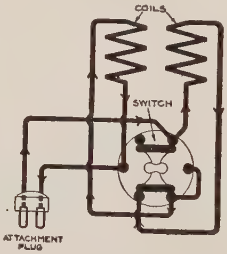

Fig. 35A

Fig. 35. Diagram of N.E. growler circuit with switch in position for 110-volt operation; coils connected in parallel.

Fig. 35A. Diagram of N.E. growler circuit with switch in position for 220-volt operation; coils connected in series.

Internal wiring and connections of the North-East growler is shown in Figs. 35 and 35A. The instrument is equipped with a standard attachment plug for connection to the line, like a lamp or a small motor. The circuit in which the growler is connected should be protected by fuses of not less than 30-ampere capacity, because the current drawn by the growler might exceed 25 amperes if a completely short-circuited armature should be tested in it, or if the growler switch should be accidentally turned on with no armature in position between the pole-pieces.

Note. **Many armatures will test clear on the growler when they are cold,** and show a decided ground after they have become heated up. When an armature is suspected, it is well to leave it on the growler, covered up tightly until it becomes warm.

Of course, reason must be used when doing this, and the armature must not be allowed to heat to the point where the leads will be loosened in the commutator.

Another armature fault, which is very difficult of detection, is grounding while the part is in motion and clearing when it comes to rest. The reason for this peculiarity is that the coils have a slight movement in the slots, and, when the armature gets to spinning, they have a tendency to fly outward.

The F.B. Armature Tester or "Growler" as an Example Showing how Armature Tests Are Made[1]

The parts of this outfit are shown in the illustration (Fig. 36).

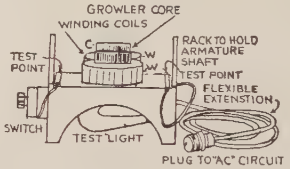

Fig. 36. The F.B. armature tester or growler.

The F.B. armature tester is connected with a 110-volt alternating light circuit. It will test an armature for short-circuited coils (Fig. 37), or for open-circuited coils (Fig. 38), and in connection with the test-light supplied with the F.B. armature tester, armatures can be tested for grounds (Fig. 39).

To Test for Short Circuits in Armature Coils

Place the armature on the core of the tester. Turn on the switch. Hold the "feeler" just above the top of the armature coils (Fig. 37), but not touching, and slowly turn the armature by hand.

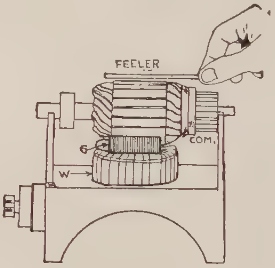

Fig. 37. Testing an armature for short-circuited coils.

If there are no shorts in the armature windings, there will be no magnetizing force in any of the coils, and consequently the "feeler" will not be attracted or pulled toward the coils.

If, however, there is a short between the windings of one coil or between the windings of separate coils, a closed circuit will be formed which will permit of a strong secondary current being induced in the shorted coil or coils.

This induced current will produce two distinct effects: It will heat the wires forming the closed coils, because of the heavy current passing through these wires, and it will also cause the shorted coils to exert a very strong magnetic pull on the "feeler." The magnetic pull on the "feeler" is very strong, and it is a positive indicator of shorted coils.

The heating of the shorted coils may show up almost instantly, or may take a minute or two, depending upon the number of turns of wire included in the closed circuit, and consequently determining the resistance of the closed circuit. The less the resistance of this circuit, the heavier the induced current, and the quicker the coil will heat.

Short circuits in armatures may exist from **three** causes:

1. A short circuit between commutator bars, generally caused by copper dust or particles of brush material collecting in the undercut spaces between the bars.

---

[1] Courtesy of the Service Station Equipment Co., Chicago, Ill. Copyrighted.

2. A short circuit caused by defective insulation between the wires of an individual coil.
3. A short circuit caused by defective insulation between wires in separate coils.

Short circuits from any of these causes will be indicated by the action of the "feeler" as described. If the "feeler" is attracted by only one coil, it indicates a short between the turns of that individual coil. If, however, the "feeler" is actuated by more than one coil, that is by coils situated in different slots in the armature, it indicates that the short is caused either from a commutator short or a short between the windings of different coils.

Always clean the space between the bars if any shorts are found, in an effort to eliminate troubles from this source.

To Test for Open Circuits in Armature

Open circuits in either the generator armature or the motor armature may be caused from two sources:

1. A broken wire in the coil windings.
2. A broken connection between the end of the coil and the commutator riser.

A poor soldering job or a dirty wire at the point where the coil end is connected to the commutator riser will also cause an open circuit and it is from this source that most open circuits result. Defective workmanship at this point can be detected by careful inspection after the particular coil or coils that are open have been located with the tester. Troubles from this source can easily be repaired and do not necessitate returning the armature to the factory for rewinding.

The condition of the commutator is also a good indicator of open circuits. Wherever an open circuit occurs the commutator bar or bars to which the coil is attached will generally be found badly burned and with a flat spot, caused by the continual arcing between the brush and the commutator every time the bar, to which the open coil is attached, passes under the brush.

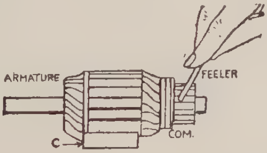

Fig. 38. Testing an armature for open-circuited coils.

To test for open-circuited coils, put the armature in the tester in the same way as described for making tests for "shorts." Then with the "feeler" make a connection between two adjacent commutator bars, as shown in Fig. 38, and then break this connection. A decided spark should occur if the coil is not open.

When contact is made by the "feeler" between two commutator bars, it forms a short circuit in the coil whose ends are connected to the bars, and a secondary current is induced in the coil.

When this current is broken by breaking the connection between the bars, a spark is produced. **If the coil is open,** through a poor contact between the coil end and the commutator, or because of a broken wire in the coil, no current will be induced in the coil and consequently no spark can occur when the contact made with the "feeler" is broken.

Make this test all the way around the commutator between each bar, and the open circuits, if any, will be clearly indicated by the absence of a spark.

To Test for Grounds in Armature

The "test-points" provided with the F.B. armature tester[1] are for use in locating either grounds or open circuits on the armatures that are being tested, or on any electrical device.

The ends of the test-points are connected to the source of current, with the indicator lamp in series. When the two points are touched together, the circuit is completed and the lamp is lighted.

In the same manner, by holding one test-point each on different parts of an electrical device, the lamp will indicate a complete circuit if it lights, and no circuit or an open circuit if it fails to light.

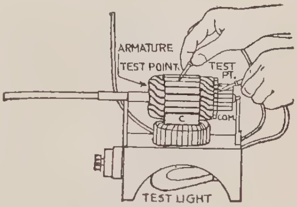

Fig. 39. Testing armature for grounded armature coils.

To test the armature for grounds, hold one test-point on the commutator and the other point on the armature core, as shown in Fig. 39. This circuit should show open and the lamp should not burn. If it shows closed, by the lighting of the lamp, it indicates that the armature is grounded.

Grounded armatures are caused by defective insulation in the armature slots or by a grounded commutator.

Grounded commutators are generally caused by defective insulation between the commutator bars and the armature shaft, and in such cases must be returned to the factory for repairs.

If the ground is caused by copper dust or brush material collecting on the end of the commutator and forming contact between bars and shaft, it can easily be cleared up by removing dust or dirt.

FIELD WINDING TROUBLES AND TESTS

The troubles occurring in a field winding are usually: open circuits, short circuits, or grounds.

An open circuit in a motor-series field winding renders the motor inoperative, because any break in a series circuit opens the circuit.

An open circuit in a generator shunt winding will prevent the generator from generating current.

The shunt-field windings, usually used on generators, are of finer wire than a series-field winding. The shunt-field winding forms a bypath or shunt for the armature current. Being of finer wire, it is of high resistance, so that it will take but a small part of the armature current. The shunt-field windings are subjected to the full voltage of the generator, as shown in Fig. 40.

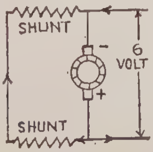

Fig. 40

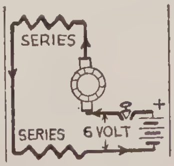

Fig. 41

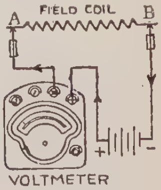

Fig. 42

---

[1] Can be secured of A. L. Dyke, Electrical Dept., Granite Bldg., St. Louis, Mo., price $24.00.

The series-field windings generally used on motors and motor-generators are of coarse heavy wire, are in series with the armature, and must carry all the current that passes through the armature (Fig. 41). The series-field windings are of very low resistance; hence they consume as little as possible of the voltage supplied to the machine.

By referring to Fig. 42, the connections to a voltmeter are made clear. If the free ends of these wires are touched together, the voltmeter will indicate the terminal voltage of the storage battery. This reading should be kept in mind.

Now, if instead of touching the ends together, they were placed on the terminals of a rather high resistance, the voltmeter would give a much **lower reading,** the value of this reading depending directly upon the amount of resistance between the ends. If there is no circuit at all, as for instance, when the ends are held apart in the hands, the voltmeter needle will stand at zero.

An open-circuited coil will be indicated by a zero reading of the voltmeter, when the two free ends or "points" are placed upon the terminals of the field coil at (A) (B) (Fig. 42), which represents a certain amount of resistance. If, on the other hand, the reading is very nearly that of the battery voltage, the field coil is in good condition.

Therefore if a voltmeter is placed on the ends of a **shunt winding,** which is of a higher resistance than a series winding, the meter would read less on a shunt winding than on a series winding, because, the wire of the shunt winding is smaller than the series winding and the resistance offered to the passage of current would be greater, with a consequently greater voltage drop, whereas, if the meter was placed on the ends of a series winding, the meter reading would be greater, or nearer the battery voltage, because the resistance offered to the passage of current in the large wire would be less.

Right here is the difference between a voltage reading and a millivolt reading. If we were making a test of the **millivolt drop** in the shunt and series field coil, then current would be passing through the coils instead of the coil being in series with the meter. We should then be measuring the **voltage drop,** which would be greater in a fine-wire shunt field than in a coarse-wire series field.

If an armature or field is short-circuited or grounded, the machine may not necessarily be inoperative altogether. This will depend upon the nature of the short or ground, but it will cause a generator to generate less output, and will cause a motor to draw more current and produce sparking.

Testing Field Windings with a Meter

Meter tests for an open-circuited, short-circuited or grounded armature and for short-circuited or grounded field-coils are the same in principle as described under the tests for a motor, and explained on pages 487, 488.

A meter test for a generator-field open circuit (Fig. 43), is different from the test of a motor-field open circuit (Fig. 4, page 487).

Disconnect the field terminals from the other parts of the generator, including the field regulating devices. Connect the negative (−) terminal of one cell of a battery to one end of the field, and the positive (+) terminal to the (+) binding post of the instrument. Complete the circuit between the 3-volt binding post and other end of field. **If an indication is obtained,** the coil is not open-circuited, but if **no indication is obtained,** the coil is open-circuited.

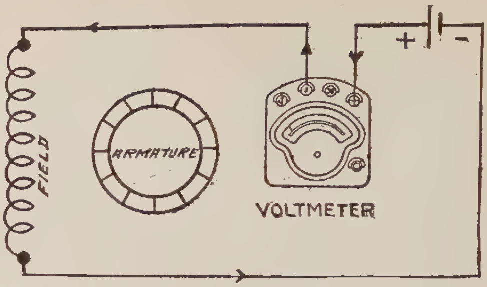

Fig. 43. Connections of voltmeter for testing for open-circuited generator fields.

Testing the Delco Motor-Generator Field-Coils with a Test-Light

To test for grounds in the field-coils of a motor-generator, place one point on the frame of the motor-generator at (F), and the other on the terminal of the field-coil at (B) (Fig. 44). Be sure that all grounds which are regularly connected to these terminals are first removed.

If the lamp lights, a ground is indicated. **If it fails to light,** the coil circuit is in good shape.

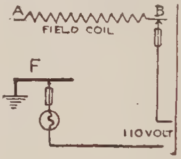

Fig. 44

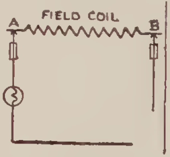

Fig. 45

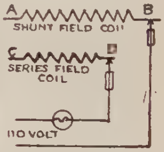

Fig. 46

To test for open circuits in the field-coil, place test-points, as shown, on each terminal of the winding, at (A) and (B) (Fig. 45).

If the lamp fails to light, the circuit is open. The coil should be replaced or repaired.

To test for short circuits between motor-generator windings: The test here is between the "shunt" and "series" field winding.

Place one of the test-points on the terminal of the shunt-field winding (B) (Fig. 46), and the other test-point on the terminal of the series winding at (D).

If the lamp lights, a short circuit is indicated between the windings.

Replacing Field-Coils

When replacing field-coils on a generator, it is not always possible to tell which way they are wound in order to make one field-pole North and one South.

Each field-pole must have opposite polarity, that is one must be South and the next North, the next must be South and the next North. The practice is to place the field-coils on the pole pieces, and then to connect them together temporarily and connect with a battery, as shown in Fig. 49. A compass then placed on the outside of the field-frame will show if each pole has a different polarity, that is if one is N and next S, and so on. Field-coils on a 6-volt generator will draw about 3 to 5 amperes. Each adjoining pole should show opposite polarity.

Most generators have field-poles which can be removed by loosening a screw which holds the pole in place. The pole-tip or flange end next to the armature holds the field-coil tight to the frame. It is very important that these field-coils be punch marked and that the frame be punch marked, so that both can be put back exactly correct, otherwise the field-coil may not fit properly and the air-gap clearance between the armature and the field-pole tip may not be as it was originally.

On a starting motor the wire in the field-coils is much larger and of less resistance than on generator field-coils, and while the same test can be made, it is only possible merely to touch battery terminals for a fraction of a second, otherwise it is practically a dead short circuit on the battery. Most starting motor coils come in pairs, and two will have the same appearance and can easily be distinguished. The idea is to alternate them on the poles.

When the polarity is correct, solder the connections and tape with cotton tape, as the ordinary friction tape will soon become oil-soaked and loosened. This tape is white and is called English twilled tape.

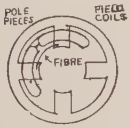

Fig. 47

Fig. 48

Fig. 47. Illustrating how field-coils are held in place on the field-poles by a strip of fiber. This method is generally used where field-poles are **not detachable** from the outside of the frame by means of a screw.

Fig. 48. Illustrating the appearance of a field-coil winding ready to apply on the field-pole.

On pole-tips which are cast to the frame and not detachable, the pole-tip is usually small at the end next to the armature. The field-coils can be slipped over the pole-tips on to the pole-piece or core. A fiber strip about ⅛″ thick (Fig. 47) is then placed under the coil in a groove, from one pole-tip to the other, and will thus hold the coils in place.

Remy Instructions on Field Polarity

Reversed field-coils: Field-coils are not likely to be connected wrong when the machine leaves the factory, and cannot possibly become reversed when in operation. This trouble, therefore, is very unlikely to be encountered unless the machine has been disconnected for repairs and is then connected up wrong.

To locate a reversed field-coil: With the field excited (connected to the battery), and the armature out of circuit, approach each field-pole with a compass, taking them in succession. If connected properly, each pole will attract the end of the compass needle opposite to that which the preceding or following pole attracts.

Care should be exercised, in making this test, to approach each pole with care, and not to slide from one pole to the next without taking the compass well away from the machine, as the polarity of the compass needle is very likely to be reversed and incorrect results to be obtained.

Finding the Polarity of Field-Poles (Ford Generator as an Example)

Care should be taken that the leads on the generator yoke are connected to the proper brush terminals. The earlier fields were wound opposite to the later, and it is therefore necessary to cross the leads on the latter. To determine how they should be connected, test the field with a battery and compass as follows (refer to Fig. 49):

The generator is placed on its end with the commutator end up and the terminal to the left as shown. A 6-volt battery is connected to the field-coil leads. Current will then flow through the field-windings or coils, and in doing so, the field-poles will become an electromagnet.

One end of a field-pole will be North (N) and the other end South (S) of each field pole, of which there are four.

Therefore, by placing a compass, say, at the frame end of field-pole No. 1, the N pole end of the compass needle (the dark or arrow-point end of a compass needle is the N pole end) will point toward the field-pole, and the end of the field-pole next to the generator frame will be the S pole and the inner end will be the N pole.

By placing the compass needle at the frame end of the next field-pole (No. 2), the S pole end of the compass needle will point to the field-pole, and the end of the field-pole next to the generator frame will be the N pole and the inner end will be the S pole.

The outer end of field-pole No. 3 will be S and the inner end N; the outer end of field-pole No. 4 will be N and inner end S. Thus it will be observed that the polarity of the field-poles alternate and those field-poles which are opposite each other are of the same polarity.

If the poles do not indicate with reference to the terminals as shown in the diagram, reverse the leads of the field-coils to the battery wires and test with the compass again. If they indicate properly now, the lead attached to the positive (+) wire from the battery is the one to be attached to the **third brush,** and the other is attached to the grounded brush.

The reason why the N pole of the compass needle points to the S pole of a magnet or field-pole is the fact that the magnetic lines-of-force flow from N to S (see Fig. 1, page 179), and the N pole end of the compass needle will always point **with** the direction of flow of a magnetic circuit. For example, the magnetic lines-of-force flow out of the N pole end of field-pole No. 1, into the S pole end of field-pole No. 4, out the N pole end of No. 4, through the frame **into** the S pole end of No. 1, thus completing a magnetic circuit; and the N pole end of the compass needle, will point **with** this direction of flow.

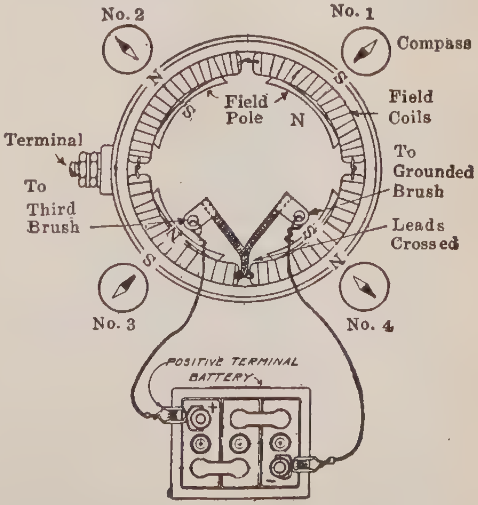

Fig. 49. Testing the polarity of field poles with a compass after placing the field coils on the field poles.

Therefore when a compass is placed over No. 4 field-pole, the outer end is the N pole and the magnetic lines-of-force will be coming out instead of going in, as at the S of No. 1; consequently the N pole end of the compass needle will point with the direction of flow, and thus the S pole end of the compass needle will be toward the N pole end of field-pole No. 4, as shown. The same action takes place in No. 3 and No. 2 field-poles. See also Index under "Magnetic circuits of field-poles."

Another Method of Determining Proper Connection of Field Terminals to Brushes

When the generator is assembled, **operate it as a motor** from the battery. If it runs in the wrong direction, the field terminals should be reversed. If it does not run at all, the field coils are mounted wrong. The proper direction of the generator when motoring is counter-clockwise when looking from the commutator end, or, in other words, **the same direction in which the engine drives it as a generator.**

CUT-OUT TROUBLES, TESTS, AND ADJUSTMENTS

Although the construction may vary, **the principle of all cut-outs is very much the same.** See also Index under "Testing the cut-out."

Sometimes, due to the cut-out points (P) (Fig. 50) sticking and not opening when the engine stops, the battery discharges for a long period of time through the cut-out at about 20 amperes, which will often burn out[1] the voltage winding (V). The result is that if the points (P) are still stuck when the generator is started again, it will charge the battery, but the battery will again discharge instantly, the moment the engine stops.

If the points (P) should be open, with a burned-out cut-out voltage winding (V), the core will not become magnetized sufficiently to draw the points together. Thus the generator will not charge the battery, or the cut-out armature may intermittently cut in and cut out in a feeble effort to close, and the ammeter will fluctuate back and forth as it cuts in and cuts out.

Function of the Cut-Out

The function of the cut-out is fully explained on pages 332, 519, and should be studied carefully.

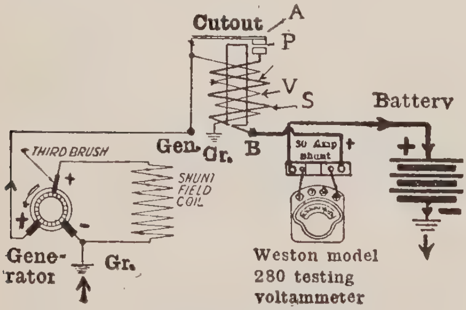

Fig. 50. Method of testing a cut-out.

There are two windings on the cut-out, a fine-wire voltage winding (V) (Fig. 50), and a coarse series winding (S).

The fine-wire voltage winding (V) is always connected across the generator main circuit, but takes very little current.

The series or winding (S) is in series with the circuit to the battery from the generator.

On the Delco some of the very old models had cut-outs, but later on the cut-out was dispensed with entirely (see page 387). On the late two-unit Delco systems the cut-out is used.

See discussion of Remy cut-out adjustment on page 351; Delco, page 409, and North East (Dodge), page 372.

Cut-Out Troubles and Adjustments

If the cut-out points stick and fail to open, the battery will discharge back through the generator.

It is well to mention here that it is **permissible for the battery to discharge from 0 to 3 amperes back through the cut-out** at low generator speed. This is usually the case, as explained on page 333, as the series coil (S) which opens the points is thus demagnetized. If, however, the points fail to open, then as high as 15 to 20 amperes will discharge through the generator, and thus will run the battery down.

If the cut-out points fail to close, the generator will not charge the battery.

Failure of the cut-out points to open may be due to:

1. **Not sufficient air-gap space** between contact arm blade (A) (Fig. 52), and the iron core of the cut-out coil (G). This can be remedied by slightly increasing the spring tension controlling the pull of the blade.

Note. The spring is not shown in this illustration. See pages 333, 351, 373. The **air-gap space** between (A) and the armature core (C) (Fig. 52) is usually .010" to .015" clearance.

If the cut-out is slow to cut in, then this air-gap should be slightly decreased by bending the contact blade, which moves the blade or armature (A) closer to the core (C). On some of the Westinghouse cut-outs, there is a screw for this purpose. Poor brush contact will also cause the cut-out to cut in late.

If the cut-out cuts in too quickly, increase the spring tension which holds the contact-arm, or increase the air-gap.

2. **Pitted points are also the cause of failure to open.** This may be caused by: (a) long usage; (b) excessively high current output of the generator; (c) insufficient spring tension; (d) improper operation of the generator.
3. **Defective windings,** such as a short circuit, may also be the cause of failure to open.

Failure of cut-out points to close may be due to:

1. Air-gap clearance (G) (Fig. 52) too great.
2. Spring tension too strong.
3. Open cut-out windings.

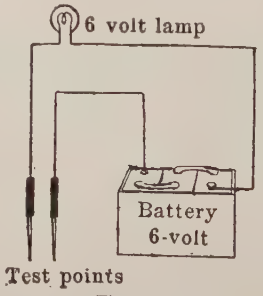

Fig. 51

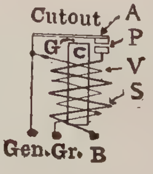

Fig. 52

Fig. 51. Test points, battery and lamp used for cut-out tests.

Fig. 52. Cut-out winding terminals.

---

[1] Burned-out cut-out voltage coils are also sometimes occasioned by running a car with the charging circuit opened without grounding the generator, or by a loose ground connection.

To Test the Cut-Out Windings

To test the cut-out voltage winding (V) (Fig. 52): Use four cells (8 volts) of a 12-volt storage battery. Disconnect the cut-out from all circuits. Place one lead from the battery on (Gen.) and the other lead on (Gr.). The cut-out points (P) will close quickly if the voltage winding is in good order.

To test the cut-out voltage winding for a ground. (Fig. 52): Place one test-point (Fig. 51) on (Gen.) and the other on (Gr.). If the lamp lights, but the cut-out points (P) when tested as in the preceding paragraph, fail to close, this indicates a ground, or too great an air-gap at (G), or too much spring tension.

To test for an open in voltage winding (V), make the same test. If the lamp fails to light dimly, winding (V) is open.

To test the cut-out series winding (S) (Fig. 52): Place one test-point on (B), which is the end of the series winding (S) leading to the battery. Place the other test-point on (Gen.). The lamp should fail to light, as the cut-out points are open at (P), but the lamp should light when the cut-out points are held closed by the hand.

To test series winding (S) for a ground (Fig. 52), place one test-point on (B), the other on (G). The lamp should fail to light.

After testing the cut-out windings, proceed as follows:

Method of Testing the Cut-In and Cut-Out Speeds of Cut-Out

1. **Connect cut-out between generator and battery,** as shown in Fig. 50, as if on the car. Use the 30-ampere shunt with testing ammeter. We shall assume the driving method is as shown in Figs. 15 and 16, page 477.
2. **Use the pulleys for the 675 speed.** Permit the belt to slip when first starting, and gain speed gradually. The cut-out should cut in, or close at about 650 to 675 r.p.m. It will be heard to click when it closes, and about 1 ampere will show on the meter.[1]

   Permit the belt to slip, and thus slow down the speed of generator, or use the pulleys for the 450 r.p.m., and see if the cut-out cuts out below 600 r.p.m.

   The cut-out, with most generators, cuts out when the generator speed is low enough to permit the battery to discharge slightly back through the series winding (S) of the cut-out, which demagnetizes the series coil, releasing the points. This discharge varies from 0 to 3 amperes.

   The foregoing refers to testing the cut-in and cut-out speeds of the generator. We will proceed with the **complete generator-driven test,** using a Ford generator as an example.
3. **Use the pulleys for the 1,425 speed.** At about 1,400 to 1,500 r.p.m. the generator should deliver 10 amperes.
4. **Use the pulleys for the 1,800 speed.** At about 1,800 r.p.m. the generator should deliver its maximum of 12 amperes. The generator is, however, capable of giving a higher amperage, but 12 amperes is the maximum according to the manufacturers' instructions. About 15 amperes is really necessary, however, to keep the battery charged. If more is attempted, the generator will heat.
5. **Use the pulleys for the 2,400 speed.** At speeds over 1,800 the amperage should not increase over 12 or 15 and should drop off at high speeds, or over 1,800 r.p.m.

If the amperage is more at the speeds mentioned above, the rate can be decreased by moving the third brush in the opposite direction to the rotation of the armature.

If the amperage is less, the rate can be **increased** by moving the third brush with the direction of rotation.

If an "external regulator" is used, adjust the regulator. See page 350 for the Remy. See also Index under "Adjusting third-brush regulated generators."

If, after adjusting the third brush, this does not give the desired readings, then operate the generator at 1,400 to 1,800 r.p.m., and note if there is a flashing at commutator and if there is a smell of burned insulation; if so, **the armature coil is probably short-circuited** and a separate test of the armature for a short-circuited coil should be made. See pages 497, 498, 499, 516. Be sure, however, that the flashing is not due to loose brushes, protruding mica, etc., as previously explained.

A short-circuited field-coil will also cause sparking, but not so much heat, because the other field-coils will take the load which is cut out of the shorted coil, and they will probably heat.

Other tests of armature coils and field-coils are shown on pages 497 to 499 and 513 to 519.

Example of Locating Cut-Out Trouble ("Overland 4" as an Example)

Trouble: We will assume that the battery cut-out fails to close and that after closing it by hand, will find that it remains closed and the generator charges the battery until the engine stops, when the points open as they should, but will not close when starting the engine again. We will assume that a new cut-out was installed, and the result remained the same. The generator makes a grinding noise when the points are closed.

Causes: The initial current from the generator flows through the binding-post of the cut-out marked "To + Gen.," through the metal framework of the cut-out and through the cut-out core.

The fine winding (V) of the cut-out core, termed the voltage or shunt coil, is connected to the core at one end and to the binding-post marked (2) at the other (see Fig. 53).

Binding-post (2) is grounded, that is to say, to be attached to some part of the metal of the chassis.

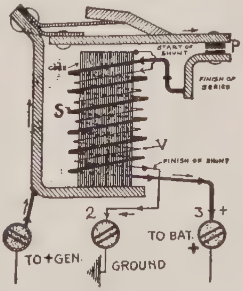

Fig. 53. Overland "4" cut-out.

As the opposite side of the generator is also grounded, it is apparent that so long as there is no break in the circuit the initial current will flow through the shunt winding of the cut-out and, energizing the core, cause the points (P) to be closed.

Next, examine the other circuit. From the binding post to the left, the current flows through the iron frame of the cut-out, through the movable arm—called the armature—which carries one of the cut-out points. When these are brought together, the path of the current is through the lower, stationary cut-out point, through the heavy winding of the cut-out, called the series or current winding (S), to binding-post (3), and thence to the battery.

---

[1] The Service Manuals, advertised in the back of this book, give the cut-in and cut-out speeds, voltages, etc., of different models of generators of all makes.

As the cut-out remains closed after having been closed by hand, it is apparent that this circuit as well as the generator is normal, providing the ammeter indicates "charge" with the points closed.

It is likely there is either a break in the fine winding of the cut-out or that the ground connection between binding-post (2) and the chassis is either broken or dirty.

The winding (S) can be tested with a 110-volt test-line wired in series with a 110-volt bulb. Do not attempt to make the test without using the bulb.

Apply one test-point on the binding post to the left, and the other on binding-post (2). The lamp should light, although not up to full candle power. Should it light and burn up to full brilliancy, the probability is that the fine winding is short-circuited or in contact with the iron of the core somewhere with its coils. On the other hand, if the lamp should fail to light at all, a break in the winding is indicated.

The remainder of the test had best be made with a 6-volt battery, as the high-voltage current is quite likely to overcome the resistance of a dirty connection and give a clear indication.

With two wires connected to a test battery—not the one on the car—test between terminals (2) and any clean part of the chassis. There should be a flash. If there is not, the proof is conclusive that the ground connection between terminal (2) and the chassis is at fault.

To corroborate this, attach a wire to terminal (2), fastening the other end underneath the head of an engine bolt or nut. Start the engine and bring it up to speed. If the generator is operative and the cut-out has tested normally, current should flow. The points should close and everything should operate satisfactorily.

The fact that a new cut-out is installed would indicate that the trouble will be found in the ground connection.

The noise of the armature is caused by one of three things: (1) the generator is not charging, and when the points are brought together by hand the battery current discharging back through the apparatus causes it to drag, knock, and growl; (2) the new armature is short-circuited in one or more coils; (3) the bearings are not all that they should be. So long as the generator is not delivering current, it simply runs idle, absorbing very little power, but as soon as it begins to generate, an extra load is thrown upon the bearings; and if these are not in good condition and in perfect alignment, the noise will result. (*Motor Age.*

CONNECTING CUT-OUT WHEN TERMINALS ARE NOT MARKED

Every cut-out has three terminals: One of these terminals may be invisible, as it is connected to the ground of the cut-out case (see Fig. 50, page 504, and Fig. 54 below).

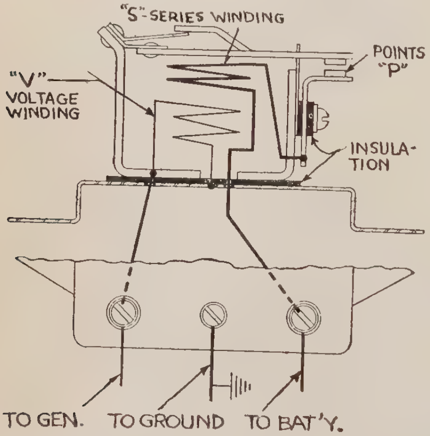

Fig. 54. Internal wiring of a typical form of cut-out (see also Fig. 24, page 520). The core on which the two windings (V and S) are wound, and which becomes magnetized and draws the armature blade (blade at top with upper point P) to it is not shown. The core is shown in Fig. 50, page 504, and page 333.

The lower part of the illustration shows the connections to the base of the cut-out. These terminals are not always marked.

To locate terminals of voltage coil (V): Use a 110-volt **A.C.** test light. Connect terminals of test light to various combinations of two terminals on the cut-out. When those two terminals are touched, which give a dim light and a buzzing of the cut-out points, the test points are across the voltage coil.

The reason **why the light dims** is that there is great resistance in the fine-wire voltage winding (V). The reason of the buzzing is the magnetization of the current flowing through the voltage coil (V), which causes the cut-out points (P) to close, but owing to the alternation of the current the cut-out core is rapidly magnetized and demagnetized, as the current flows alternately in opposite directions. Thus the points are closed and released rapidly, causing the buzzing effect.

To locate terminals of current or series coil (S): Use the 110-volt test light. Close cut-out points by hand. Place test light on terminals, and test as above. Those two terminals which give a bright light with the cut-out points closed, and no light with the cut-out points open, are connected to the current coil.

This is **due to** the low resistance of the heavy winding of the current coil (S). The lamp goes out when the cut-out points are open because the circuit is then open.

Determination of terminals: The one terminal which was used in both tests above should be connected to the generator. The other terminal of the voltage coil should be grounded. The other terminal of the current coil should be connected to the ammeter and battery (see Fig. 50, page 504).

The **reason why** the one terminal which was used during both tests above should be connected with the generator is that this terminal is connected to both the current coil (S) and voltage coil (V) (see Fig. 50, page 504).

ADJUSTING OUTPUT OF DIFFERENT GENERATORS

The third-brush type of generator is the type used most, and the adjustments of the different makes of third-brush regulated generators are shown on pages as follows:

Delco third-brush regulated generator	pages 407-409
Remy third-brush regulated generator	page 363
North East third-brush regulated generator	pages 374, 375
Bijur third-brush regulated generator	page 364
Ford third-brush regulated generator	page 516

Adjusting the charging rate of generators using an electro-magnetic vibrator regulator instead of a third brush to increase or decrease the output is usually by means of an adjusting screw which increases or decreases the spring tension of the regulator. Some of these regulators control the voltage output of the generator and some control the current output, and some makes control both the current and voltage, as explained on pages 346-348. See also page 350.

The average amperage charge of the generator to the battery, with lights off for winter use, is approximately 18 amperes, and in summer 12 to 14 amperes. In some instances the generator is set to give 1 ampere for each plate, that is, if the battery has 13 plates, the rate is set for 13 or 14 amperes with all lights off.

Too high a charging rate will produce sparking at the brushes, which will pit and burn the commutator and will also necessitate taking up on the chain tension which often produces a singing noise. The bearings will also feel the effects in time of a higher charging rate, owing to the increased tension of drive chain.

When increasing the charging rate, be sure it is not enough to produce sparking. If sparking is produced, see if brushes and commutator are in proper condition, and if so, and sparking continues, then the charging rate should be set back.

The main point is to keep the battery charged without over-charging, and this can be determined by testing the battery which should show around 1280 s.g.; the temperature of the solution should not rise above 105° F. (see page 572).

To tell when a battery needs charging and when to increase the generator output, see page 563.

INSTRUCTION No. 45

EXAMPLE OF A MODERN METHOD OF MAKING ELECTRICAL TESTS

(Ford Generator, Motor and Cut-Out as an Example)[1]

The F.B. Test Stand, designed for testing the Ford starting motor and third-brush regulated generator and the cut-out, as described, will be used as an example in the following discussion.

Most all generators of the present day are of the third-brush type. Tests of other makes of generators would, therefore, be similar in principle to the test of the one selected as an example. They differ however in the amperage generated and in the speed at which the cut-out cuts in and cuts out.

It is impossible in this book to give data for the test of all generators. We recommend therefore that the repairman purchase the Service Manuals which give data concerning the speed, amperage, and voltage to test different makes of generators, cut-outs, starting motors, etc. See also the advertisements in the back of this book, describing these data books. The Wiring Manual as mentioned in the advertisements is also very necessary for general automobile electrical work.

MODERN ELECTRIC TESTING EQUIPMENT

Testing equipment is divided into two distinct classes: (1) equipment for testing and repairing the starting and lighting system **while it is installed on the car;** (2) equipment for testing and repairing the various units of the system after they have been **removed from the car.**

The first tests are made with a combination voltmeter and ammeter, such as the F.B. test set (or the Weston, described on page 464, or other makes of instruments).

The second tests are made with a testing stand, an example of which will now be given.

The F. B. Test Stand[2]

This stand is designed solely for use with the F.A. starting and lighting systems used on the Ford car. The illustration (Fig. 1) and parts will give an idea of how a modern testing stand is constructed.

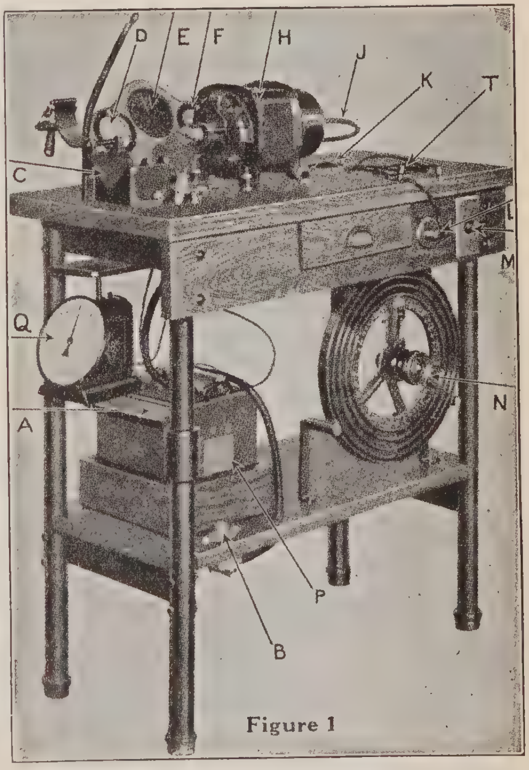

Figure 1

Parts for Testing Starting Motor

B is the **starting switch** connected between **battery** **(P)** and the wires leading to the top of the stand for testing the starting motor on a "free-running" test.

D is the **motor ammeter** connected in the circuit just mentioned, and shows the amperes of current used in the test. It reads 0 to 1,000 amperes.

A is a **swinging shelf** for the **scale** (Q) which is used for the "torque" or "kick" test of the starting motor. When a torque test is made, the motor is placed in **stand** (C) and connected with the battery.

A **brake-arm,** one foot long, is attached to a sleeve which slides over the motor shaft. The swinging shelf with scale is pulled out and an **extension** from the brake arm rests on the scale.

The **starting-switch** (B) is pressed, and when the motor stalls or cannot turn because of the resistance to rotation by the scale, the pound pull on the scale indicates the **torque** of the motor armature shaft.

If the motor is in good condition, the scale (Q) should read 12 to 14 pounds and the ampere-meter should show a current draw of 600 to 750 amperes.

As the gear ratio between the Bendix gear on the motor and the gear on the flywheel on the engine is 12 to 1 (Ford starting motor), this means that the motor under these conditions is exerting a turning effort of 168 pounds on the end of the starting crank 1 foot long (12 [gear ratio] x 14 pounds = 168 pounds).

---

[1] We are indebted to the Service Station Equipment Co., Chicago, Ill., for data and information concerning the Ford tests given in the pages following.

[2] The later model of this test stand is now equipped with a bench lathe, attached to the front of the stand, and driven by the universal motor and a jack shaft on the stand. The lathe has a swing of 7". Extreme distance between centers, 12". It is furnished with slide rest, slotted face plate, arbor clamp dog, ¼" drill chuck, and saw arbor. Both head and tail stock are provided with centers. The lathe can be used for turning, sanding, and under-cutting mica of armature commutators and for many other jobs which are necessary to do around a service station. Price $241. Can be secured of A. L. Dyke, Electrical Dept., Granite Building, St. Louis, Mo.

Parts for Testing Generator

C is a **stand** for holding the motor or generator. If the generator is given a "free running" or "motoring" test as a motor, it is connected with a battery in the same manner as a starting motor.

H is a **universal motor,** so called because it will operate on any 110-volt lighting circuit, either alternating or direct current.

When the generator is given a "driven" test, it is placed in stand (C) and connected to the universal motor which drives it, by means of a flexible coupling.

M is the **toggle-switch** which connects with the lighting circuit (110-volt) and the universal motor.

N is the **rheostat** connected with the universal motor which varies the speed of the latter. The generator is driven at the same speed as the universal motor which drives it.

E is the **tachometer,** connected by a **flexible shaft** (J) with the universal motor and indicates the speed in revolutions per minute of the generator which is being driven. The tachometer readings are from 0 to 2,500 rev.

F is the **ammeter** used in connection with the generator tests, and reads from 0 to 30 on the "charge" and "discharge" sides.

T are **test-points** connected with the 110-volt lighting circuit, and using a "tell-tale" red light (**K**) mounted flush with the test-stand.

L is the **switch** connecting the test-light (**K**) with the test-points (T) and the lighting circuit.

All instruments are protected by 10-ampere fuses mounted under the test table.

A cut-out is provided and mounted on the test stand so that the generator can be connected up and tested as if on the car.

GENERAL INSPECTION OF GENERATOR AND MOTOR TROUBLES

Before going into the details of the location of the various faults of the generator and motor, which are the two main units of the starting and lighting system, and the ones that generally cause ninety per cent of the trouble, we will explain the general effects of the more common troubles on the various parts of the machine. A careful inspection of the machine, having in mind these effects, will often instantly locate the trouble so that no electrical tests are necessary.

Ninety per cent of generator and motor troubles are indicated by the condition of the commutator. If the commutator is burned and blackened uniformly over its entire circumference, it is due, as a rule, to dirt and grease which have collected on the commutator, or to carbon or copper dust from the commutator itself, or from the brushes, which cause sparking and burning of the commutator.

The collection of carbon or copper dust on the commutator is generally due to the commutator becoming roughened and starting to cut, or by the use of a brush which is not of the proper composition and which acts more or less like a file against the commutator.

Poor contact between the brushes and the commutator, due to insufficient spring pressure or sticking brushes, will cause the commutator to burn pretty uniformly, due to the constant arcing between the brushes and the commutator. The same effect of a burned commutator will also be caused by a loose connection somewhere in the circuit which is constantly making and breaking the circuit. The flame of the arc resulting from the causes named above is generally of a reddish color, and is very distinct from the bluish tinge in the arc resulting from other causes.

An open circuit in the armature is nearly always detected by a **"flat" on the commutator,** because every time the brush comes in contact with the commutator bar which has an open coil attached to it, an intense blue spark is made as a result of the breakage of the circuit at this point under the brush and the segment is burned away, causing what is commonly known as a "flat."

The burned bar as well as the "flat" indicates the nature of the trouble, namely, an open circuit, and immediately locates the coil in which the trouble exists.

Short circuits in armature coils are indicated by flashing at the commutator and also by the smell of burning insulation.

A short-circuited field-coil is also liable to cause sparking, but not undue heating of the armature. However, the particular field-coil that is shorted will become much hotter than the other field-coils.

The windings of the generator, both on the armature and field, consist of many turns of fine wire as compared with the motor windings which have only a few turns of heavy wire in both armature coils and field coils.

The result of this construction is such as to give rise to many more sources of trouble in the generator than in the motor.

In addition, the troubles of the generator are further influenced by open circuits or grounds in the wiring system, including the cut-out, which connects it to the battery. All of these affect the behavior of the generator and are the immediate cause of generator troubles.

On the motor side, a ground or short in the wiring has no bad effect on the motor proper. The conclusion is that the majority of troubles experienced will be with the generator, as it is so vitally affected by the proper operation of a number of other things, while motor troubles should be very few, and in general confined to mechanical troubles, and on the electrical side almost solely to commutator and brush troubles.

No repairs should be attempted on armatures on which grounded, shorted, or open windings have been located, but the complete armature should be returned to the factory for repairs or replacement. If the trouble is such that it can be easily located and repaired, such as an open circuit due to poor contact between the ends of the coil and the commutator bar, or a short due to copper dust between bars, there is no need of returning the armature to the factory. Any troubles, however, that involve rewinding of the armature should be remedied by returning the armature to the factory.

Most of the troubles experienced with the cut-out will be caused by the contact points becoming corroded and pitted so that the cut-out points will fail to make a contact, thus leaving an "open" in the generator circuit, or else they will stick and fail to open, causing the battery to discharge back through the generator. This trouble is easily taken care of, as explained under "cut-out troubles," by cleaning the contact points.

If, on making a test of the cut-out, it is found that there are open or shorted or grounded coils in it, the instrument should be returned to the factory for repairs or replacement, and under no circumstances should the service man attempt to rewind the coils.

When the cut-out is installed on the car when it leaves the factory it is in perfect condition, and if it fails to operate from causes other than dirty contact points, as just described, the chances are that the trouble lies in a defective magnet winding. Any attempts to increase or decrease the spring tension on the cut-out points or adjust the opening between them will only make matters worse.

No attention other than cleaning the contact points should be required for the cut-out, and if it will not work properly under these conditions return it to the factory for repairs.

USE OF TEST-POINTS

The F.B. Test Stand is equipped with a set of test-points consisting of two brass points insulated with fiber handles attached to a flexible cord which is fitted with a Hubble plug.

On the front of the stand is a Hubble socket into which this plug is inserted, and when this is done it connects into the circuit the standard 110-volt lamp which is attached to the under side of the table and which lights the red "tell-tale" glass whenever the circuit is completed through the test-points.

Whenever these points are touched together, or whenever a circuit is completed by holding the points on any electrical circuit that is complete or continuous, a circuit is established allowing the current to pass through the lamp, in this way indicating that there is a continuous and complete circuit. This principle is utilized to locate open circuits, grounds, and shorts.

For example, **if it is desired to test an open circuit in the field-windings,** hold one of the test-points on either terminal of the field. If the field-winding is not open, that is, if there is not a broken wire or connection in it, the circuit will be complete, and it will be indicated by the lighting of the bulb.

For testing for grounded field-coil, hold one test-point on one terminal of the field-coil and the other terminal on the frame of the machine.

If there is no ground, that is, if there is no contact between the field-coil and the frame of the machine, there can be no circuit. Consequently the indicator will not light. On the other hand, if there is a ground, the circuit will be completed to the lamp and it will indicate the ground by the lighting of the bulb.

Test points with a high-voltage lamp are shown in Fig. 2 and with a low-voltage lamp in Fig. 3.

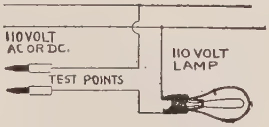

Fig. 2. Test-points and lamp for use with a 110-volt circuit.

The test-points furnished with the F.B. equipment are designed for use on 100-volt circuit, either A.C. or D.C., and the advantage of this higher voltage over a lower voltage is very considerable. For example, if there is a partial ground due to copper or brush dust which has settled between the commutator bars, the higher voltage tends to show it up more clearly and often burns out the foreign substance which is causing a ground and thus clears up the trouble. Fig. 2 shows the test-point circuit using 110 volts.

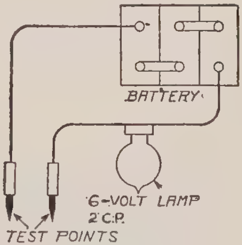

Fig. 3. Test-point and lamp for use with a 6-volt storage battery.

The same principle of using test-points can be utilized with a 6-volt battery, using a standard 6-volt bulb in the place of 110-volt lamp. Such a set as this is often very convenient, especially in making tests around the car where it is not always possible or convenient to utilize a 110-volt set. Fig. 3 shows the method of connecting up the test-point set with a 6-volt battery.

MOTORING TEST OF GENERATOR

A considerable number of the first installations of the F. A. Starting and Lighting Equipments on Ford cars were assembled with the Ward-Leonard automatic cut-out assembled on the dash, while in the later systems the cut-out is assembled on top of the generator.

If the generator to be tested is from one of the systems where the cut-out is mounted on the dash, the generator lead is connected directly to the generator terminal marked (T) (Fig. 4).

If, however, the generator has a cut-out mounted on it, the terminal lead is connected to the terminal on the cut-out (Fig. 5).

Do not put the flexible coupling on the generator shaft for making the "motoring" test. This is a "free running" test, and the generator must not pull any load while making it. The coupling is used for driving the generator and is not needed for this test.

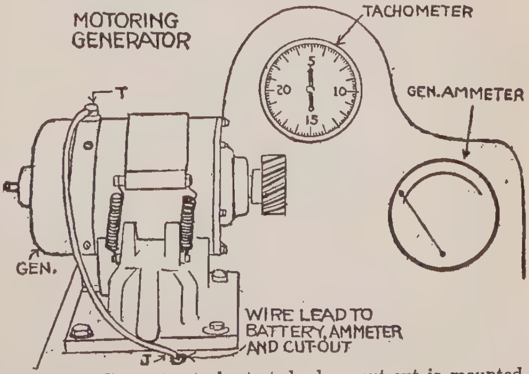

Fig. 4. Generator to be tested where cut-out is mounted on dash of car.

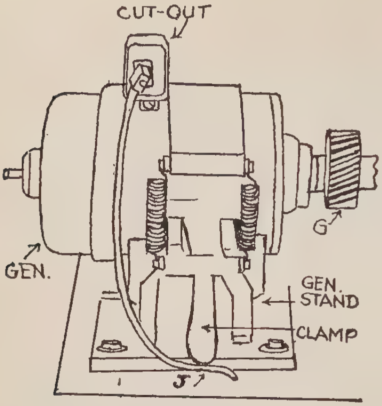

Fig. 5. Generator to be tested where cut-out is mounted on generator.

By this connection the generator is connected to battery and meter and cut-out on the F. B. Test Stand in the same way that it is wired up on the car.

The generator is now ready for the motoring test, that is, to send the current through it as a motor and to note its performance. The results will indicate whether the generator is in good condition, and if not, it will to a great extent indicate the troubles that may be looked for in it.

The generator motoring test can be conducted under two different conditions, namely: when the generator is not equipped with a cut-out mounted on top of it, and when it has a cut-out mounted on it.

Motoring Test Without Cut-Out on Generator

After the generator has been set up as described for the motoring test, it is necessary only to press the starting-motor switch, clearly indicated in Fig. 1, which action short-circuits or cuts out the Ward-Leonard cut-out on the Test Stand so that the current from the battery passes directly through the generator and causes it to run as a motor.

The generator ammeter mounted on the right-hand side of the instrument board will indicate the amount of current being taken to motor the generator, and is indicated by the needle on this instrument reading to the left of the zero center. The amount of current taken should be about 4 amperes, and the generator should turn in a clockwise direction, looking at it from the drive end, without any undue noise or sparking at the brushes.

Motoring Test With Cut-Out Mounted on Generator

For making the motoring test when the cut-out is mounted on the generator the same procedure is followed and the same results should obtain, but it is first necessary to short or cut out of the circuit the cut-out which is mounted on the generator. This is done by using the special wire jumper which has a snap connector on either end, and is provided with the outfit. One of the connectors is snapped on the main terminal of the generator marked (A), and the other connector is snapped on the terminal marked (C) in Fig. 6. By attaching this jumper in this way it has the effect of taking the cut-out out of the system.

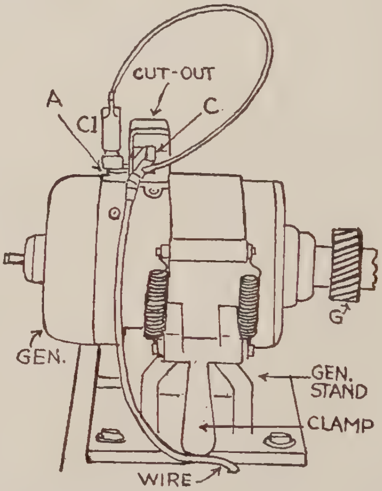

Fig. 6. Method of shorting or cutting out the cut-out on the generator when making the motoring test of the generator.

The starting-motor switch is then pressed, as in making the test without the cut-out mounted on the generator, and the same readings on the ammeter will apply to this method of installation.

GENERATOR TESTS

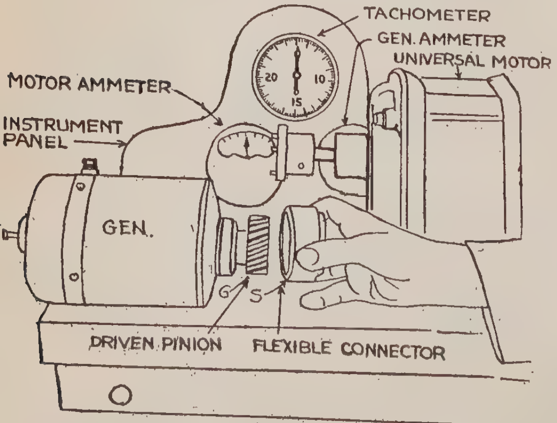

Fig. 7. Hooking up the generator with the drive motor for the generator driven test.

The next hook-up is for making the complete generator test. The first thing that is necessary is to make a connection between the generator and the universal motor, so that it can be driven at the desired speeds.

When the generator is taken off the car for test, it has a gear keyed to its shaft on the driving end. It is not necessary to take this gear off to make the test, but rather this gear is used as part of a flexible connector to hook the generator to the universal motor. The generator half of the flexible connector shown in Fig. 7 is slipped over this gear and locked to it by tightening the screw (S) shown in Fig. 7.

The flexible coupling is of the conventional type, driving through a leather washer. The other half of the coupling is attached permanently to the universal motor shaft. Put the generator in the generator stand, as previously described, turning the flexible connection until the three driving pins on the motor half of the connector fit into the leather washer and then lock the generator in position.

If the generator has no cut-out mounted on it, the generator lead is connected directly to the main generator terminal, as shown in Fig. 4. If there is a cut-out on the generator, the generator lead is connected to the main terminal on the cut-out, as shown in Fig. 5.

The generator will then be connected into the system electrically, the same as it would be in the car, except that the motive power will be furnished by the universal motor instead of the Ford engine.

The first test to make on the generator is to determine whether it is cutting in at the proper speed; that is, whether or not it starts to generate sufficient voltage and current to operate the cut-out, which action connects it to the battery. This is done by starting the universal motor by throwing in the starting switch and then slowly increasing the speed until the cut-out operates. The operation of the cut-out can be noted in two ways: first, a distinct click will be heard when it closes and also the generator ammeter will show a reading of about 1 ampere which will be indicated by the needle of the ammeter to the right of the zero center the instant that it operates. This is probably the best way of noting the action of the cut-out.

If the generator is in good condition, the cut-out should close at about 650 r.p.m., which speed will be shown by the tachometer.

It may be that in the case where the cut-out is mounted on the generator **the cut-out is defective** and will not close the circuit, so that no reading will show in the ammeter. If this happens, the cut-out can be cut out of the circuit by putting the jumper across the two terminals (C) and (A) (Fig. 6), as described under "Motoring Test." The generator tests can then be completed as described, and the cut-out tested independently, as described under "Test for cut-outs."

The next test is to see if the generator is delivering 10 amperes at a speed of 1,400 r.p.m. This test is made by slowly increasing the speed of the generator and noting its output on the ammeter at this speed.

Next, **the test for regulation** is made to see that the third-brush type of regulation with which the generator is equipped is controlling the output of the generator properly at high speeds. This test is made by moving the controlling handle on the rheostat to the right until a speed of from 1,700 to 1,800 r.p.m. is reached. At this speed the generator should not be delivering more than 12 amperes, as will be indicated by the ammeter, as this is the maximum current that the generator is supposed to give. It should be held constant at this rate by means of the third-brush regulation.

STARTING-MOTOR TESTS

First take off the Bendix gear, and place the motor in the generator holder, locking it in place by following the same methods as were used with the generator. See that the heavy terminal again comes on top, and that the motor shaft now extends to the left instead of to the right.

It will be noted that the motor has a square flange on the drive end, and one of these four sides should be placed flush against the upright projection on the back and left-hand side of the generator stand. This actually prevents the motor frame from turning in the stand when the torque test is being made.

Then connect the heavy motor lead to the motor terminal, being sure to make a good connection. The motor is now attached electrically to the storage battery under the same conditions as on the car, and connection is made by pushing the starting switch on the front of the table, allowing current from the storage battery to pass through the motor.

Motor "Free-Running Test"

The motor mounted for the free-running test is shown in Fig. 8. Press the starting-switch lever and the motor will spin rapidly, making what is known as a "free-running" test. The behavior of the motor under this test will, as explained later, indicate clearly any trouble which may exist in it.

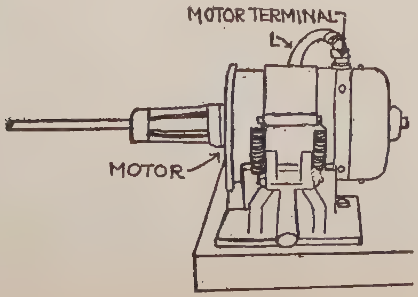

Fig. 8. Free running test of starting motor.

If the motor is in good condition, it should spin over without any undue sparking at the commutator and should draw about 75 amperes, as indicated by the motor ammeter on the left-hand side of the instrument board.

Torque or "Kick" Test of Motor

Attach the brake arm to the motor shaft by simply sliding it on until the inner end of the brake arm enters the bearing housing on the end of the motor housing. This will bring the thumb screw on the other end of the brake arm in the same plane as the counter bore in the end of the motor shaft used for holding the Bendix gear on it. Then turn the brake arm until the thumb screw fits this counter bore and tightens snugly, as shown in Fig. 9.

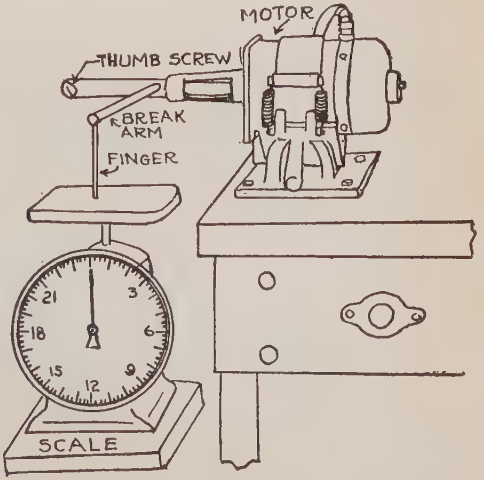

Fig. 9. Method of making a torque or "kick" test of the motor. (Note that the word "break arm" in the drawing should read "brake arm.")

Next pull the swinging shelf out into its extreme position, as shown in Fig. 9, and attach the scale to the shelf by sliding it on the scale holding clip mounted on top of the shelf. Now when the brake arm is placed on the scale it will bring the finger on the end of the brake arm approximately in the center of the scale. If the scale needle does not point exactly to the zero mark, it can be adjusted by the adjusting thumb screw on the upper part of the scale. We are now ready to measure the torque or "kick" of the motor in foot pounds.

How to Make Motor Torque Test

Press the starting switch, which will send the full current from the battery through the motor, causing it to try to rotate. Resistance to rotation is furnished by the scale, and the motor can make only a very small part of a turn when it will stall, which also gives a name to this test known as the "stalling test." Note the reading on the scale, and then quickly note the reading on the motor ammeter.

If the motor is in good condition, the scale should read 12 to 14 pounds, and the ammeter should show a current draw of between 600 to 750 amperes.

As the gear ratio between the Bendix gear on the motor and the gear on the fly wheel on the engine is 12 to 1, this means that the motor under these conditions is exerting a turning effort of 168 pounds on the end of a starting crank one foot long, which is sufficient to turn over any Ford engine under extreme conditions of stiffness.

In making this motor test do not hold the starting switch closed any longer than is necessary to take the readings, otherwise the battery will be unduly run down. It might be well to add at this point that in making a test on both the generator and motor, it is taken for granted that the battery is fully charged. The best method of determining this is by the use of a hydrometer.

In making the generator tests, and especially the final running test, sufficient charging will be given the battery to keep it in proper shape for all the motor tests that are made, but if it should run down it should be fully recharged before making the test.

LOCATING AND REPAIRING GENERATOR TROUBLES (MECHANICAL)[1]

The results of the generator tests given under this heading are those that should be expected when the machine is right in every detail. It is taken for granted that the generator is removed from the car because it is defective and will not successfully pass the generator tests, and it is now necessary to locate and repair the trouble within it.

All troubles with the system can be classed under two headings: "mechanical troubles," and "electrical troubles."

We will take up the **mechanical troubles first,** as it is not only necessary to correct them to get the proper results in the generator, but furthermore, the generator could not be run properly to make the electrical tests unless it is right mechanically. The mechanical troubles experienced are as a rule confined to the following:

1. Loose driving gear.
2. Broken bearing.
3. Armature off center.
4. Shaft bent.
5. Commutator burst.

It is very apparent that a visual inspection and examination will locate any of these troubles. **First take hold of the gear by hand;** see that it is properly and firmly keyed to the shaft. Turn the armature by hand and see that it runs freely and noiselessly. If it sticks or turns hard, examine the machine to see, first, if there is a **broken bearing.** The only remedy for this is, of course, a new bearing.

If the armature is off center, and the bearings are all right, it may be due to a loose pole-piece, and this can be caused by the heavy screws (S) (Fig. 10) which hold the individual pole-pieces to the generator frame having become loosened. Under either conditions the magnetic pull on the pole-pieces will cause them to be drawn toward the armature and will have the same effect as if the armature was off center. **The remedy** for such trouble is to pull the field-piece back into its proper position by tightening up on the screws which hold it in place.

A bent shaft will be a rather unusual source of trouble. **The remedy** is a new armature, it being impossible to straighten for an alignment of bearings.

The final trouble, namely, a **burst commutator,** can be repaired only by putting in a new one. It has been our experience, however, that when a commutator bursts or throws the pieces, a great deal of other damage is done, such as broken brushes or brush-holders, and very considerable damage as a rule to the armature windings. Our recommendation in a case of this nature is the installation of a **complete new armature,** instead of attempting to put on a new commutator and to do the work of connecting up the armature leads to it.

In making the mechanical inspection, it will be necessary to get at the various parts of the generator to do so. The brushes are located at the rear end of the generator and can be inspected by removing the rear-end cover band. This is done by taking out two screws which hold this housing to the generator frame, shown in Fig. 10, marked (A).

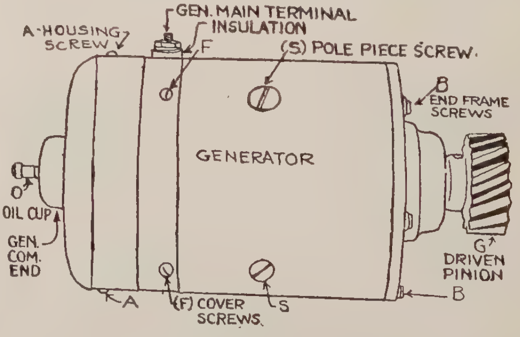

Fig. 10. Illustration of generator, showing pole-piece screws, frame screws, etc.

In order further to disassemble the generator, lift the brushes clear from the commutator by pulling them up in the holders by means of the brush pigtails. They will be held in this position free from the commutator by the pressure of the springs against the side of the brushes.

---

[1] See also "Digest of Troubles," page 454.

Next take out the screws (B), which attach the front end-cover to the generator frame, and pull this cover free from the frame. The front end-cover and armature will then disassemble completely from the frame.

At this point we are in position to **examine the generator completely for all mechanical troubles,** but if it is necessary further to disassemble the generator to get at the brush rigging in the rear end-cover, this can be done by taking out the four screws (F) which hold it in place and then loosening the cover from the frame. It will be noted, however, that the cover can be moved away a short distance only as governed by the length of the wires which are attached to the brushes. **If it is desired to remove it completely,** wires can be disconnected.

Figs. 11 and 12 show **the detail construction of the F.A. generator** with all parts clearly marked. A study of this drawing will assist the service man to understand the complete construction and enable him to disassemble and rebuild the machine properly.

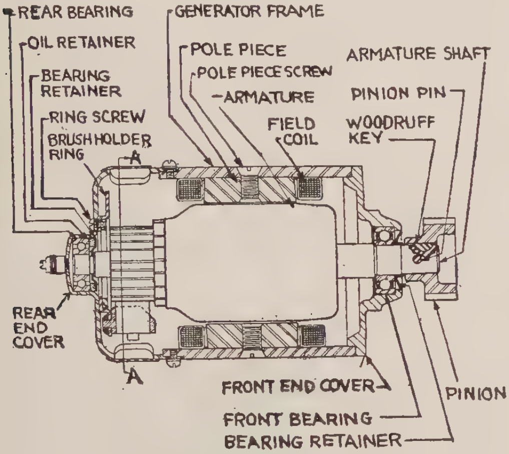

Fig. 11. Longitudinal section of generator.

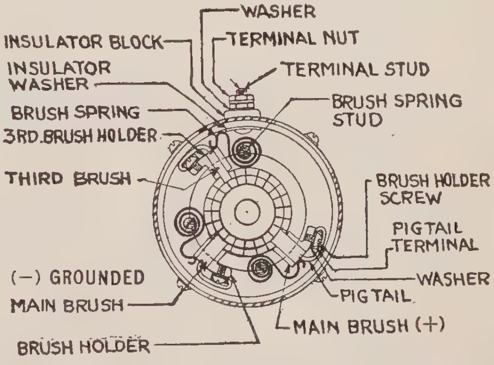

Fig. 12. Cross-sectional view of commutator end of generator. The (−) grounded brush is on the left, and insulated (+) brush on the right.

LOCATING AND REPAIRING GENERATOR TROUBLES (ELECTRICAL);[1] OPEN CIRCUITS

Open Circuits

Having inspected and repaired the generator for mechanical troubles, we then **locate the electrical defects,** which are nearly always the cause of our troubles. All electrical troubles are the result of:

1. An open circuit or partially open circuit.
2. A ground or short circuit.

In case of an open circuit, or partially open circuit, which is generally caused by poor contact, the more common sources of trouble are as follows:

1. A dirty commutator.
2. Worn commutator.
3. Brushes stuck.
4. No spring pressure on brushes.
5. Brushes too short or broken.
6. Broken brush connection.

The more uncommon sources of trouble in open circuits are caused by:

1. An open field.
2. Open armature.
3. A broken connection between commutator and armature winding.

To locate the electrical troubles in the generator, we first make use of the motor test which gives us a good indication of where to look for our difficulty.

If the generator fails to motor and there is no current passed through it, as indicated by no reading on the generator ammeter, we know immediately that we have an open circuit.

If the generator motors very slowly and we have a reading of less than 4 amperes on the scale, it shows that there is a partial open circuit or a poor connection in the generator, which does not allow the proper amount of current to pass through it. This, then, puts our trouble in the open-circuit class, and we go after the locating and localizing of this trouble in the following manner:

Locating Open Circuits

Using the test-points, first test for an open circuit between the main generator terminal marked (T), (Fig. 13), and the insulated brush marked (B). This will test the connection between these two points.

Then test between the insulated brush (B) and the commutator (C).

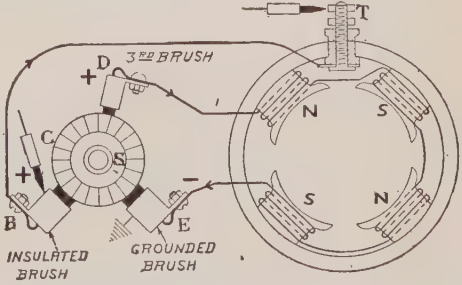

Fig. 13. Testing generator for open circuits with test-points and lamp. The test-lamp and points (Fig. 2, page 509) are used for making the tests. (The brush holder is shown removed and turned over.)

Next disconnect the lead from the grounded brush (E). Then by following out the same line of test as can be clearly seen in Fig. 13, we test between the commutator (C) and the third brush (D) and then between the commutator and the grounded brush.

If the open circuit is in any one of these connections or between any of the brushes and the commutator, it can be localized in this way.

---

[1] See also "Digest of Troubles," page 454.

Commutator and Brush Troubles

Commutator troubles, such as dirty or burned commutators, high mica, etc., are fully treated on pages 491 to 493.

Brush troubles are treated on pages 493 to 496.

Open Field

This test is for testing the shunt field of the generator, by holding one of the test-points on the third brush at (D) (Fig. 14), and the other on the end of the connection (1) which has been taken off the grounded brush-holder (E). This will show us whether the shunt field is all right.

If the test indicates an open circuit, first inspect the joints (2, 3, 4) between the field-coils to see that they are not broken, and then test each field separately by holding the test-points on the ends of each coil. In this way the open circuit can be located in one particular field-coil.

To repair, it will be necessary to disconnect this coil from the other coil and take it out of the machine for further examination. To do this, the pole-piece will have to be removed by taking out the two screws which clamp it to the generator frame.

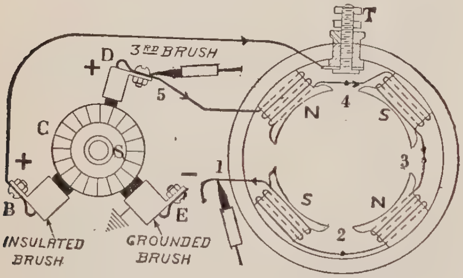

Fig. 14. Testing generator for open field-coils.

It will then be necessary to locate the exact point of the break by unwinding the coil until the rupture is located. Carefully make a good connection at this point, and rewind the field and replace, and reconnect, and then repeat very carefully the test to see that the open circuit has been properly taken care of.

Open Circuit in Armature Coil

There are a number of methods of testing for open circuits in armatures. We particularly recommend the use of the F.B. Testing Set which consists of a very high-grade ammeter and a voltmeter substantially mounted in a walnut case with self-contained shunts for giving three ranges of readings on each instrument and special leads and connectors adapted exclusively for Ford work.

With this instrument are given very careful instructions for easily and accurately locating armature and field troubles on various units of the F. A. starting and lighting system, as well as locating grounds and other troubles in the wiring and battery system.

The following is a simple method for locating open circuits in the armature, requiring the use of an ammeter and one cell of any storage battery, which must be in first-class condition. An ammeter with a range 15 to 25 amperes best answers the purpose for this test.

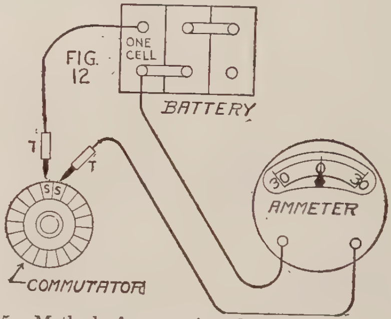

Fig. 15. Method of connecting the ammeter and battery for locating open circuits in armature coils.

The method of using the ammeter and battery and how to wire them up is shown in Fig. 15. The two wires which come with the meter with test-points (T) are preferable, similar to those furnished with the F. B. Test Stand, but any No. 14 or 16 wire with contact-points attached to the end to act as test-points will answer the purpose.

The theory of the test is to send a current through each of the armature coils, one at a time, by holding one each of the test-points on adjacent commutator bars (SS). The current from the battery will pass through the armature windings, and the ammeter will indicate the amount of this current. **If the armature winding is not open in any case,** all of the readings will be approximately the same.

If, however, the ammeter should show very much less on one set of bars than on the others, it indicates that the circuit in that coil is open, caused either by the burning out of that coil or by a broken connection in the wire or a broken connection or poor contact between the commutator bar and the armature coil.

Readings are taken on adjacent commutator bars all the way around the commutator, and if they all read the same there is neither an open circuit nor any other trouble with the armature.

If one or more, however, show a low reading, the cause of an open circuit resulting from one of the causes just mentioned must be located.

If the trouble is a poor connection between the commutator bar and the armature winding, it can easily be repaired by a proper job of soldering, but if the trouble exists in a broken or burned-out armature coil, the complete armature must be returned to the factory for repairs.

LOCATING AND REPAIRING GENERATOR TROUBLES (ELECTRICAL); SHORT CIRCUITS AND GROUNDS

Short Circuits and Grounds

If, when the motoring test is made, taking it for granted that all mechanical troubles have been eliminated as instructed, the generator does not run as a motor and shows more than four or five amperes reading on the ammeter, or if it runs very slowly and still shows a larger current draw than it should for proper running, it indicates that the current from the battery is not passing through the windings of the field and the armature in the proper way, but that all or part of it is being lost or shunted through some grounded connection or some short circuit, and in this way is not doing any effective work.

Again the common sources of this trouble are:

1. Grounded brush rigging.
2. Grounded main generator terminal.

And the more uncommon troubles are:

1. Grounded commutator.
2. Grounded armature coil.
3. Grounded field.
4. Short-circuited armature.
5. Short-circuited field.

Brush Rigging Grounded

To test insulated brush rigging, either lift the brush clear of the commutator, holding it in this position by allowing the brush spring to press against the side of the brush, or place a piece of paper under the brush to insulate it from commutator (Fig. 16).

Then test between the brush-holder and the frame. If this shows a ground, the trouble is in poor insulation between this brush-holder and the cover to which it is attached. It can be found only by proper inspection, and must be repaired by replacement with proper insulating parts.

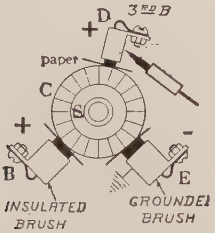

Fig. 16. Insulating the brushes from the commutator with paper preparatory to testing for grounded brush rigging.

Main Terminal Grounded

To make the test for the main terminal, disconnect the lead from it (T) (Fig. 17) to the insulated brush-holder (B), holding one of the test-points (7) on the end of this lead; the other on the frame of the generator (6).

If this shows a ground, carefully examine the insulation on the lead which has just been disconnected and also the insulating bushings and washers that insulate the generator terminal (T) from the frame.

The test on the third brush is made in the same manner, by first disconnecting the field-lead to it, insulating it from the commutator by the paper method or raising it free from the commutator, and then making the test. The grounded brush-holder, of course, is grounded permanently, and this test does not apply to it

Grounded Field

Disconnect the field-lead to the grounded brush (E) (Fig. 17), as well as the lead to the third brush (D), as shown. This then leaves the field with no electrical contact with the rest of the system, and one test-point placed on either one of these terminals and the other on the frame of the generator should show clear.

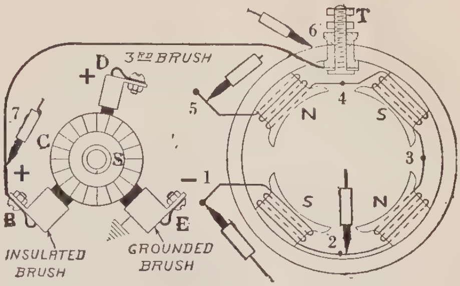

Fig. 17. Tests for grounds in the field-coils and in the commutator.

If it shows a ground, follow the same method of testing for an open field, that is, disconnect the fields from each other where they are soldered together (2, 3, and 4), and test each field-coil separately for a ground. When it has been located, take the pole-piece out and endeavor to locate by inspection just where the wire is touching the frame. After it has been located, insulate it properly with tape, and replace. Be sure to make test after replacing, first on the individual coil and then on the entire field-system before permanently connecting up.

Grounded Commutator

The commutator (C) is entirely insulated from the armature shaft (S) to which it is permanently attached by mica or other suitable insulating material, and there should be no electrical contact between it and the shaft.

The test for a grounded commutator can be made while the armature is in place in the generator frame, or preferably while it is disassembled completely from the machine.

In order to make the test while the armature is in place in the generator, it is first necessary to lift the brushes free and clear of the commutator and to hold them in this position, or else to place pieces of paper between the brushes and the commutator so as to insulate them from it, as in Fig. 16.

Then hold one test-point on the commutator (C) and the other on the armature shaft (S), and if the commutator is free from grounds no current will pass, as indicated by the lamp not lighting.

This test will show whether the commutator as well as the armature windings are free from grounds; but if this test shows a ground, it may be a ground between the commutator and the shaft or between the armature windings and the armature core. If the ground cannot be located and easily repaired by a careful examination, the complete armature should be returned to the factory for repairs or replacement.

Grounded Armature Coils

In addition to a grounded commutator, **one or more of the armature coils may be grounded to the armature core.** If the ground cannot be detected by visual examination the test-points can again be brought into use for localizing the grounded coil.

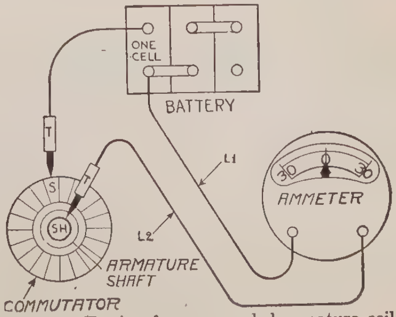

Fig. 18. Testing for a grounded armature coil.

The proper connection for making these tests is by using **one cell only** of any storage battery connected to a set of test-points with the 30-ampere scale ammeter in circuit, as shown in Fig. 18.

Hold one test-point on the armature shaft and the other on one bar of the commutator. The ammeter will give approximately **equal readings** on all commutator bars successively, if there are no grounded coils in the armature.

If there is a grounded coil, the ammeter will show a larger reading when the test-point is touched to the bar to which the grounded coil is connected. In this way any grounded coil is quickly detached and located.

The ground may be between the individual commutator bar (S) and the shaft (SH), or between the armature coil and the armature core. If the ground is in the commutator, it can usually be detected by a visual examination, and often it can also be located in the coil in the same way. Unless it can be easily repaired, the complete armature must be returned to the factory for repairs or replacement.

If the ground is not in the windings, but is in the commutator, it will have to be repaired, as instructed under "Grounded Commutator."

Short-Circuited Armature Coils

The same method for locating a short circuit in the armature windings in the generator is followed as was used for locating open circuits in armature windings. Fig. 15 shows the method of connecting up for this test. The test-points are held on adjacent bars and current from the cell passes through the armature coils, and the amount is indicated by the ammeter.

If all the readings between the adjacent bars are approximately equal, it indicates that the coils are all in good shape, but if one or more of the readings show higher than the average, it indicates that this coil is short-circuited.

The trouble is caused by defective insulation on the coils, allowing the different sections or layers of the coil to come in contact, thus cutting out more or less of the turns in the coil and rendering them useless. The effect is an increase of current through the shorted coil due to the reduced resistance and constant heating of the coil and sparking at the commutator bar connected to the defective coil.

Do not attempt to repair a shorted armature, but return it to the factory for repairs.

Short-Circuited Field

It is possible that one or more of the field-windings may be shorted, resulting from defective insulation, so that the full effect of the field-turns are not being utilized.

A diagram of the field-windings and means for sending a current through the coils by the use of test-points attached to any standard 6-volt storage battery with an ammeter in circuit is shown in Fig. 19. The ammeter preferably should read up to 30 amperes.

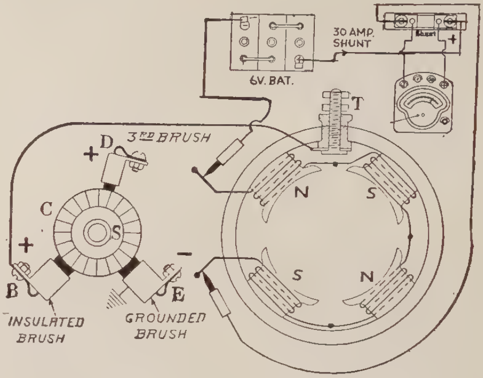

Fig. 19. Testing field-coils by sending current through them from a battery.

First, as will be noted from the illustration, the field-winding connection has been disconnected from the grounded brush (**E**) and also from the third brush (**D**). Test-points are then held on the two winding connections that were just disconnected and the current from the 6-volt storage battery passes through the fields and is indicated on the ammeter.

The normal resistance of the field windings on the F. A. generator varies from $2\frac{7}{10}$ to $3\frac{3}{10}$ ohms, depending on whether they are wound with single cotton enameled wire, in which case the resistance is about $2\frac{7}{10}$ ohms, while if it is wound with double cotton-covered wire, the resistance is about 3 ohms.

With a standard 6-volt storage battery in good condition the ammeter should show from $2\frac{2}{10}$ to $1\frac{8}{10}$ amperes passing through the fields when the test is made. **If the reading is noticeably higher** than this, it indicates that some of the windings on the field-coils are cut out of circuit by being shorted, and it is then necessary to determine in which coil the short occurs.

To do this, take off the insulating tape at the point where the join is made between the individual field-coils, and then measure each coil separately in the same way as above.

The amount of current shown on the ammeter by this test should be four times as great when measuring a single coil instead of four of them in series. Consequently, for a good coil the reading on the ammeter should show from $8\frac{8}{10}$ to $7\frac{2}{10}$ amperes. If any of the coils show a decidedly **higher reading** than this or than any of the other coils, it indicates that it is shorted.

Having located the shorted coil, it will be necessary to take it out of the machine, unwind it until the defective spot in the insulation has been located, then insulate it properly and rewind. Be sure and retest after the coil has been reinstalled in the generator.

THIRD-BRUSH SETTING

The current generated by the F. A. generator should be 10 amperes at a generator speed of about 1,400 to 1,500 r.p.m. Any increase in the speed of the generator beyond this point would tend to increase the current very rapidly, if it were not for some system of regulation for holding this current down to a maximum.

Third-Brush Regulation

On the F. A. generator the system of regulation used is known as the "third-brush" system, so called because a third brush is used in this system.

Just how this third brush is connected to the generator field so that the voltage across the field erminals is equal to the voltage generated between he generator brush and the third brush, is shown n Fig. 13, also Fig. 12.

As the current generated in the machine increases, due to the increase of speed, the magnetic ield becomes distorted or twisted out of line, so that he voltage between the third brush and the generaor brush is decreased. Consequently the field trength is decreased approximately in proportion o the increase of speed, and the current is held by his method to a maximum value of approximately 12 amperes.

The output or the current developed by the generator may be varied by shifting the third brush which s held in place by a bolt in a slotted opening in the brush-holder ring. The bolt is held permanently in position by a hexagonal nut, which is turned with a special wrench furnished with the F. B. equipment.

To increase the output of the generator, loosen the hexagonal nut and move the third brush in the direction of rotation of the armature by tapping the brush-holder, then tighten firmly in this position.

To reduce output of generator, move brush-holder in direction opposite to rotation of armature.

After any adjustment of the third brush, the brush should be sanded. Follow the same instructions and methods given for sanding the regular brushes (page 494). It is very important that the contact between the third brush and the commutator be pretty nearly perfect in order to get proper regulation. After the adjustment and sanding in of the brushes have been made, the generator should then be run through the regular generator test, and a readjustment of the brush should be made if it does not come up to the generator test specifications.

LOCATING AND REPAIRING MOTOR TROUBLES (MECHANICAL)[1]

Motor troubles are classified the same as generator troubles, namely: "mechanical" and "electrical."

Before proceeding with the location of any electrical troubles in the motor, it is first necessary to be sure that all mechanical difficulties are taken care of. Practically the same mechanical troubles can exist in the motor as are possible in the generator, namely:

1. Broken or worn bearing.
2. Armature off center.
3. Shaft bent.
4. Commutator burst.

Bearing Trouble

The motor, unlike the generator, is equipped with **solid bearings,** the front one of a high grade of bronze bushing and the rear bearing of a soft composition bearing metal. As the motor is actually run only a few hours during the course of the year, there is no occasion for these bearings showing any great amount of wear, especially if no dirt is allowed to get in them whenever they are taken down.

If, however, either one or both become badly worn they should be **replaced with new bushings.**

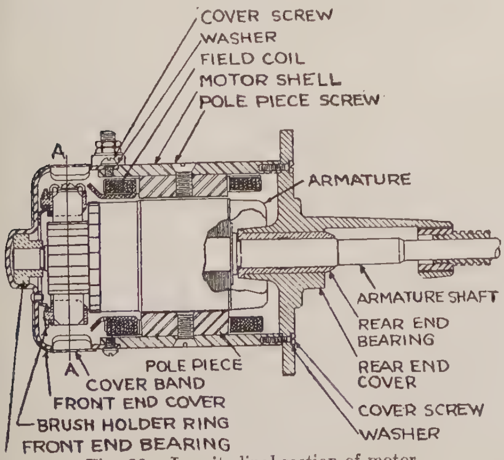

Fig. 20. Longitudinal section of motor.

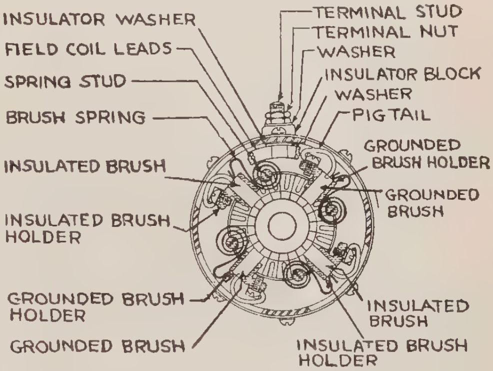

Fig. 20A. Cross-sectional view of front of motor.

Armature Off Center

A broken or worn bearing will allow the armature to locate itself in an off-center position in respect to the pole-pieces to such an extent that it is possible that the armature will rub against the pole-pieces. The **remedy is new bearings** to center up the armature, or it is possible that one or more of the pole-pieces may become loosened, having the same effect as placing the armature off center. The remedy is to pull this pole-piece sungly back into place by tightening screws which hold it to motor frame.

Shaft Bent

There is likely to be more trouble from a **bent shaft** in the motor than in the generator, especially if the operator is careless when starting his car and gets a "kick back" from having his spark lever advance too far, or from the engine being in bad condition. A severe back-kick is liable to bend the shaft. As a general rule, the shaft **cannot be properly straightened** and the complete armature should be returned to the factory.

Commutator Burst

This trouble is a very unlikely one, but if the commutator should burst it always does considerable damage, especially to the brushes and brush rigging. Our suggestion is the same as on the generator, namely, the return of the complete armature to the factory for repairs and substitution of a new armature.

The assembly of the F. A. motor is shown in Fig. 21. Figs. 20 and 20A show the details of its construction. A careful study of these will enable the operator to understand its construction and the proper method of assembling and reconstructing.

---

[1] See also "Digest of Troubles," page 454.

LOCATING AND REPAIRING MOTOR TROUBLES (ELECTRICAL)

Electrical troubles on the motor are classified as on the generator:

1. Open circuits.
2. A ground or short circuit.

An open circuit may be caused by:

1. Dirty commutator.
2. Worn commutator
3. Brushes stuck.
4. Insufficient spring pressure.
5. Brushes too short or broken.
6. Broken brush connections.
7. Open field.
8. Open armature.
9. Broken connection between commutator and armature windings.

Open Circuits

To locate the electrical troubles in the motor, we first determine whether there are any open-circuit troubles. To do this make a free-running test on the motor as previously described.

If the motor fails to run and there is no reading shown on the motor ammeter, it indicates that there is no current passing; consequently the circuit is open.

Or, if the motor runs very slowly and takes considerably less than 75 amperes, it indicates that there is a partial open circuit or poor connection or contact at some place in the motor circuit.

T- STARTING MOTOR MAIN TERMINAL
A- SCREWS FOR COMMUTATOR COPPER BAND
F- END HOUSING COVER SCREWS
S
T
A
F
STARTING MOTOR
S

Fig. 21. Assembly of starting motor.

Take off the motor cover band by taking out the two screws (A) which hold it to the frame so that the brushes and commutator can be examined and tested, as shown in Fig. 21. Using the test-points, the open circuit can be localized by the same method as was used with the generator.

Diagrammatic connections of the motor are shown in Fig. 22. First, either raise all the brushes free from the commutator, or else insulate them by putting paper between them and the commutator.

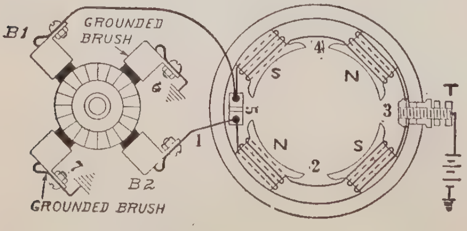

Fig. 22. Connections of the motor showing where to make tests.

Hold one test-point on (T) and the other test-point on the brush pigtail at (B1), which will test one-half of the motor field-circuit from the main terminal (T) up to the brush (B1).

Still holding the test-point on (T), put the other test-point on (B2). This will test the other half of the motor field-circuit.

If either one or both show an open circuit, it is either in the lead to the brushes or in the field-windings, which is easily localized by narrowing the test down.

Using the test-points, proceed in the same way to test between (B1) and the commutator, first lifting the brush (B2) off the commutator and seeing that brush (B1) makes a good contact on the commutator. Then make the same test on (B2).

The open circuits in the fields, brushes, brush rigging, etc., are all taken care of in the same manner as has previously been described for generator troubles. The commutator should be cleaned and repaired, as should the brushes and brush rigging according to these same instructions.

Short Circuits or Grounds

If, when making the free-running test, the motor fails to turn or turns very slowly and a much larger current than 75 amperes is shown by the ammeter, it indicates that there is a ground or short circuit in the motor connections. These troubles are the result of the same causes as in the case of the generator, namely:

1. Grounded brush rigging.
2. Grounded main motor terminal.
3. Grounded armature.
4. Grounded fields.
5. Short-circuited armature.
6. Short-circuited field.

Test for Motor Grounds

First make a combination test for a ground in the main terminal, the field coils, the two insulated brush-holders, and the connections between the coils and brush-holders.

To do this first insulate the two grounded brushes shown in Fig. 22, by placing paper between the brushes and the commutator, or by raising them in the brush-holders so that they will be held free from the commutator.

Then hold one test-point on the main terminal (T) and the other test-point on the frame of the motor. **If no ground is indicated,** it will show that all of the parts are clear. **If a ground is indicated,** it will then be necessary to localize it.

Disconnect the two leads that are attached to the insulated brush-holders (B1 and B2), and hold them clear of the motor frame. Then test for a ground with one point on the main terminal (T) and the other on the motor frame. **If a ground is still indicated,** it is in the field coils or the main terminal.

In order further to localize the ground, the fields must be disconnected from the main terminal (5) and the field and the terminal must be tested separately for a ground.

A ground in the main terminal will be due to defective insulating bushings, which bushings must be replaced with new ones.

A ground in the field-coils is more likely to be due to the field connectors which connect the various coils together (2, 3, and 4) touching the motor frame, as they are not insulated at the point where the connection is made between each coil. All of the wire used in the motor construction is very heavy, and when once bent or pushed in place clear of the frame and metal parts of the motor, there is practically no danger of a ground.

The remedy for a ground in any of the various parts of the motor is the proper insulation of the grounded part. The field-coils are taken out of the frame and handled in the same way as described for the generator coils. Be sure to make a good job of reconnecting the coils when replacing, as they carry a very large current when cranking the motor, and a defective joint would offer a high resistance and cut down the efficiency of the motor.

Brush Rigging Grounded

On the motor two of the brush-holders marked (B1) and (B2) are insulated from the motor frame as shown in Fig. 22, while the other two brushes marked (6) and (7) are grounded to the frame. (B1) and (B2) can be tested for grounds by holding the brushes off the commutator and using the test-points.

Grounded Commutator or Grounded Armature Coil

The test for a grounded motor commutator is made in the same manner as a test for a grounded commutator on the generator, namely, by using the test-points and holding one point on the commutator segments and the other on the armature shaft.

If a ground is indicated on this test, it may be either in the commutator or in the armature coils. Usually it can be located by visual inspection, as the motor windings consist of only a few turns of bare wire to a coil and are well exposed for examination.

If the ground cannot be easily located and repaired, the armature should be returned to the factory for repairs.

Short Circuits in Armature Coils

On account of the very low resistance of the motor armature coils, **it is not practical to locate a shorted armature by the same methods as are suggested for the generator armature.** In fact, if the trouble cannot be located visually, as indicated by burned or flattened commutator bars, the only practical method is the use of a specially designed instrument commonly known as a "growler."

The F.B. growler is specially designed for use with the F.A. motor and the F.A. generator, and a grounded or shorted coil is instantly detected and located in either the generator or motor armature with it. See page 500.

Open Circuits in Motor Armature

The motor armature, being wound with only a few turns of heavy copper wire, **has a very low resistance,** and consequently the methods used for testing for open circuits in the generator armature cannot be used satisfactorily for the motor armature.

On account of the few turns in the motor armature coils and the very large size of wire used, there is practically no trouble experienced from "open coils." The only point at which there is danger of an open is at the point of connection between the ends of the coils and the commutator bar. An open at this point can always be detected by visual examination. **It is generally caused by defective soldering. The remedy** is to pull the leads out of the slot in the commutator riser, clean them thoroughly, and resolder properly.

An open motor armature coil can also easily and quickly be detected by a "flat" on the commutator, caused by the constant arcing due to an open coil. Such arcing burns the commutator continuously at one point until it has made a flat spot. A flat further increases the trouble by causing **the brushes to jump at each turn of the armature** when they come in contact with the defective spot on the commutator.

In all cases of armature trouble due to shorts, grounds, or open circuits, the complete armature should be returned to the factory for repairs.

LOCATING AND REPAIRING CUT-OUT TROUBLES

Automatic Cut-Out

The function of the cut-out is automatically to connect the generator to the battery when the generator has attained sufficient voltage to charge the battery, and to disconnect the two when the voltage of the generator falls below that of the battery so as to prevent the battery discharging through it.

This action is accomplished by the circuit being made and broken by the two contact points of special metal. Normally these points are open or separated. The points are brought in contact by the action of the magnet which has two windings on it, one very fine winding called the voltage coil and connected across the generator terminal, and the other a heavy winding called a series coil and connected in the main line between the generator and the battery. These connections and the details of the cut-out are shown in Figs. 23, 24, and 25.

Action of the Cut-Out

When the generator has attained sufficient voltage it will send a current through the voltage coil (Fig. 23) which will energize the electromagnet and draw the contact points together. This action will close the main circuit between the generator and the battery, through the heavy winding or series coil.

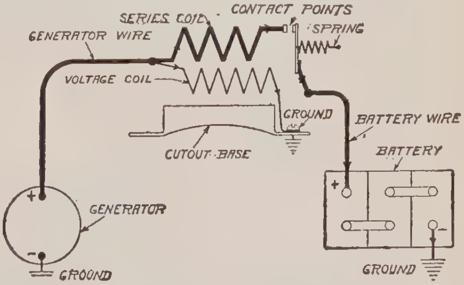

Fig. 23. Circuit of cut-out.

When the voltage in the generator decreases to a point lower than the voltage of the battery, the current from the battery will flow backward through the series coil, but the current through the voltage coil will still be in the same direction. The result is that the two opposing currents will demagnetize the electromagnet and the spring pull on the contact-point lever will separate the points and break the circuit.

The cut-out is one of the most important units in connection with the starting and lighting systems, since its failure to operate either in closing the circuit or not opening it at the proper time can easily put the entire system out of commission.

Two types of cut-outs are in use on Ford cars. The first is known as the **dash type,** because it is mounted on the inside of the dash. This type has now been discontinued permanently.

The second type is known as the **generator type** and is mounted permanently on top of the generator. It is the standard cut-out now being installed on all jobs equipped with F. A. starting and lighting systems.

Both cut-outs are identically the same in action, but slightly different in construction. Fig. 24 shows the dash type, and Fig. 25 shows the generator type.

Cut-Out Troubles

Troubles due to cut-outs are caused, first, by **failure to close** and, second, by **failure to open.**

Failure to close may be caused, first, by an open circuit in the voltage coil, or a shorted voltage coil, and, second, by failure of the contacts to make a connection due to dirty or corroded points.

The cut-out fails to open because the points become welded together, and this welding action is caused, first, by continual opening and closing of the contact points and excessive sparking due to imperfect operation of the generator, and, secondly, fails to open by the sudden breaking of the circuit in the voltage coil, thus killing the demagnetizing effect of it and allowing the current through the series coil to energize the magnet and keep the contact points together.

How to Locate Troubles

First take the cover off the cut-out for inspection; see that the contact points are open, and that they are bright and clean. If they are dirty or corroded they can be cleaned with very fine emery cloth or with a very fine jeweler's file.

Generator Type

With the test-points, first try out the voltage coil to see that it is not open, by holding one point on the ground at (G) (Fig. 25), and the other on terminal (**M**). The lamp should light and the cut-out points should close with a decided click if the voltage coil is in good shape. If it is shorted or grounded, the light will still indicate a closed circuit, but the cut-out points will not close.

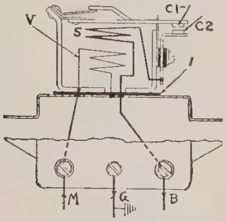

Fig. 24

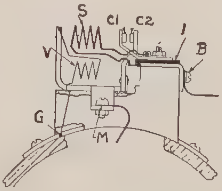

Fig. 25

Fig. 24. Dash type of cut-out; placed on the inside of dash of the car.

Fig. 25. Generator type of cut-out; placed on top of the generator.

Then test the series coil, by holding one test-point on terminal (**M**) and the other at point (**B**). No current should pass between these two points, as the circuit is broken by the fact that the cut-out points are separated. Then test for a ground in the series coil by holding one test-point at (**B**) and the other test-point on the base of the cut-out.

If the open circuits or grounds cannot be readily located and easily fixed by a visual inspection of the cut-out, we recommend the substitution of a new instrument instead of any attempts to rewind the cut-out.

Dash Cut-Out

The same inspection and tests are made on this type of instrument (Fig. 24), except that the test-points are held at the points (**M**) and (**G**) for making the voltage coil test, and on (**M**) and (**B**) for making the open-circuit test on the series coil, and at (**G**) and (**B**) for making the grounded test on the series coil.

To test the generator type it is not necessary to dismount it from the generator, but the battery lead should be disconnected from it until after the tests have been made and the instrument repaired, because if the cut-out is accidentally or intentionally closed the battery will discharge through the generator.

After the tests on the generator type have been made and the trouble eliminated if possible, the battery connection should be made for the regular generator test, and the cut-out should be tested to see that it cuts in at the proper speed and opens properly when the speed of the generator falls too low.

On the dash-type instrument after inspection and repairs have been made, or to test a new instrument, provision is made for this test on the F. B. Test Stand.

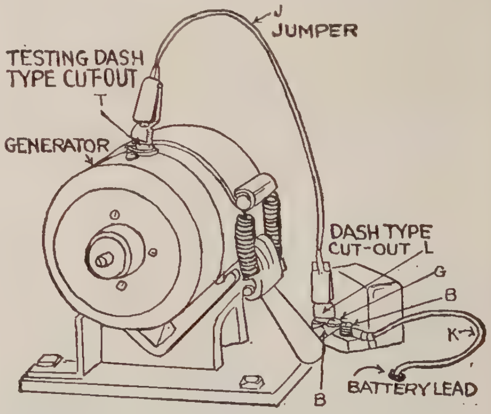

Fig. 26. Method of connecting the dash type of cut-out with the generator for testing the cut-in and cut-out speeds when driving the generator on test.

How to connect the dash-type cut-out to the system on the stand is shown in Fig. 26. The middle or ground terminal is attached to the copper strip fastened to the generator base (G) (Fig. 26). The battery lead is then connected to the battery terminal on the cut-out and, using the jumper, the generator terminal on the cut-out is connected to the main terminal on the generator. This hook-up then puts the cut-out in the circuit, identically the same as if it were attached to the dash of the car, and it can then be tested for the cutting-in speed and for proper opening at low generator speeds.

INSTRUCTION No. 46

THE STORAGE BATTERY; GENERAL DESCRIPTION: Connections; Care

GENERAL DESCRIPTION AND DATA

Storage batteries are described as being devices for storing electrical energy, which may be used for various purposes. They do not store the current, however, but generate electricity chemically, as will be explained farther on.

Storage batteries are also called "accumulators," and, under certain conditions, they are called "secondary" batteries.

The storage battery is used on automobiles for starting, ignition, lighting, operating the electric horn, and for various other purposes. The storage battery is used for starting the gasoline engine, by supplying current to an electric motor which causes the crank shaft of the engine to revolve.

Storage battery for ignition: Where a storage battery is used for ignition purposes alone, it is usually smaller; its capacity being from 40 to 60 ampere-hours. Its rate of discharge is about 2 to 5 amperes.

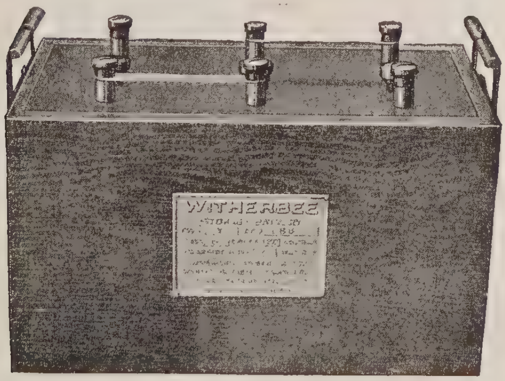

Fig. 1. A storage battery designed for **ignition and lighting.**

Storage battery for ignition and lighting: Where used for ignition and lighting, and not for starting purposes, the capacity ranges from 40 to 120 ampere-hours. The sizes in general use are of 40, 60, 80, 100, and 120-ampere-hours capacity.

The lighting and ignition battery is never subjected to a greater discharge than 5 to 15 amperes. For this reason, the connectors which connect one cell with another are of lighter construction than those of a battery used for lighting, ignition, and starting.

Lighting-battery plates are heavier and thicker in construction, being designed for service of low-discharge rates.

Storage battery designed for ignition, lighting, and starting: The usual capacity of a battery used for this combined purpose is from 90 to 100 ampere-hours. A generator operated from the engine keeps the battery charged, otherwise it would have to be recharged from an outside source.

The connectors on a battery of this type are very heavy, as the discharge, when operating a starting motor, sometimes runs as high as 450 amperes; the usual rate being from 150 to 200 amperes.

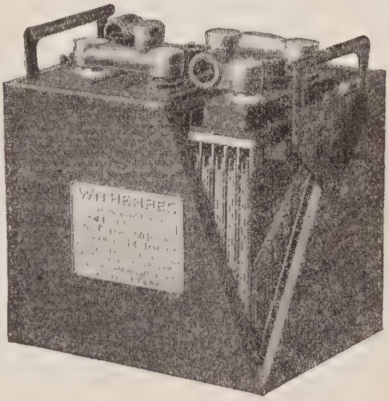

Fig. 2. A storage battery designed for **starting, lighting, and ignition.** Note the heavy construction of the connectors. One end is opened in order to show the plates of one cell.

The more plates per cell, or the greater the plate area, the greater is the batteries' capacity. Therefore, where batteries are designed for starting, lighting, and ignition, there are several thin plates; but a large plate area is used. Hence the large capacity that is essential where a high discharge is required.

Meaning of Amperes and Volts and Ampere-Hour Capacity

The meaning of "amperes" and "volts" is explained on page 175. The standard measure of the energy put into a battery is in terms of ampere-hours.

A volt is the unit of pressure which is necessary to cause electric current to flow.

A coulomb is the unit of electrical quantity: such a quantity of electricity as would pass in one second in a circuit whose resistance is one ohm, under an electromotive force of one volt.

An ampere is the practical unit of electric current—such a rate-of-flow of electricity as transmits one coulomb per second. The current rate-of-flow of 10 coulombs per second is 10 amperes; 50 coulombs per second is 50 amperes, etc. The amount of electricity is not of so much interest as the rate-of-flow—the ampere. Therefore this term is the one more generally used.

A higher electrical pressure (voltage) is required to force the same current through a small wire than through a larger one or through one of increased diameter. A higher voltage is required to force the same current through a long wire than through a shorter one.

The capacity of a battery is measured in ampere-hours. The volume of current flow is measured in amperes. A current of one ampere, flowing for one hour, is the unit by which capacity is measured, and is called "ampere-hour."

The ampere-hour capacity obtainable from a battery depends upon the amount of current consumed by the ignition, starting, or lighting system, and the capacity or quantity of electricity the battery is made to deliver. Lowering the consumption and increasing the capacity of the battery increases the ampere-hour capacity. The capacity of a battery is independent of its electrical pressure. Thus, a flow of 10 amperes, maintained for 8 hours, amounts to 80 ampere-hours.

The ampere-hour capacity of a battery, as stated, is dependent upon the rate of discharge. The lower the rate, the greater will be the capacity.

The same battery that has a capacity of 100 ampere-hours, at the 10-ampere discharge rate per hour, will have a capacity in excess of 100 ampere-hours if discharged at a lower rate, say of 5 amperes per hour.

An example: A certain battery will develop the following ampere-hour capacities at the indicated rates:

50.4 ampere-hours at a 3-ampere discharge rate for16.8 hours.
42.5 ampere-hours at a 5-ampere discharge rate for 8.5 hours.
36. ampere-hours at a 7½-ampere discharge rate for 4.8 hours.
30.0 ampere-hours at a 10-ampere discharge rate for 3.0 hours.

Ampere-Hour Discharge Rate of Battery for a Starting Motor

Let us take as an example a starting motor which requires 200 amperes for 3 seconds to crank the average engine. This means that 600 ampere-seconds (200 x 3) are taken from the battery. This is one-sixth of an ampere-hour.

If, when running the car, the generator delivers 6 amperes to the battery, it will require 2 minutes of running to replace the current taken out.

The voltage per cell of a fully charged battery during discharge at the 200-ampere rate will drop to 1.8 to 1.6, depending on the kind of plates and separators used.

If a battery has thick, **heavy plates and rubber separators instead of wood,** the acid cannot act as readily on the plates as it can when there are more plates but thinner. Acid cannot circulate as readily through the hard rubber as through porous wood. Furthermore, if the active material on the plates is hard, then the acid cannot act as readily as when it is soft.

For these reasons, the plates and separators used for the starting battery, which has a very heavy discharge, are **not as thick,** and the **separators are more porous,** and the active material is somewhat softer. The life of the starting battery of course is not as great as with a battery designed for a very low rate of discharge.

Voltage of Battery Cells

The voltage of a storage battery is determined by the number of cells. Each cell gives, on open circuit, from 2.1 to 2.2 volts when charged, no matter how many plates or what the size of the plates. If there are 3 cells to a battery, then the voltage would be 6.6 volts; that is, on open circuit, immediately after charging.

On a discharge, a charged battery will drop to 2 volts per cell, and if, say, an 80-ampere-hour battery is discharged for 8 hours at a rate of 10 amperes per hour, the voltage would gradually drop from 2 volts per cell to 1.7 volts at the end of the 8 hours, at which time it is discharged.

After this period, the voltage rapidly drops to zero voltage, in a manner similar to that in which the pressure of compressed air in a tank dies down if the air is drawn off.

The usual practice in determining the voltage of a storage battery is to count the number of cells. If there are three cells connected **in series,** which they usually are, each cell is considered as 2 volts, no matter how large or how small they may be.

A 3-cell battery would therefore be termed a "6-volt battery," a 6-cell battery would be termed a "12-volt battery," and so on. The 3-cell, or 6-volt battery represents the number of cells in general use on most cars. The Dodge uses 6 cells, or a 12-volt battery.

Capacity of a battery: The length of time a battery will maintain a certain current output, or ampere-hour discharge, depends upon the capacity of the battery, and the capacity depends upon the plate area exposed to the electrolyte. For instance, an ordinary jump-spark coil requires approximately 2 amperes. Therefore a 60-ampere-hour-capacity battery would operate the coil for approximately 30 hours, as the discharge rate is low. If the discharge rate was high, the ampere-hour capacity would be less.

Battery rating: It is customary for battery manufacturers to rate the battery as a "60-ampere-hour battery," or as a "100-ampere-hour battery," etc. This means that the battery is capable of giving 1 ampere for 60 or 100 hours respectively, if fully charged, and is discharged at a rate of 1 ampere.

The voltage of a battery does not entirely depend upon the size of the cell or the plate area of the cell. A battery is usually rated at 2 volts per cell, but the voltage varies slightly under certain conditions. We are of course considering a fully charged cell. The internal resistance of a cell is what governs the voltage.

If the battery is discharged, the internal resistance is greater, because the electrolyte, being less dense, offers resistance, and consequently less voltage. The higher the gravity up to a certain point, the less is the resistance. Too high a gravity (too much acid) is detrimental to the plates. When a very high discharge is made upon a cell, this calls for rapid circulation of the acid. Therefore, if separators are not porous, the internal resistance would be affected.

The capacity of a battery is usually rated in ampere-hours, meaning that a fully charged battery will discharge at a certain rate a constant current for a certain time until the voltage drops to a certain value (1.8). The rate of discharge is found by dividing the ampere-hour capacity by the hours, as, for example, 8 hours: 90÷8=11¼ amperes for 8 hours.

The capacity depends upon the plate area exposed to the electrolyte. If a square foot of positive plate surface is exposed to the electrolyte, the capacity is usually rated at from 40 to 60 ampere-hours, that is, at an 8-hour rate. This, however, varies. Temperature, as well as free circulation of the electrolyte, also affects the capacity of a battery.

Determining What Capacity of Battery to Use

Suppose a battery is to be selected for lighting purposes alone:

The first step in determining the proper size of battery for "lighting duty" is to decide upon the voltage of the lamps. Tungsten lamps, which consume about one-third the current required by carbon lamps, should invariably be used.

The second step is to determine the amount of current that the battery will be required to deliver. Do this by ascertaining, first, the number of lamps to be used, the voltage of each, and then determine the quantity of current each will take. Then add the total, which will give the total amperage required.

In some cases not all the lamps will be operated at the same time, and this should be taken into consideration. Allowance should also be made for any other current-consuming devices that may be used.

Knowing the amount of current that the battery will be required to deliver, you can select a battery of the proper capacity by referring to the table (Fig. 3).

How to Determine Number of Cells and Plates to a Cell by Number on Battery

In the U.S.L. battery lists, the first letter stands for a certain general type or construction.

For example, in type C-607, the letter "C" indicates the use of "C" plates, "C" jars, "C" covers, etc. The last two figures signify the number of plates per cell, and the first figure signifies the number of cells in the battery. Thus, battery type C-607 has 6 cells of 7 plates each; type A-317 has 3 cells of 17 plates each.

The suffix, or right-hand letter, indicates a particular assembly or arrangement of the jars in the battery box. For example, the letter "B" in type C-607-B indicates that the 6 jars are assembled side by side in the battery box.

Exide starting, lighting and ignition batteries: Take, for instance, the 3-XC-13-1 battery. The number "3" signifies that the battery is made up of 3 cells; the letters "XC" signify that the plates, separators, jars, covers, etc., which go to make up the battery, are of the type known as "XC"; the number "13" signifies that there are thirteen plates in each cell; the figure "1" signifies that the cells are assembled in the wood case side to side, this being known as No. 1 assembly.

When the cells are assembled end to end, the assembly is known as No. 2.

The same method of designation is followed out in the LX and SX batteries, also listed in the table of "Exide" batteries.

Types of Batteries (Exide as an Example)

Types JX, LX, LXR, LXRV, MHA, PHA, PHC, SX, and XC have been designed and built to meet the particular requirements of starting, lighting, and ignition service for passenger automobiles and power boats.

Types KXD, LXRE, and XE have been especially developed to meet the requirements of the exacting starting, lighting, and ignition service on motor trucks and tractors.

Types KZ and ZA have been produced particularly for motorcycle lighting and ignition service.

Capacity of Exide Batteries

The ampere-hours obtainable from a battery are greater for a **long low-rate** or intermittent discharge than for a **short high-rate** discharge. By an intermittent discharge is meant discharges of a few hours each spread over a period of three days or more.

The following table shows the **capacities at different discharge rates** for the various Exide types of batteries.

TYPE AND SIZE OF CELL	CRANKING CAPACITY	LIGHTING CAPACITY (IN AMPERE-HOURS)						IGNITION CAPACITY IN AMPERE-HOURS
	AMPERES FOR 20 MIN.	DISCH'G'D INTERMITTENTLY	1 AMPERE RATE	3 AMPERE RATE	5 AMPERE RATE	7½ AMPERE RATE	10 AMPERE RATE

Fig. 3. Capacity of Exide batteries.

Age of Batteries

The age of batteries can be told by repairmen, as many of the manufacturers have codes which give the date from which time-adjustment can be made. These codes are letters or figures stamped on the connector, the name plate, or the battery box.

Some of the codes as supplied to us by the manufacturers are:

EXIDE AGE OR DATING CODE

Month	Stamp	Month	Stamp
Oct., 1917	Y	Nov., 1918	K
Nov., 1917	Z	Dec., 1918	L
Dec., 1917	&	Jan., 1919	M
Jan., 1918	A	Feb., 1919	O
Feb., 1918	B	Mar., 1919	Q
Mar., 1918	C	April, 1919	R
April, 1918	D	May, 1919	S
May, 1918	E	June, 1919	T
June, 1918	F	July, 1919	U
July, 1918	G	Aug., 1919	V
Aug., 1918	H	Sept., 1919	W
Sept., 1918	I	Oct., 1919	Y
Oct., 1918	J	Nov., 1919	Z

EXIDE AGE OR DATING CODE—*Continued*

Month	Stamp	Month	Stamp
Dec., 1919	&	Jan., 1921	M-1
Jan., 1920	A-1	Feb., 1921	O-1
Feb., 1920	B-1	Mar., 1921	Q-1
Mar., 1920	C-1	April, 1921	R-1
April, 1920	D-1	May, 1921	S-1
May, 1920	E-1	June, 1921	T-1
June, 1920	F-1	July, 1921	U-1
July, 1920	G-1	Aug., 1921	V-1
Aug., 1920	H-1	Sept., 1921	W-1
Sept., 1920	I-1	Oct., 1921	Y-1
Oct., 1920	J-1	Nov., 1921	Z-1
Nov., 1920	K-1	Dec., 1921	&-1
Dec., 1920	L-1		

Note. Since October, 1917, the date of shipment from the Exide factory has been stamped on the top of the first inter-cell connector link from the negative end of the battery and not on the nameplate.

Willard

When batteries are put into service, the date is shown in plain figures for the month and year on top of the connector. The customer can have his battery registered at the Willard service stations.

The Willard code uses the first letter as the year since 1916, using A for 1916, and so on alphabetically. The second letter indicates the month in alphabetical order except that I has been dropped.

Prest-O-Lite

Wet storage batteries shipped from the factory are branded with numerals, for example: "9-21," which is September, 1921.

Green seal or bone-dry batteries, when shipped to distributors, are not branded. Distributors are supplied with plates, with a space on them for inscribing the battery's date of service. This is on the side of the battery, and is usually inscribed by the distributor by means of a set of dies.

How to Tell if a Battery Has Been Repaired or Rebuilt

A rebuilt or repaired battery can usually be determined by noticing if the connectors have been removed. When these have been replaced and burned, a bright spot will appear in the end of each connector, and usually the numbers which were moulded on the connector will have been taken off.

Standard Size of a Starting and Lighting Battery as Determined by the S. A. E.[1]

Overall width, from side to side of case, not to exceed 7½".

Overall height, from bottom to top of handles, not to exceed 9½".

Overall length, measured from end to end of case, including handles, shall vary according to capacity and details of design. Handles shall, as standard, be placed at the ends of the battery. The space occupied by the handles, hold-down devices, shall be in the direction of width of battery. Terminals and connections shall not extend above handles.

ASSEMBLY OF STORAGE-BATTERY CELLS

The arrangement of the cells in the battery box can be across the battery box, termed "side assembly," or lengthwise with the battery box, termed "end assembly."

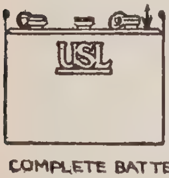

Fig. 4

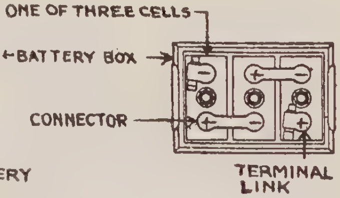

Fig. 5

Fig. 4. Side view of a complete storage battery.

Fig. 5. Top view of a 3-cell battery (6 volts) with one row of cells arranged as a "side assembly."

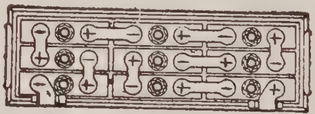

Fig. 11. Top view of a 9-cell battery (18 volts) with three rows of cells arranged as an "end assembly."

Cell Connections

The battery voltage is determined by the number of cells it contains, each cell being of a 2-volt capacity.

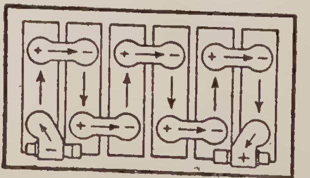

Fig. 12. Arrows show direction of current flow from cell to cell during discharge on a 6-cell, 12-volt battery, where the cells are side by side. Current would flow out from the (+) terminal to the circuit, then back to the (—) battery terminal. All cells are connected in series.

---

[1] Society of Automotive Engineers.

Cells are usually connected in series, that is, the (−) terminal of one cell is connected with the (+) terminal of the next cell, and so on, as shown in Fig. 12. It is possible to connect cells so that a lower-voltage lamp or ignition circuit can be used on a higher-voltage battery.

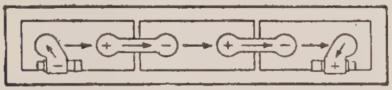

Fig. 13. Arrows show path of current from cell to cell on a battery during **discharge,** on a 3-cell, 6-volt battery. All cells are connected in series.

When a battery is discharging into a circuit, the current flows from the (+) terminal of the battery to the circuit, back to the (−) terminal of the battery. The arrow points in Fig. 12 show the path of the current when discharging.

When a battery is being charged by a generator, the current path through the battery is in the opposite direction.

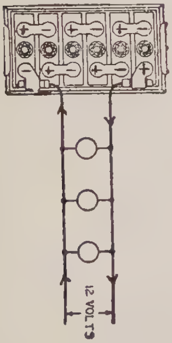

Fig. 14

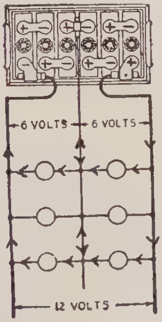

Fig. 15

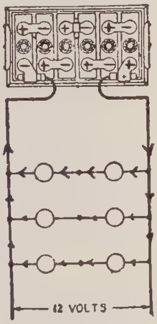

Fig. 16

Fig. 14. A 6-cell (12-volt battery) supplying current for one circuit of 12-volt lamps. Lamps are connected **parallel** across the circuit or line. If each lamp takes 1 ampere, the **discharge** of the battery would be **3 amperes.**

Fig. 15. A 6-cell (12-volt) battery supplying current for two lamp circuits of 6 volts each circuit. The third wire is the **neutral wire,** and connects with a neutral link or connection of the battery. Thus a neutral wire divides the battery circuit into three cells on each side.

The lamps are connected **parallel** across the line. If each lamp takes 1 ampere, then 3 amperes would be taken from the three cells on the right and 3 amperes from the three cells on the left, or **3 amperes from the six cells.** Therefore it is plain that the load on each side should be divided equally, so as not to discharge one side more quickly than the other.

This battery would be charged by connecting the end terminals (+) and (−) with a 12-volt charging circuit.

If one lamp burns out, it would not affect the other lamps.

The circuit of 3 lamps on the right would be from the (+) terminal of the battery to the lamps on the right, to the neutral wire, to the (−) terminal of the third cell in the center (right).

The circuit of 3 lamps on the left would be from the (+) terminal (top center cell at the left), to the neutral wire, through the lamps, to the (−) terminal of the battery.

Fig. 16. A 6-cell (12-volt) battery supplying current for one circuit of 12 volts. Two lamps are connected **in series** and then **parallel** across the line. Each lamp is 6 volts and two in series would operate on 12 volts.

If each lamp required 1 ampere, each of the two lamps across the line would draw 1 ampere; thus **3 amperes** would be the **battery discharge.** If one of the two lamps across the line should burn out, the other lamp would go out, as its circuit would be open. The other lamps, however, would not be affected.

Amperes do not express quantity. It will no doubt appear to the reader that the battery in Fig. 15 or Fig. 16 would be discharging 6 amperes. This is the result of considering amperage in terms of **quantity** of electricity; whereas it should be considered as expressing **rate of flow, or speed** of current.

In order to produce **light,** it is necessary to have **power,** and in Figs. 15 and 16, we have assumed that each 6-volt lamp draws **1** ampere. Therefore, the **power** required to light **each lamp** is 6 volts×1 ampere=6 watts per lamp.

In Fig. 15, we have six lamps, each requiring 6 watts power, or a total of 6×6=36 watts are necessary to cause the six lamps to burn. The battery supplies power at a pressure of 12 volts; consequently the **current discharging** from the battery would be 36 watts÷12 volts=**3 amperes.** For the same reasons, the current in Fig. 16 would also be **3 amperes.**

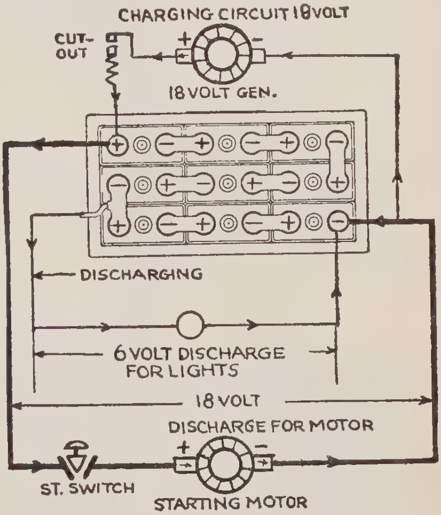

Fig. 16B. A 9-cell (18-volt) battery connected so that it **will discharge** at 18 volts for a starting motor and at 6 volts for a lighting circuit. The **battery is charged** by an 18-volt generator.

The charging circuit is from the (+) brush of the generator, through the cut-out points when closed, to the (+) terminal of the battery, through the nine cells connected in series, to the (−) terminal of the battery, to the (−) brush of the generator.

The discharging circuit of the starting motor is from the (+) terminal of the battery, to the starting switch, to the motor brush, through the motor field and armature, to the (−) brush, to the (−) terminal of the battery. This circuit is never on when the generator is charging the battery.

The discharging circuit for 6-volt lights: The lead wire for the lighting circuit is tapped on to the connector which connects with the lower cell at the left. Thus (+) current is derived from this lower left cell. The circuit is then through the lamp to the (−) terminal of the cell on the lower right. Note that there are 3 cells, or 6 volts used for the lighting circuit.

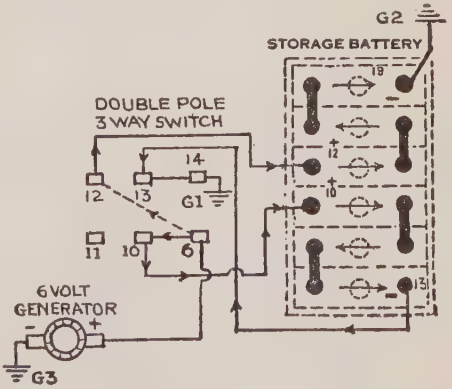

Fig. 17. A 6-volt generator **charging** a 6-cell (12-volt) battery.

Circuit of generator charging battery: We shall assume that we have a double-pole switch and that it is thrown to the right, so that 10 and 6 and 13 and 14 are connected.

The circuit for the three lower cells would then be from the (+) brush of the generator to (6), to (10), to the (+10) terminal of the battery, then through the three lower cells to the (−13) battery terminal, to (13) on the switch, to (14) which is grounded (G1), to the (−) grounded brush of the generator (G3).

The circuit for the three upper cells would be from the (+) brush of the generator to (6), through a permanent connection to (12), to the (+12) terminal of the battery, through the three upper cells, to the (−) grounded terminal of the battery (G2), to the (−) ground of the grounded brush of the generator (G3).

This would be termed **a series and multiple connection.** There are two sets of three cells of batteries connected in series; then the two sets are connected **in multiple** with the generator. This is the principle used on the 1917 "Maxwell 25," where a 6-volt generator and a 12-volt starting motor were used (see Index for Maxwell diagram).

The starting motor circuit is shown below (Fig. 17A). We shall assume that the switch lever has been thrown to the left, thus connecting 10 and 11, and 12 and 13; 6 and 14 have been cut out, opening the generator circuit.

The starting-motor circuit is then from (+12) of the battery, to (12) on the switch, to (13) on the switch, to battery terminal (−13), through the three lower cells to (+10), to (10) on the switch, to (11), to the (+) brush of the starting motor, through the starting motor field and armature, to the (−) grounded brush of the starting motor (G3), to the (−) grounded terminal of the battery (G2), through the three upper cells, to (+12), where we originally started.

This would be termed **a straight series connection.** The six cells of the battery are connected in series with the starting motor.

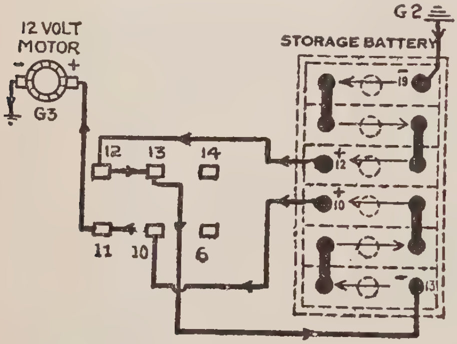

Fig. 17A. This illustration presents the same 12-volt battery as shown in Fig. 17. It is now being used on **discharge** to operate a 12-volt motor. Note how the battery connections are changed at the switch, in order to place the six cells in series, thus obtaining 12 volts from the battery.

Fig. 18. A 6-cell (12-volt) battery with cells connected in series. In this case we should have a voltage of 12 volts at the battery terminals.

If each cell had a capacity of 80 ampere-hours with this straight series connection, we should obtain only an **80-ampere-hour capacity** from the six cells at **12 volts.**

Watts = volts × amperes; 12 volts × 80 amperes = 960 watts. Therefore the **watt capacity** is 960.

Fig. 18A. A 6-cell battery with two sets of three cells connected **in series,** which would be 6 volts for each set. The two sets are then connected to the line **in multiple.** At the (+) and (−) terminals of the wires, we should have 6 volts, or the voltage of three cells in series. If the cells are of 80 ampere-hour capacity, we should have an **80-ampere-hour** capacity for each set of three cells in series, or a **160-ampere-hour capacity** for the two sets connected in **multiple** at 6 volts.

The watt capacity would be the same as in Fig. 18; for example, 6 volts × 160 amperes = 960 watts. Therefore the total output or capacity, as shown in Figs. 18 and 18A, is the same, the only difference being the rate of output.

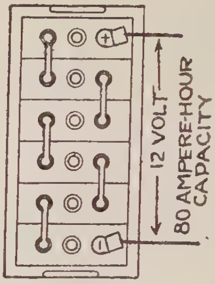

Fig. 18

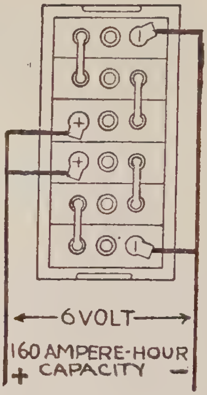

Fig. 18A

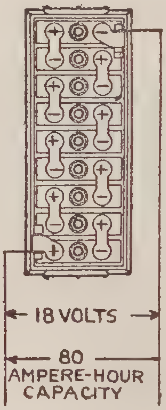

Fig. 18B

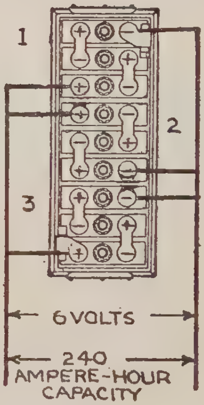

Fig. 18C

Fig. 18B. A 9-cell (18-volt) battery with cells connected in series. The terminal voltage is 18 volts. **The ampere-hour capacity is 80 ampere hours,** assuming that each cell is an 80 ampere-hour capacity battery.

Watt capacity would be 18 volts × 80 amperes = 1,440 watts.

Fig. 18C. A 9-cell (18-volt) battery with three sets of three cells connected **in series,** which would be 6 volts for each set. The three sets are then connected to the line **in multiple.** At the terminals, or wires, we should have 6 volts, or the voltage of three cells in series.

If cells are of 80 ampere-hour capacity, we should have an **80 ampere hour capacity** for each set of three cells in series, or **240 ampere-hour capacity** for the three sets connected in **multiple,** at 6 volts.

The watt capacity would be the same as in Fig. 18B. For example, 6 volts × 240 amperes = 1,440 watts.

The capacity of the battery, as will be observed in the examples given, is greater when the cells are connected in **multiple** than when connected in **straight series. The voltage, however,** is less; thus the watt capacity is equalized.

PARTS OF A MODERN STARTING, LIGHTING, AND IGNITION BATTERY (THE EXIDE USED AS AN EXAMPLE)

The external parts of the Exide type "3-XC-13," manufactured by the Electric Storage Battery Co., Philadelphia, Pa., are shown in the illustration (Figs. 20 and 21). By referring to page 523, we find that 3-XC-13 means 3 cells using plates, separators, jars, covers, etc., of the XC type; the 13 signifies that there are 13 plates in each cell. If there are 13 plates in each cell, then there would be 7 negative plates and 6 positive plates, as there are always more negative than positive plates.

The internal parts consist of, first, a wooden case for holding the cells. The cells are then placed in the wooden case, made of hard wood, thoroughly coated with an acid-proof paint. The jars in which the plates are placed are made of hard rubber. There are three jars or cells in this case; thus it is a 6-volt battery.

Note in Fig. 21, that a section is cut away to show the parts of the cell in the jar at the end of the case.

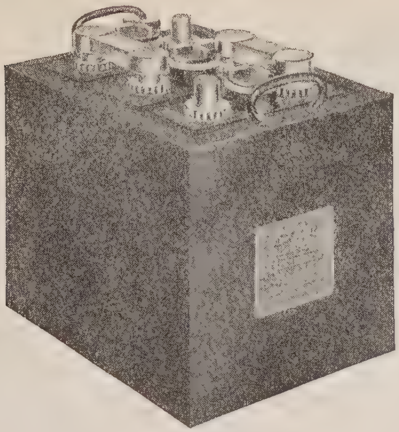

Fig. 20. Starting and lighting battery. Note the heavy connections. (Exide type 3-XC-13.)

Observe, first, that there is a negative plate, then a separator, then a positive plate, and so on, until there are 13 plates per cell (Fig. 21).

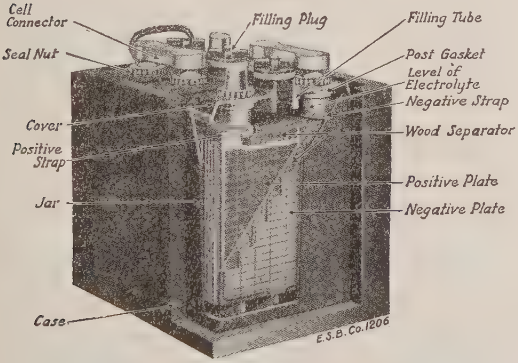

Fig. 21. The Exide type "3-XC-13," 3-cell battery; shown in section.

Jar:[1] The cell container is a rubber jar of special composition which will withstand the vibration of the car and any ordinary handling without breakage. The plates rest on stiff ribs or bridges in the bottom of the jar (Fig. 27), allowing space for the gradual accumulation of "sediment."

The plates are different in color, the positive (lead oxide) being a deep chocolate color, and the negative a gray (pure lead).

The plates are pasted and formed in groups. A positive and a negative plate of the Exide make are shown in Figs. 22 and 23.

Group: A set of plates burned to a strap is known as a "group," either positive or negative.

Fig. 24 shows a negative group of seven negative plates.

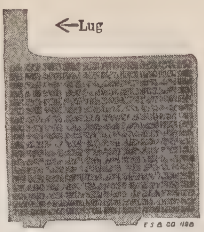

Fig. 22

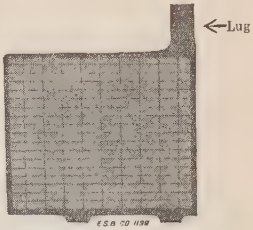

Fig. 23

Fig. 22. "Positive" plate, brown or dark.
Fig. 23. "Negative" plate, gray or light color.

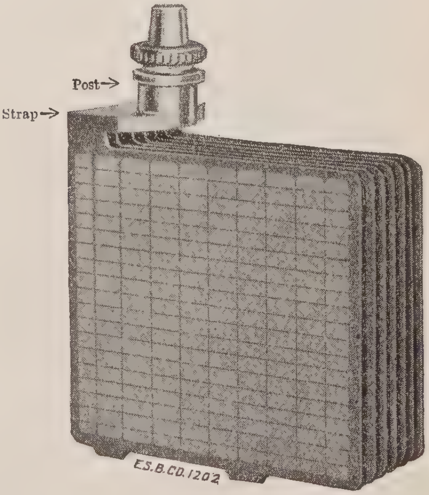

Fig. 24. A group consisting of seven negative plates and post and strap burned to lugs of plates.

A positive group would be arranged in the same manner, except that there would be one less plate of the positive group, or six plates.

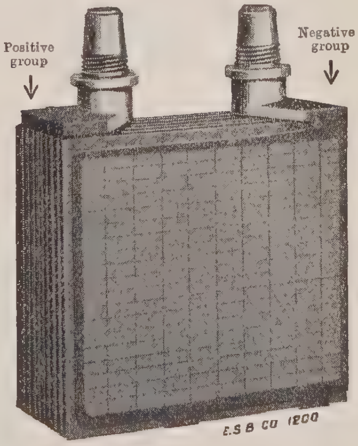

Fig. 25. Two groups, or the negative and positive plates, are called "elements." The two groups are interleaved, that is, the positive group of 6 plates is placed between the negative group of 7 plates, with wood separators between them. Thus two of the negative plates are always on the outside.

Element: A positive and a negative group together with the separators constitute an "element," as explained above.

---

[1] The Exide battery is now using a composition case called Gummite, which is a very hard and durable substance in which some of the batteries are being assembled. This case takes the place of the rubber jars formerly used with each cell and of the wood case. The case is made with three compartments so that the plate elements are put right in these compartments and then sealed with the regular cover.

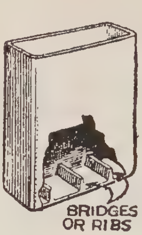

Fig. 26. Separators, which are placed between the plates.

Fig. 27. Jar with side open to show ribs at the bottom on which the element rests.

Separators: When the positive and negative groups are assembled together, the adjoining plates are insulated, or kept out of contact with each other, by means of wood separators, ribbed side against the positive plate. The separators (Fig. 26) are made of wood particularly adapted for the purpose and given a special treatment to remove harmful substances (explained farther on).

Lugs: Both the positive and negative plates are provided with an extension or "lug" at the top of each plate (see Fig. 23). The positive lugs come at one side of the jar and all the negative lugs at the other, thus enabling each set to be burned together with a connecting "strap," giving one positive and one negative pole. The burning is done by a hydrogen flame, or an electric arc, which melts or fuses the metal of both lugs and strap into an integral union.

Straps: The straps (Fig. 24) are made of a hard lead alloy and are burned to the lugs on the plates. The straps are provided with "posts" to which the cell connections are made.

Connectors are then placed so as to join the posts of one (−) group to the post on a (+) group in the next cell. See Fig. 21, "cell connector," showing how the connectors are placed. The connectors are burned to the posts. Sometimes they are not burned well, and a loose connection which causes heating and resistance is the result.

Electrolyte: The fluid, known as "electrolyte," is dilute sulphuric acid. The element (explained above, see Fig. 25) is placed in the jar with the electrolyte. This is also termed the "battery solution" (explained farther on).

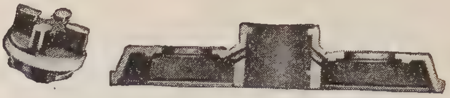

Fig. 28. Exide filling plug and sectional view of cover with plug removed.

Illustration (Fig. 28) shows the *filling plug*, together with a section of the cover with the plug out. The *filling tube* is the opening in the cover through which water may be added to replace evaporation, and through which hydrometer readings may be taken. The plug is so arranged as to catch electrolyte spray and return it to the cell, thereby keeping the top of the battery dry. It should always be kept tightly in place, except when adding water or testing.

When the complete element is placed in the jar and the electrolyte is in the jar, before the connectors are burned or welded in place, the cover and vent tube are placed over the top of the jar and sealed. The connectors are then burned to the posts.

Cover: The jar cover and method of sealing and venting is very important. The cover on the "Exide" battery (Fig. 28) is flanged in such a way as to give a more perfect seal to the jar than the old flat type of cover, and each cell is a separate sealed unit.

Vent or filler plugs are made of hard rubber, and screw into an opening in the cover. They are necessary in order that the gases generated in the battery when charging or discharging may escape, but the acid cannot splash out. They are also removed for the purpose of refilling, or putting water into the jar.

The small vent-hole should be kept open, as it is very necessary that the gases escape.

By looking down into the filler tube when adding water, it can be seen when the electrolyte is at the bottom of the tube, which is the correct level.

There are a number of different methods used for refilling and for ventilation. The purpose is the same in all, however.

Terminals: The **positive** terminal is marked (+), and can always be determined by the **dark** color. The **negative** terminal is a **light-gray** color, and is marked thus (−).

For directions for **testing a wire lead** from a generator or battery for its polarity, if not marked, see Index under "Polarity, how to find."

THE DRY STORAGE BATTERY

The difference between the **"wet storage battery"** and the **"dry storage battery"** lies chiefly in the method of preparing the acid.

The **"wet storage battery"** uses **liquid electrolyte,** and it is the sulphuric acid in this electrolyte which conducts the current, or, in other words, the sulphuric acid in the solution between the plates allows the current to flow through it. For a certain amperage discharge a certain amount of sulphuric acid must be used. The less acid, the greater the resistance.

When a battery is charged, the acid is mostly in the solution. When a battery is discharging, the acid is **diffused** or circulated through the separators into the plates, and the plates gradually absorb the acid from the solution. The **capacity** of a battery therefore depends upon the diffusion or circulation of the acid.

If a battery is discharging at a slow rate, the **diffusion** action is slow; if discharging at a high rate, as, for example, when used for operating a starting motor, the discharge is heavy and the **diffusion** action must be very rapid (see page 529 for meaning of diffusion).

When a charged battery is put on discharge, the diffusion action is more rapid because there is very little sulphate to clog the pores of the active material. As the discharge progresses, sulphate begins to form on the active material on the plates and fills up the pores, and diffusion is slower. Badly sulphated plates or clogged separators will cause slow diffusion.

Where batteries are used for stationary work and discharge rates are moderate, as with farm lighting batteries, etc., the diffusion action is slower, and it is thus possible to use larger cells and a greater quantity of solution with a lower acid gravity, which is easier on the plates and separators.

With a battery for automobile use, for lighting and starting work, the battery must be very compact, and only a limited space is provided for the solution. Thus a higher acid gravity must be used in order to obtain rapid diffusion, because at a half-discharged point, most of the acid would be in the plates and not in the solution.

The **"dry storage battery"** does not use liquid electrolyte. Usually, sulphuric acid is mixed with some kind of silicate base which, after being poured into the cells, turns to a **jelly substance,** and the principle or action is then similar to the use of liquid electrolyte.

This type of battery is not a new idea, and it would appear to be a very satisfactory battery for low-rate discharge. For a high rate of discharge, however, as with a starting motor, the question arises as to whether or not the **diffusion** action would be rapid enough.

It is claimed by some of the dry-storage battery manufacturers that this type of battery is an advantage, in that no separators are used, and that there being no liquid, it will not freeze, etc

As we are unable to obtain sufficient information from manufacturers of this type of battery, it is not our intention to condemn it, but inasmuch as the majority of automobiles are using the "wet storage battery," it is with this type that we shall deal in our instructions.

INSTRUCTION No. 47

THE STORAGE BATTERY; INTERNAL CONSTRUCTION; PRINCIPLE OF ACTION: Electrolyte; Hydrometer Tests

GLOSSARY TO THE STORAGE BATTERY INSTRUCTION[1]

This glossary is provided for reference, in case the reader is not familiar with words or terms used.

Acid: As used in this book, this word refers to sulphuric acid (H_2SO_4), the active component of the electrolyte.

Active material: The active portion of the battery plates: peroxide of lead on the positives, and spongy metallic lead on the negatives.

Alternating current: Electric current which does not flow in one direction only (like direct current), but rapidly reverses its direction or "alternates" in polarity, so that it will not charge a battery.

Ampere: The unit of measurement of the rate of flow of electric current.

Ampere hour: The unit of measurement of the quantity of electric current. Thus, 2 amperes flowing for ½ hour, equals 1 ampere-hour.

Arc burning: Making a joint by means of electric current which melts together the metal of the parts to be joined.

Battery: Any number of complete cells assembled in one case.

Battery terminals: Devices attached to the positive post of one end-cell and the negative of the other, by means of which the battery is connected to the car circuit.

Buckling: Warping or bending of the battery plates.

Burning strip: A convenient form of lead in strips, for filling up the joint in making burned connections.

Case: The containing box, which holds the battery cells.

Cell: The battery unit, consisting of an element complete with electrolyte in its jar, with cover.

Cell connector: The metal link which connects the positive post of one cell to the negative post of the adjoining cell.

Charge: Passing direct current through a battery, in the direction opposite to that of discharge, in order to put back the energy used on discharge.

Charging methods: "Series" method and "Constant Potential" method—see page 579.

Charge rate: The proper rate of current to use in charging a battery from an outside source. It is expressed in amperes and varies for different sized cells.

Corrosion: The attack of metal parts by acid from the electrolyte; it is the result of lack of cleanliness.

Cover: The rubber cover which closes each individual cell; it is flanged for the sealing compound, to insure an effective seal.

Diffusion: The act of spreading or circulating in every direction. The action of the acid mixing with the water that is left in the pores of the plates and at the surface of the plates from discharge, is explained as follows: When the battery is **being discharged,** the acid in the pores of the plates and right at the surface of the plates breaks up into water and sulphates, the sulphate going into the plates as lead sulphate. This leaves water in the pores of the plates and at the surface of the plates. In order for the storage-battery action to continue, fresh acid must be obtained from the reserve outside of the plate or in the cell, and this is accomplished by this outside acid **diffusing** or mixing with this water and forming acid again in the pores of the plates and at the surface of the plates.

Dry-storage battery: A type of battery using a paste or jelly substance instead of liquid electrolyte. See page 528. The "wet" battery is in general use, and is the type dealt with in these instructions.

Discharge: The flow of electric current from a battery through a circuit. The opposite of "charge."

Electrolyte: The fluid in a battery cell, consisting of specially pure sulphuric acid, diluted with pure water.

Element: One positive group, and one negative group, with separators, assembled together.

Filling plug: The plug which fits in and closes the orifice of the filling tube, in the cell cover.

Flooding: Overflowing through the filling tube. With the "Exide" automatic filling tube, this can usually occur only when a battery is charged, with the filling plug out.

Freshening charge: A charge given to a battery which has been standing idle, to insure that it is in a fully charged condition.

Gassing: The bubbling of the electrolyte caused by the rising of gas set free toward the end of charge.

Generator system: An equipment, including a generator, for automatically recharging the battery; in contradistinction to a straight storage system where the battery has to be removed to be recharged.

Gravity: A contraction of the term "specific gravity," which means the density, compared to water as a standard. See "Specific gravity" below.

Grid: The metal framework of a plate, supporting the active material, and provided with a lug for conducting the current and for attachment to the strap.

Group: A set of plates, either positive or negative, joined to a strap. Groups do not include separators.

Hold-down clips: Brackets, for the attachment of bolts, for holding the battery securely in position on the car.

Hydrogen flame: A very hot and clean flame of hydrogen gas and compressed air, used for making burned connections.

Hydrogen generator: An apparatus for generating hydrogen gas for lead burning.

Hydrometer: An instrument for finding the specific gravity of the electrolyte.

Hydrometer syringe: A glass barrel enclosing a hydrometer and provided with a rubber bulb for drawing up electrolyte.

Jar: The hard-rubber container, holding the element and electrolyte.

Lead burning: Making a joint, by melting together the metal of the parts to be joined.

Lug: The extension from the top frame of each plate connecting the plate to the strap.

Maximum gravity: The highest specific gravity which the electrolyte will reach by continued charging; indicating that no acid remains in the plates.

Oil of vitriol: Commercial name for concentrated sulphuric acid (1.835 specific gravity). This is never used in a battery and would quickly ruin it.

---

[1] From **Exide Manual** except sections in smaller type. See page 556 for "Storage Battery Troubles" and page 454 for "Digest of Troubles."

Plates: Metallic grids, supporting active material. They are alternately positive (brown) and negative (gray).

Polarity: Electrical condition. The positive terminal of a cell or battery, or the positive wire of a circuit, is said to have positive polarity; the negative, negative polarity.

Post: The portion of the strap extending through the cell cover, by means of which connection is made to the adjoining cell, or to the car circuit.

Rectifier: Apparatus for converting alternating current into direct current.

Resistance: Material (usually lamps or wire) of low conductivity, inserted in a circuit to retard the flow of current. By varying the resistance, the amount of current can be regulated.

Rubber sheets: Thin, perforated hard-rubber sheets, used in combination with the wood separators in some types of batteries. They are placed between the grooved side of the wood separators and the positive plate.

Sealing compound: The acid-proof compound, used to seal the cover to the jar.

Sealing nut: The notched round nut which screws on the post and clamps the cell cover.

Sediment: Active material which gradually falls from the plates, and accumulates in the space below the plates, provided for that purpose.

Separators: Sheets of grooved wood, specially treated, inserted between the positive and negative plates to keep them out of contact.

Short circuit: A metallic connection between the positive and negative plates within a cell. The plates may be in actual contact or material may lodge and bridge across. If the separators are in good condition, a short circuit is unlikely to occur.

Spacers: Wood strips, used in some types to separate the cells in the case, and divided to provide a space for the tie bolts.

Specific gravity: The density of the electrolyte compared to water as a standard; often abbreviated as "gravity" or "sp. gr." or "S. G."

Starvation: The result of giving insufficient charge, in relation to the amount of discharge, resulting in poor service and injury to the battery.

Strap: The leaden casting to which the plates of a group are joined.

Sulphated: The condition of plates having an abnormal amount of lead sulphate, caused by "starvation," or by allowing the battery to remain discharged.

Tie bolts: Bolts which, in some types, extend through the battery case between the cells, and clamp the jars in position.

Top nut: The hexagon nut which, in batteries with bolted connections, screws on the post, and holds the connectors and sealing nut in place.

ELECTROLYTE

Electrolyte (also termed battery solution) **is put into the jar in which the plates are submerged.** It consists of chemically pure sulphuric acid having a specific gravity of 1.835 (H_2SO_4),[1] diluted with water (H_2O), the proportion being about 1 part of sulphuric acid to 2½ parts of water, by volume, this proportion of water and acid being such that the density of the solution will have a specific gravity of about 1.300 at 70° F. See table, Fig. 5, page 535.

Concentrated sulphuric acid (full strength) is a heavy, oily liquid having a strength or specific gravity of about 1.835. If put into a battery, it would quickly ruin it, and must, therefore, first be diluted with **pure water** to the proper strength for the particular type of battery cells to which it is to be added.

Chemically pure electrolyte: Both the water and the sulphuric acid used in making electrolyte should be **chemically pure** to a certain standard. This is the same standard of purity as is usually sold in drug stores as "CP" (chemically pure), or by the chemical manufacturers, as "battery acid."

In this connection, the expression "chemically pure" acid is often confused with acid of "full strength." Acid may be of full strength (approximately 1.835 sp. gr.) and at the same time not chemically pure.

If this chemically pure acid of full strength be mixed with chemically pure water the mixture would still be chemically pure, but not of full strength. On the other hand, if a small quantity of some impurity be introduced into chemically pure acid, it would not materially reduce the strength, but would make it impure.

The usual method of determining the strength or density of electrolyte is by taking its specific gravity. The method is possible on account of the fact that sulphuric acid is heavier than water. Therefore the greater the proportion of acid contained in the electrolyte, the heavier the solution, or the higher its specific gravity. The mixing of electrolyte is explained on page 534.

Specific Gravity

By specific gravity is meant the relative weight of any substance compared with water as a basis. Pure water, therefore, is considered to have a specific gravity of 1, usually written 1.000, and spoken of as "ten hundred." One pound of water is approximately one pint. An equal volume of concentrated sulphuric acid (oil of vitriol) weighs 1.835 pounds. It therefore has a specific gravity of 1.835, and is spoken of as "eighteen thirty-five." Acid of course is much heavier and denser than water.

If water is mixed with the sulphuric acid, it will reduce its specific gravity from 1.835. The more water that is added, the nearer its specific gravity will come to that of water (1.000). Thus when a hydrometer reading is taken, and shows the specific gravity to be 1.100, it will be seen that it is almost water.

Why Four Figures Are Used in Reading Specific Gravity

As stated, **water is taken as a standard unit, or as 1,** or if divided into one thousand parts, it would then be expressed decimally as 1.000 (1,000/1,000), and if mixed with acid to a certain proportion, say 1.400, it would mean 1,400/1,000, or 1.4 ($1\frac{4}{10}$).

If **acid,** which is heavier than water, is mixed with it, it **will increase the weight or gravity** of the solution or mixture.

If a sufficient amount of acid is used to make a 1.400 specific-gravity solution, it simply means that instead of the volume weighing 1 lb., which it would do if pure water, it will weigh $1\frac{4}{10}$ lbs., which, reduced to a decimal fraction, would be 1.4.

A solution often tests in fractions, which necessitates carrying out the decimals to a greater length, in order accurately to express the gravity of the solution, as, for instance, 1.275. Therefore quite often, in fact more often than not, four figures are necessary with most of the readings. Thus instead of expressing a reading as 1.4, the two extra ciphers are added so as to make any gravity be expressed uniformly in thousandths, instead of in tenths.

---

[1] See page 536 for meaning of H_2SO_4, etc.

Farther on, explanations will be given, showing that **when a battery is fully charged, the specific gravity is 1.275 to 1.300.** This is as strong a mixture as dare be used in a battery. When the battery is fully charged, the acid and water are combined in the solution. But when the battery is being **discharged, the acid goes into the plates;** when it is fully discharged, there is very little acid left in the solution. If its specific gravity were tested under these conditions, it would be found that it is almost water, and (when the battery is fully discharged) would have a specific gravity of about **1.120 or 1.150.** This explains the fact that the solution in a battery freezes when the battery is discharged.

A STORAGE-BATTERY HYDROMETER

A hydrometer is used to test the specific gravity of the electrolyte when it is being mixed, and also for testing the specific gravity of the solution in a cell to see if it is charged or discharged.

If a battery is fully charged, the specific gravity will be between 1.275 and 1.300.

If fully discharged, the specific gravity will be between 1.150 and 1.120. See table in Fig. 1.

Note. Where a battery is used for starting motors, 1.275 to 1.300 sp. gr. at 70° F. is the "full charge," or top mark for battery specific gravity. A battery with gravity below 1.225 can hardly inject the requisite energy into the starter to spin the engine, so that 1.225 is practically the low mark. Then 1.280 minus 1.225 = .055, termed "55 points," covers the range between full charge and complete discharge.

Of course, a battery with gravity below 1.225 can operate the lights at a lower gravity. Suppose you try a hydrometer diagnosis and find the reading to be 1.255. Then 1.280 minus 1.255 = 22½ out of the 55 points of full range, from which you know that your battery is half-charged or half-discharged. 1.260 indicates three-quarters charged or one-quarter discharged.

A battery's capacity is considerably less during zero weather than in summer heat. Hence the importance of seeing that it is kept fully charged.

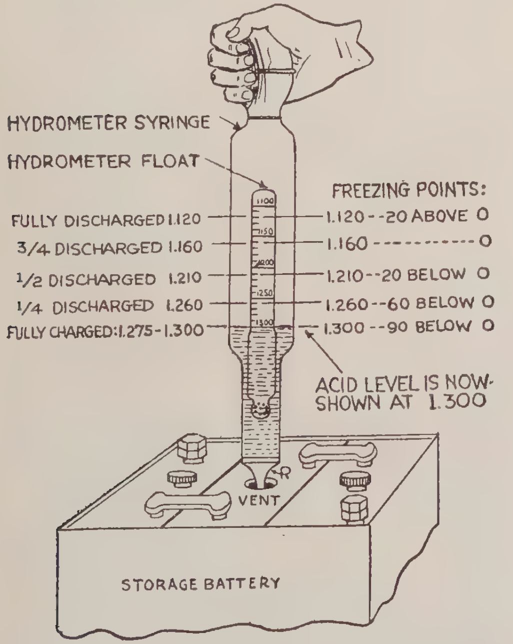

Fig. 1. A **hydrometer syringe** for testing the specific gravity of electrolyte or battery solution. Note the table showing **"charged"** and **"discharged"** readings and **"freezing points"** of electrolyte.

Construction of a hydrometer syringe: This device consists of a closed glass tube with a rubber bulb at one end and a rubber or glass tube (R) at the lower end, termed the nozzle. Inside of the glass tube a hydrometer is provided, with a graduated scale. A reading of this scale shows the specific gravity of the electrolyte.

Method of use: To test the specific gravity of the electrolyte in a cell, the vent plug is removed and nozzle (**R**) is inserted. The rubber bulb is depressed, which draws the electrolyte into the glass tube when released. Thus if a sufficient quantity is drawn into the tube, the hydrometer will float in the electrolyte. A small quantity of small shot is placed in the bottom of the hydrometer in order that it may sink to a certain depth, and to cause it to stand upright.

It will be observed that the highest specific gravity readings of the scale are at the lower part of the hydrometer, whereas the lowest readings are toward the top of the hydrometer.

The denser the electrolyte, the less will the hydrometer sink into it; therefore the specific gravity reading will be **higher.**

The less dense the electrolyte, or the nearer it approaches the density of water, the deeper the hydrometer will sink into the electrolyte; therefore the specific gravity reading will be **lower.**

To prevent the hydrometer from sticking to the side of the barrel, it is necessary that the syringe be held in a vertical position. The reading is taken at the surface of the electrolyte and when there is no compression on the bulb.

When the specific-gravity readings of electrolyte are taken, the temperature of the latter is supposed to be at 70° F. If the electrolyte is warmer or colder than this, it will affect the reading, as will be explained farther on under "Temperature corrections of hydrometer readings."

Pointers on the Use of the Hydrometer

When to take a hydrometer reading: Take a reading of each cell with the hydrometer syringe at least once a week, and just before adding water.

Electrolyte should be kept above the level of the plates. If not above, add pure water.

If hydrometer readings are taken after adding water, they are of no value, as only water or very weak electrolyte will be drawn into the syringe. This is due to the water being lighter than the electrolyte, and therefore remaining on the surface.

If the electrolyte is below the top of the plates, or so low that enough cannot be drawn into the barrel to allow of a proper reading of the hydrometer, fill the cell to the proper level by adding pure water; then do not take a proper reading until the water has been thoroughly mixed with the electrolyte by the gassing at the end of a recharge.

Take hydrometer readings at any time that any part of the electric system does not work properly, as they may indicate the trouble in the battery.

In using the hydrometer, certain points should be kept in mind: In the first place, the liquid taken up by the hydrometer from one cell should never be put into another cell, as this will be likely to cause some trouble, because of "high acid" in one cell, or weakened electrolyte in another.

Also care should be taken, when using the hydrometer, not to have any air bubbles form in the cell, as it is very difficult to get these out, and, as a result, the extra electrolyte is spilled. When heated up, the bubbles disappear and the level of the electrolyte sometimes falls below the tops of the plates.

When all cells are in good order, the specific gravity will test about the same (within 25 points) in each cell. (Note: gravity readings are sometimes expressed in "points"; thus the difference between 1.275 and 1.300 is 25 points.)

Some of the Troubles of a Battery as Indicated by a Hydrometer Reading

The storage battery is heir to many troubles, to so many, in fact, that a "Digest of Storage Battery Troubles" is provided on page 556. A few of the most common tests of a battery with a hydrometer are given below.

When the gravity will not rise above 1.225 or 1.250 from the generator charge on the car, this may be due to excessive use of lights, together with slow running of the car, which cuts down the charging current from the generator; or it may be due to trouble in the system. See "Digest of Storage Battery Troubles."

The remedy for the first-mentioned case is to use the lights sparingly, until the gravity rises above 1.250. If the gravity will not rise above 1.250 within a reasonable time, look for trouble in the system. See also page 478, under "Examine battery."

If, after the battery has been fully charged, the gravity again falls to 1.250 or less, it indicates that there is trouble somewhere in the system which must be located and corrected, and the battery should be charged from an outside source.

A cadmium test or high-ampere discharge test should then be made to find out if the trouble is within the battery and which one of the cells is causing the trouble. This subject is treated farther on.

The specific gravity readings of all cells of a battery should normally rise and fall together, as all cells of a battery, as used with most systems, are connected in series so that the charging and discharging current passes through all alike.

If the hydrometer reading of one cell should be considerably lower than the readings of the other cells in the battery, and if this difference should increase from week to week, it is an indication of trouble in that cell.

The trouble may be due to an internal short circuit in one of the cells, causing the cell to discharge itself, or it may be due to a leaking jar, as a slight leak will allow electrolyte to escape, and if the leak is not noticed, the addition of water to replace its loss will lower the gravity.

A discharged battery should be recharged immediately, for if it is left discharged, the plates will become sulphated (explained farther on).

How the Temperature Affects the Hydrometer Readings

Electrolyte, like most substances, expands when heated. Its specific gravity is affected, therefore, by a change in temperature, and the hydrometer readings will be affected accordingly.

Standard Temperature

The temperature adopted as the standard for a basis of comparison of specific gravities of electrolyte is 70° F. Thus, when we say that a specific-gravity reading of 1.280, taken by a hydrometer, indicates full charge, and that 1.225 or 1.220 indicates practical discharge for starter purposes, or that 1.150 indicates a total discharge, we mean that these are the specific gravities when the electrolyte has a temperature of 70° F.

Suppose a hydrometer reading is taken when the temperature of the electrolyte is much warmer, say 100 degrees Fahrenheit (expressed as 100° F.), above zero, instead of 70° F. What is the result? As previously stated, the electrolyte expands as it gets warmer. Thus it becomes lighter and less dense, and therefore the hydrometer will sink deeper into the solution, thus causing a **lower specific gravity reading.**

For example: See Fig. 1. Note that the lower readings are toward the top of the hydrometer, and that the higher readings are toward the bottom of the hydrometer.

Assume that a test is made at a temperature of 100° F. above zero, and the electrolyte level was even with the figure 1.270, on the hydrometer. This would indicate that the specific gravity of the electrolyte was 1.270. As a matter of fact, it would be 1.280, arrived at by what is termed "temperature correction."

Temperature Corrections

It has been found that if 70° F. is taken as a standard temperature for making hydrometer specific-gravity readings, then **for every 3 degrees rise in temperature above 70° F. it will be necessary to add 1 point on the hydrometer reading,** because the hydrometer sinks 1 point deeper into the solution with every 3 degrees of rise in temperature above 70° F.

Therefore with a temperature of 100° F. above zero, there would be a difference of 30 degrees (100—70=30), and if 1 point must be added for every 3 degrees of rise in temperature above 70° F., we should have to add (30÷3=10) 10 points; thus the **corrected reading** would be 1.270+10=1.280.

When colder than 70° F., the electrolyte becomes thicker, or more dense. In this case, the hydrometer will **rise,** thus giving a greater specific gravity reading. Hence, we should **deduct,** instead of adding, points.

For example: Refer again to Fig. 1. Note that the higher readings are toward the bottom of the hydrometer.

Assume that a hydrometer test is being made at 40 degrees Fahrenheit (40° F.) above zero, and that the electrolyte level is even with the figures 1.290. In this case the actual reading would be 1.280, arrived at by the "temperature correction" rule.

For every three degrees of temperature below 70° F., 1 point is deducted, because the hydrometer rises 1 point higher in the electrolyte with every three degrees of drop in temperature below 70° F.

Therefore with a temperature of 40° F. above zero, there would be a difference of 30 degrees (70—40=30), and if 1 point must be deducted for every three degrees of drop in temperature below 70° F., we should have to deduct (30÷3=10) 10 points; thus the **corrected reading** would be 1.290—10=1.280.

Although the two actual readings (1.270 and 1.290) differ by 20 points, the difference is all due to temperature. If the temperatures were the same, the readings would be the same. Thus, when the temperature is much above or below the normal (70° F.), the hydrometer readings should be "corrected for temperature."

Since the change of temperature does not alter the actual amount of acid in the electrolyte, but changes its specific gravity only, the readings taken with a hydrometer should be corrected, as stated above, by adding or deducting, as the case may be, one point for each three degrees of change in temperature above or below 70° F.

Temperature corrections are unnecessary when you compare the gravities of the different cells of a battery at any one time, since all have about the same temperature when in health, and affected alike.

Temperature corrections are also unnecessary, when you use the hydrometer, for testing, say, the middle cell, which we will call the "pilot cell," to secure an approximate index of the battery's condition. That is, corrections are in general unnecessary, except when there is reason for a really critical study of the battery's condition, as when you suspect things are not going well with the battery.

Note too that the actual proportion of water in the electrolyte slightly affects the gravity independently of the state of charge. That is, the more water there is, the lower the gravity. Therefore to derive the greatest benefit from the hydrometer readings, try to keep the electrolyte surface between a point ¼″ above the plates and the electrolyte level designated for the battery, either on the name plate or in the instruction pamphlet that you receive with the battery. Use the glass tube level-tester (page 562) consistently in conjunction with the hydrometer, and add water promptly when it is needed.

Battery Thermometer

For convenience, a thermometer (Fig. 2) has been designed with a special red ink scale opposite the temperature scale, and a glance at it tells how many **points to add or subtract from the hydrometer reading** when making tests of the electrolyte at different temperatures, in order to correct for temperature.

For example, an electrolyte temperature of 94° above zero means: **add** 8 points to the actual hydrometer reading.

An electrolyte temperature of 46° above zero means: **deduct** 8 points from the actual hydrometer readings.

An electrolyte temperature of 70° above zero indicates that no correction is to be made, as this is the normal temperature.

Electrolyte in Tropical Climates

Electrolyte is weaker in batteries used in tropical climates, and is purposely made so, because batteries operated in tropical climates give better results if the solution is weaker than that used in batteries for cooler climates.

Places where freezing of water never occurs are regarded as tropical climates.

Specific Gravity and Temperature Table

A table showing the variation of the specific gravity with temperature is given above. Note that instead of using 70° F. as a standard temperature, 60° F. is used in this table. Some manufacturers use 60° F. and others 70° F.

The specific gravity of the acid in a fully charged battery should not exceed 1.300 at 60° F. If hydrometer readings are taken at other acid temperatures than 60° F. allowance must be made for the temperature of the acid.

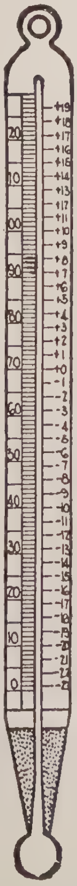

Fig. 2

The figures in black are acid gravities at 60° F. The others represent readings of these same gravities at the different temperatures shown at the top of each column, i.e., 1.300 at 60° becomes 1280 when the electrolyte temperature is raised to 110°, etc.

Read the temperature—read the hydrometer—then follow down that temperature column below which is nearest the observed acid temp., find the figures nearest the observed specific gravity reading, and trace horizontally across to the black column—these black figures are the true acid gravity and should form the basis for any acid adjustment.

Baume Scale

On some hydrometers **another scale is sometimes used, called a Baume scale.** It also is sometimes used for ascertaining the specific gravity of electrolyte. The hydrometer scale as shown in **Fig. 1** is in general use.

Fig. 4.

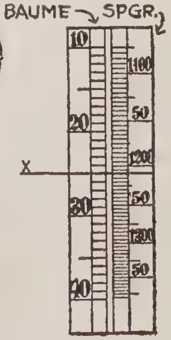

Fig. 3.

A comparison of the Baume scale and specific-gravity scale is given in the accompanying table, and also in the scale of the hydrometer in Fig. 3. Note the scale at (X). If the hydrometer is level in the electrolyte at this point, the Baume reading would be 25, or the equivalent of a 1.208 specific-gravity reading.

COMPARISON OF THE BAUMÉ AND SPECIFIC GRAVITY SCALES AT 60° FAHRENHEIT.

Degrees Baume	Specific Gravity	Degrees Baume	Specific Gravity	Degrees Baume	Specific Gravity	Degrees Baume	Specific Gravity

Ball Electrolyte Tester

An electrolyte tester (seldom used) is shown in Fig. 4.

If the acid is at its proper strength (30° to 32° Baume, or 1.260 to 1.280 specific gravity), both balls will remain in the center of the tube when the battery is fully charged.

If both balls float, the acid is too strong and it should be reduced by adding water.

If both balls sink when the battery is discharged, the battery should be fully charged, and then if the white ball does not float, stronger acid should be added.

Voltmeter, Cadmium, and High-Rate Discharge Tester

A voltmeter is also used for testing the voltage of batteries on charge or discharge, as is also a "cadmium test meter," and a "high-rate discharge" test. These tests are generally used by repairmen, and will be explained under the discussion devoted to the repair of storage batteries.

Freezing of Electrolyte

The freezing point of electrolyte depends upon its specific gravity. There is little danger of freezing except with a discharged battery.

Water will freeze at 32° F. Hence, if the battery were to be discharged by some means to the point of where the electrolyte is near the gravity of water, the electrolyte would of course freeze near this point.

In order to avoid freezing of the electrolyte, the battery should always be kept in a fully charged condition. A table is given in Fig. 1 which shows the freezing points of electrolyte.

When a battery is stored away for a period of time, care should, therefore, be taken that the battery is kept in a fully charged condition.

If the electrolyte becomes frozen, the expansion will sometimes break the jar. If it does not, simply place it in a warm place and it will come back to its normal charge. It is best, however, to recharge it first, and then pour out the old electrolyte and put in new electrolyte of a specific gravity of 1.300.

MIXING ELECTROLYTE

On page 530 we discussed the meaning of electrolyte and what it is composed of. We shall now deal with the mixing of electrolyte.

When mixing electrolyte, the following precautions should be observed:

1. A glazed stone vessel or a lead-lined tank should be used. Never use tin or any metal other than lead. Glass, porcelain, stone, rubber, or glazed earthenware can be used.
2. Put the water in the vessel first.
3. Fill the hydrometer syringe with chemically pure sulphuric acid and add it to the water by holding the nozzle under the surface. Stir the solution with a glass rod or clean piece of wood.
4. Rinse the syringe and test the strength of the solution. If it shows only about 1.160 sp.gr., allow it to cool, when it will be stronger.
5. If not strong enough, add more acid.
6. If too strong, add water.
7. The pure acid should not be allowed to remain in the syringe.

Specific Gravity of Electrolyte to Be Mixed

If the specific gravity of full-strength sulphuric acid were tested with a hydrometer it would show approximately 1.835, which of course is too strong to put into a battery cell. Therefore its density and strength must be reduced by diluting it with pure water.

The density or specific gravity of electrolyte[1] that should be put into a cell should never exceed 1.400 sp. gr. In fact, this might be termed the standard density or specific gravity of electrolyte sold by supply houses, and which should be kept on hand by battery service stations. In other words, the usual practice is to mix the acid and water in such proportions that the density of the solution will have a specific gravity of 1.400.

The 1.400 sp.gr. electrolyte can then be reduced to 1.300, 1.280, 1.275, 1.260, or to any density or specific gravity desired.

When to Use Electrolyte

When at the desired density, **it is used to adjust the specific gravity of the solution in a battery which is on charge,** providing the specific gravity fails to rise to its proper value.

It is also used to refill batteries after repairing, and also to restore any lost through slopping and leakage.

The loss of solution from evaporation, occasioned during charging and discharging, consists ordinarily entirely of water, and pure distilled water is used to replace it.

Loss due to slopping or leakage is a loss of solution, and must be replaced with solution.

Too much acid strength will reduce the life of the battery.

Proportions of Water and Acid to Mix

For the proper proportions in which to mix full-strength concentrated acid and pure distilled water, in order to make a mixture of 1.400 specific gravity (or any other gravity) electrolyte, reference should be made to the chart (Fig. 5). It will be noted that the curve shows the proportion by weight and also by volume.[1]

Meaning of "By Volume" and "By Weight"

The term **"by volume,"** as used in the curve (Fig. 5), refers to the use of measurements, such as pints, quarts, etc. If 1½ parts of water is the "volume" called for in the curve at the left, then use, say, 1½ pints of water and 1 pint of acid. See explanation under Fig. 5.

The term **"by weight,"** used in the curve, refers to the use of weight measurements, as on a scale. An example of mixing 1.400 sp. gr. electrolyte by weight would be, to follow the vertical line from 1.400 (Fig. 5) to the curve marked "Parts by Weight"; then follow the horizontal line to the left, which will

---

[1] The Gaselli Chemical Co., Cleveland, Ohio, with branches in all large cities, carries electrolyte ready prepared in densities of 1.100, 1.300, 1.400, and 1.800.

1.400 is the best proportion to purchase. The electrolyte is usually shipped in carboys, weighing about 150 lbs.

The General Storage Battery Co., St. Louis, Mo., also supplies electrolyte in small or large quantities, as well as separators, plates, and other battery supplies.

[1] This chart, or curve, is taken by permission from the Exide (copyrighted) instruction book.

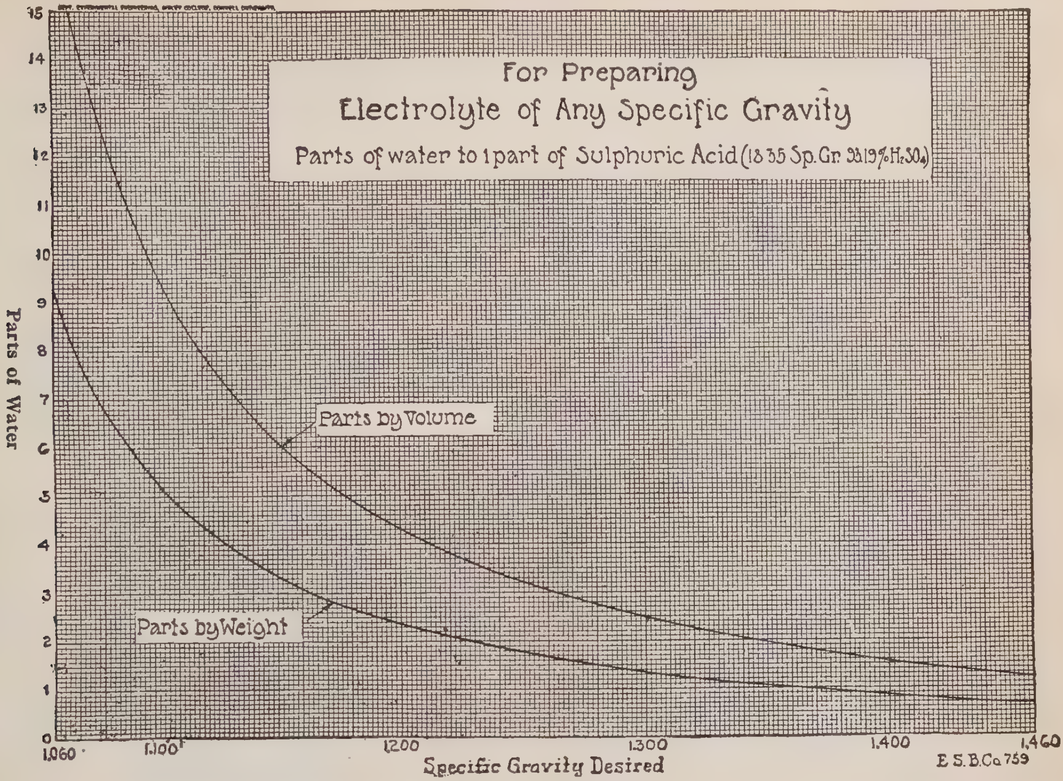

Fig 5. Curves showing the proper proportions of distilled water that should be used with one part of sulphuric acid; the parts are given by volume and also by weight.

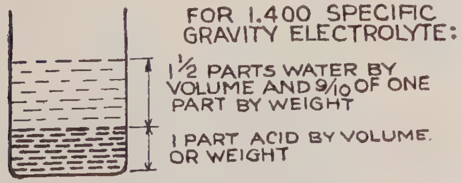
How to read: If, for example, a solution of 1.400 sp. gr. electrolyte is desired, first find the 1.400 on the bottom line of the chart; then follow the vertical line until the curved line (parts by volume) is reached. Follow the horizontal line to the extreme left of the scale, and it will be found to indicate 1.5. This shows us that, for electrolyte solution of 1.400 sp. gr., 1½ parts of pure water is the quantity to be used with 1 part sulphuric acid, and a test with the hydrometer should show a reading of 1.400, if the temperature of the solution is 70° F.

If the temperature is more or less, then corrections in the hydrometer reading should be made in accordance with directions given under "temperature corrections" (page 532). The horizontal lines in the chart are divided into tenths.

show that 9/10 is the amount of water by weight to use with 1 part by weight of acid. Therefore, take 1 lb. of acid, and then 9/10 lb. of water, which, by volume, would be 1½ times 1 part of acid.



FOR 1.400 SPECIFIC GRAVITY ELECTROLYTE:
1½ PARTS WATER BY VOLUME AND 9/10 OF ONE PART BY WEIGHT
1 PART ACID BY VOLUME OR WEIGHT

Fig. 6.

A careful reference to the illustration (Fig. 6) will probably assist in making the meaning clear.

Why Electrolyte of 1.275 to 1.300 Sp. Gr. Is Used

The reason why 1.275 to 1.300 specific gravity acid is used in a charged battery may briefly be stated as follows:

The resistance of the electrolyte to the passage of current internally in the cell is greater when the electrolyte is weak. The resistance is less when the **electrolyte is stronger, or more dense (up to a certain point).**

Since density, or a higher specific gravity, is a better conductor than a lesser density, or lower specific gravity, the voltage increases with the increase of conductivity (i.e., the strengthening of the electrolyte). Therefore the internal resistance of a cell is less when the gravity is higher.

With too high a gravity (too much acid), the lead part of the plates will be **attacked,** and the active material on the plates would be changed to lead sulphate when idle.

Thus it will be clear that the proper proportion of acid to use is a highly important detail.

"Adjusting" the Specific Gravity of the Electrolyte or Solution in a Battery—also Termed "Balancing" Electrolyte

Many batteries have been ruined by having the electrolyte too strong, or by adding acid at the wrong time to bring up the gravity—termed **"doping"** the battery. Sulphuric acid does not evaporate; the water evaporates. Therefore when the electrolyte falls below the level of the plates, pure water only should be added. And, as previously stated, when water is being added, the battery should have a **charging current** run through it to mix the water with the electrolyte before taking a hydrometer reading. The reason for this will now be explained.

When through a hydrometer reading, the specific gravity is shown to be 1.150, the battery is discharged, meaning that the acid is **in the plates,** and the solution consists mostly of water. If acid should be added under these conditions, the solution would show a higher specific gravity reading, yet the battery would be discharged. Then when the battery was charged, the acid in the plates would mix with the acid that was added, and thus a very high specific gravity reading would result. The excess acid would attack the plates and cause sulphation.

The addition of a stronger acid solution, or electrolyte, should be made only under certain conditions.

When and How to Adjust the Gravity of the Solution

When a battery is fully charged, the specific gravity reading should be 1.275 to 1.300—usually about 1.280.

When the battery is charged, the acid is **out of the plates** into the solution; this is the proper time to adjust or balance the electrolyte, and not when the acid is **in** the plates, at which time the battery is discharged. It is customary to adjust the electrolyte in a battery two or three times a year.

Therefore an adjustment of the specific gravity of the solution in a battery should be made only when the battery is fully charged.

When the specific gravity of the electrolyte is tested with the object of balancing or adjusting the electrolyte, the battery should be charged under its normal rate (usually specified on the plate on the battery). Then test the electrolyte with the hydrometer, from time to time as the charging progresses, until after four or five hours no further increase of the specific gravity is noticed. When the charge is complete, as indicated by the gravity remaining constant for five hours, the gravity in all the cells should be between 1.275 or 1.280 to 1.300. If the gravity in one or more cells does not come between these limits, it should be adjusted or balanced.

If the gravity reads over 1.300, withdraw some of the electrolyte and replace with distilled water, using a syringe for the purpose. The amount of water to be added depends upon how much the gravity exceeds 1.300; ability to judge comes with experience.

If the gravity reads less than 1.275, some of the electrolyte should be withdrawn and replaced with diluted acid of 1.400 sp. gr., until the solution in all cells tests 1.280. The battery is then placed on charge at the finish rate, until the gravity remains constant.

If at the end of the charge the gravity of the electrolyte is above or below the limit, acid or water should be added as required, and the battery should be put on charge again.

If the adjustment necessary is considerable, or if the solution is suspected of having been "doped," it will be found more convenient to empty out the solution and refill with electrolyte of specific gravity estimated to bring it right, allowing for the effect of the old solution held in the cells. Experience will enable the operator to gauge this quite accurately.

When emptying a battery of its solution, it is best to draw the solution out instead of turning it upside down to pour it out, because the sediment in the bottom of the jar will work its way between the plates.

After any adjustment, charge for some minutes to allow the gassing to mix the solution thoroughly before taking hydrometer readings.

If the temperature is far from normal, correct the hydrometer readings by adding one point (.001 sp. gr.) for each 3 degrees above, and subtracting one point for each 3 degrees below 70° F. (See page 532).

Always wipe off the top and sides of the battery with weak ammonia after adjusting electrolyte.

If the electrolyte of one cell tests lower than the others, it indicates that this cell is not in good order. It may have an internal short circuit, or a leaky jar, or perhaps new separators are required. See "Digest of Storage-Battery Troubles."

The activity of the electrolyte increases as its temperature increases. Thus in warm or tropical climates it is advisable to use electrolyte of lower gravity than that specified for temperate zones.

The subject of **using a battery solution over again** after installing new plates, as well as **the proper strength of acid to use after overhauling a battery,** is discussed farther on.

Exide Instructions for Adjusting Electrolyte

It will be unnecessary to adjust the strength of the solution except in the cases called for, otherwise harm may result.

To adjust the strength to between 1.270 and 1.300 (1.200[1] and 1.230),[1] the simplest procedure is as follows:

1. Be sure the battery is completely charged.
2. Have ready some electrolyte with a strength of 1.285 (1.215).[1] This may be prepared as outlined on page 534.
3. Dump the solution out of the cells, and at once fill the cells with the prepared electrolyte. Do not allow the battery to remain empty.
4. Charge for an hour at the charging rate given in the table on page 577 ("Initial Charge and Repair Charge").
5. If the hydrometer reading is still below 1.270 (1.200),[1] or above 1.300 (1.230),[1] adjust again until it is between these limits.

STORAGE BATTERY: CHEMICAL TERMS

H_2O: **Water,** a liquid which is made up of hydrogen two parts (H_2), and oxygen one part (O).

H_2SO_4: **Sulphuric acid,** a liquid chemical compound of hydrogen (a gas) 2 parts (H_2); sulphur (a solid) 1 part (S); and oxygen (a gas) 4 parts (O_4).

Pb: **Lead,** which is a solid.

PbO: **Litharge,** consisting of lead 1 part, and oxygen 1 part.

PbO_2: **Lead peroxide** (a solid), made up of lead 1 part (Pb), and oxygen 2 parts (O_2).

$PbSO_4$: **Lead sulphate** (a solid), made up of lead 1 part (Pb); sulphur 1 part (S), and oxygen four parts (O_4).

Litharge: Oxide of lead.

Oxide: A compound of oxygen and a base.

Peroxide: The oxide of a base which contains the largest portion of oxygen.

---

[1] These alternative figures apply to tropical climates.

Sulphate: When speaking of storage batteries, it is lead sulphate that is meant, the substance into which the active material of both positive and negative plates is charged or discharged.

There are four elementary substances as follows:

H: **Hydrogen,** a gas.

O: **Oxygen,** a gas.

S: **Sulphur,** a solid.

Pb: **Lead,** a solid.

Two of these are gases and two solids. The sulphur which is used to form the compounds mentioned above as H_2SO_4, and $PbSO_4$ does not entirely separate itself from them, but remains with O_4. The compounds, however, split up into H_2 and SO_4. Pb, and SO_4.

INTERNAL CONSTRUCTION OF A STORAGE BATTERY

The pasted plate: A grid for the Faure type of plate is shown in Fig. 7. It is the plate now used for automobile storage-battery work.

The Plante type of plate (Fig. 8) is not used very much for automobile starting and lighting purposes, as the Faure plate is much lighter and delivers a much greater capacity per pound of weight, and is also easier to manufacture.

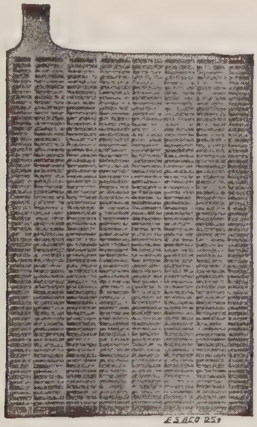


Fig. 7. A lead grid for a pasted type of plate ready for the paste.

Each cell is composed of a certain number of negative plates and a certain number of positive plates. There is always one more negative plate to a cell than there are positive plates.

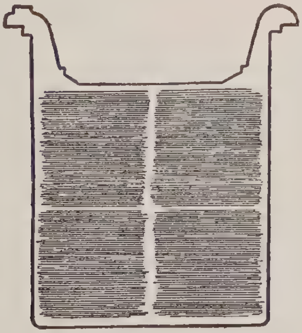

Fig. 8. Plante type of plate.

The reason there is an odd number of plates in a cell is that there is one more negative plate than positive. A negative plate is placed at each end, so that there will be action on both sides of all positive plates. The positive plates are thicker and have more active material. The positive plates also have a tendency to recede from the negative, and if a positive plate were placed at either end, it would buckle and bend away from the negative plate.

The positive plate and the negative plate are each made of lead (Pb), and are cast in the form of grids (Fig. 7) so that paste can be inserted into the grids.

The paste which is set into the lead grids goes through a forming process of charging and discharging, and is hardened and is converted into what is termed **active material.**

There are many different formulas for making this paste which are trade secrets of different manufacturers. The base, however, for forming the active material for the plates is an oxide of lead, usually red lead (Pb_3O_4) (lead 3 parts, oxygen 4 parts) for the positive plate, and litharge (PbO) (lead 1 part, oxygen 1 part) for the negative plate.

The litharge for the negative plate is formed into a paste by combining it with diluted sulphuric acid (H_2SO_4), and then working it up to a desired putty-like consistency for applying to the grid.

Owing to the tendency of litharge on the negative plate to contract, when subjected to the electrochemical action which takes place in the cell, it is necessary to use what is termed an **"expander."** Barium sulphate ($BaSo_4$) or magnesium sulphate, lamp black, or graphite are also used by some battery manufacturers.

The red lead is likewise made into a paste for the positive plate, by mixing with diluted sulphuric acid (H_2SO_4). It is necessary to use a "binder" with this paste in order to prevent shedding. Ammonium sulphate $[(NH_4)_2SO_4]$ is largely used for this purpose.

After the paste is applied to the grids of the plates, the plates are dried. The paste will then harden and turns to lead sulphate ($PbSO_4$) on both the negative and positive plates.

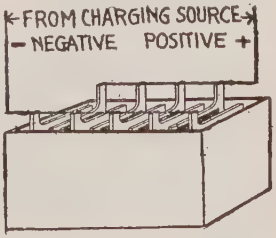

Fig. 9. Forming the plates.

Forming: The plates are then placed in the charging tank (Fig. 9) with the negative and positive plates alternating, and with plenty of space between them. All the positive plates are connected with the positive terminal of a direct-current charging source, and the negative plates are connected with the negative terminal of the charging source. There is, of course, electrolyte in the tank, of about 1.100 or 1.200 specific gravity, when used for forming. The passing of the charging current through the plates forms peroxide of lead (PbO_2) on the positive plate which turns to a dark-brown color, and to gray, spongy, porous, soft lead (Pb) on the negative plate.

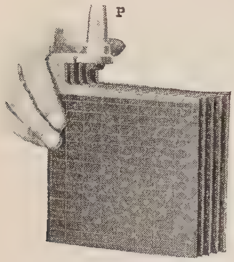

Fig. 10

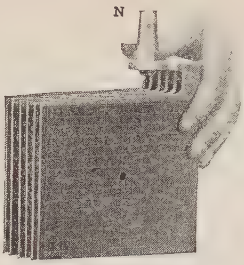

Fig. 11

Fig. 10. A positive group of 5 plates.

Fig. 11. A negative group of 6 plates.

The illustrations are taken from the catalogue of the General Storage Battery Co., St. Louis, Mo., and are the plates of type 116, 11-plate starting and lighting battery.

The average starting and lighting batteries use either 11 or 13 plates, of about 80 to 100 ampere-hour capacity.

In a 13-plate battery, there would be 7 negative (gray) plates and 6 positive (dark-brown) plates. In an 11-plate battery, there would be 6 negative plates (Fig. 11) and 5 positive plates (Fig. 10). The negative plates are always on the outside, as shown in Fig. 13.

The positive plate lugs are burned to a positive strap and post (**P**) (Fig. 10), and the negative plate lugs are burned to a negative strap and post (**N**) (Fig. 11), forming two groups of plates.

Fig. 12. Separators are placed between the positive and negative plates. The illustration represents a set of California redwood separators used in the General storage battery.

Separators (Fig. 12) are placed between the negative and positive plates, which are then interleaved as in Fig. 13, and this forms an **element** ready to be placed in the jar which contains the electrolyte.

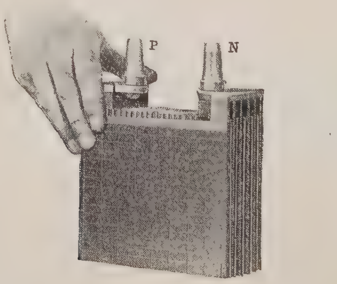

Fig. 13. An element, consisting of the positive and negative plates (Figs. 10, 11) interleaved with separators (Fig. 12) between the positive and negative plates.

The electrolyte for a new battery, where plates have been formed, is of about 1.300 specific gravity. In some cases it is stronger and in others weaker, depending on the condition of the separators. If new, they will soak the acid up; hence the reason for using an electrolyte of higher specific gravity (explained farther on).

The element (Fig. 13) is then placed in the hard rubber jar (Fig. 14) in which the electrolyte was placed first. The **cell cover** and **vent tube** (Fig. 15) are then placed over the top of the plates.

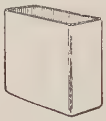

Fig. 15

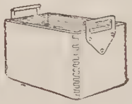

Fig. 14 Fig. 17 Fig. 16

The cells are then placed in the **battery box** (Fig. 16) and are then connected together with **connectors** (Fig. 17), which are burned on to the posts. Sometimes this joint between connector and post is not welded perfectly and the loose connection offers resistance and reduces the voltage and causes heating.

Each cell, when charged, gives approximately 2 volts, therefore 3 cells connected in series would give 6 volts; thus it would be termed a "6-volt battery." If there are 6 cells connected in series, then the terminal voltage would be 12 volts; if 8 cells in series, 16 volts; if 12 cells in series, 24 volts.

The battery is then charged by being connected in series with a source of "direct" current. The electric current flows from the positive (+) brush of the generator to the (+) terminal of the battery, to the positive plates, to the negative (—) plates (internally), out through the (—) plates, back to the (—) brush of the generator, through the armature, to the (+) brush again.

When the battery discharges, the current flows from the battery positive (+) plates, to the (+) terminal, through the circuit, to the negative (—) terminal and plates, to the positive plate (internally).

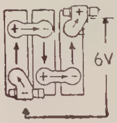

Fig. 18

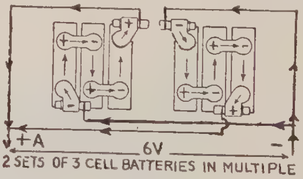

Fig. 19

Series connections of one cell with another, as shown in Fig. 18, form the usual method of connecting batteries. In this example, there are 3 cells connected in series; therefore it is a 6-volt battery. Note that the arrow points show the direction of current flow when the battery is discharging. If it were being charged, the current flow would be in the opposite direction. The **ampere-hour capacity** would be that of one cell.

Two 6-volt (or any other voltage) batteries could be connected in multiple, on the principle shown in Fig. 19. In this instance, there are two 3-cell batteries of 6 volts, as in Fig. 18. Each set is connected in "series," and the two sets are connected in "multiple." Therefore we have a terminal voltage at (+**A**) and (—**B**) of 6 volts, or the voltage of 3 cells.

The ampere-hour capacity would be twice that of the battery (Fig. 18).

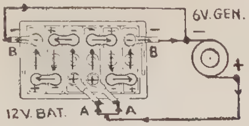

Fig. 20.

A 12-volt battery could be charged, by a 6-volt generator, if "multiple" connections were made as in Fig. 20, by connecting the two halves in multiple, as shown. The dynamo (generator) voltage, of course, must always be slightly higher than the battery voltage, otherwise the generator would have a tendency to operate as a motor.

Note that the generator current starts at the (+) brush, thence to (+) terminals (**A**) of battery, through each set of 3 cells, out through (−) battery terminals (**B**), to (−) brush of generator.

A 6-volt lighting circuit or ignition circuit could be operated from this circuit, by connecting with the circuit at (**A**) and (**B**). See also page 525, showing how a 12-volt starting motor operates from a 12-volt battery, and how a 6-volt generator charges the battery.

PRINCIPLE OF THE ACTION OF A STORAGE BATTERY WHEN DISCHARGING AND CHARGING[1]

Under the subject of "Electromagnetic Induction" (page 183) the fact is brought out that **when a conductor or closed loop of wire is passed through a magnetic field at right angles to the field,** an electromotive force (e.m.f.) will be set up at the terminals of the wire, which will cause electricity to flow in the wire if the circuit is completed. This action is called generating electricity "magnetically," or by "induction."

In a storage battery, the electricity is not stored, but, through a "chemical action," electromotive force (electric pressure) is created between the plates, causing electricity to flow. In other words, the storage battery **converts chemical energy into electrical energy when discharging,** and **electrical energy into chemical energy when charging.** For instance, if two different metals are placed in a liquid which will produce a chemical action more on one than on the other, an electromotive force (electrical pressure) will be produced which will cause electric current to flow.

This flow of current will continue until the metals or substances are entirely changed. If these chemical changes which split up the gases and solids form gases, the gases escape and are lost, whereas if they form solids by combining with the metal, they are not lost. When a battery is charged at too high a rate, or is overcharged, or when it is fully charged, it will be noticed that there will be an excessive passage of the gases.

Primary cells (Fig. 21), such, for example, as the gravity cell[2] used for telegraph work, consisting of a negative zinc plate and a positive copper plate, produce, just as soon as they are immersed in a solution of blue stone and water, an electrical pressure between the plates when the circuit is closed. Thus chemical energy is converted into electrical energy. It cannot, however, convert electrical energy into chemical energy.

The chemical action of the electrolyte on the zinc sets free gas bubbles which are charged with electricity and which deposit themselves on the copper plate. The copper plate serves merely to collect the bubbles, and is thus termed a positive (+) plate. The zinc, which is acted upon by the solution, is termed the negative (−) plate.

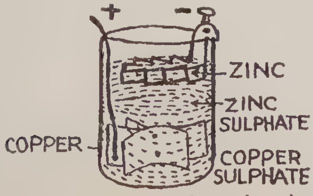

Fig. 21. A gravity cell: one form of a primary cell.

The internal circuit is from zinc plate (−), to copper plate (+); **the external circuit** is from copper plate (+), through circuit, to zinc plate (−).

Almost any salt or acid will act as an electrolyte if it will combine chemically with one of the elements, and if it does not offer too much resistance in doing so.

The current strength will vary according to the kind of plates or elements used, and will be greater when the chemical action is greater between the negative plate and the solution, or electrolyte.

Either alkali or an acid solution can be used for electrolyte in different kinds of batteries.

A secondary, or storage-battery cell: By the primary cell described above we converted chemical energy into electrical energy. With a storage battery a direct current of electricity is passed through the cells, which produces a chemical change which will put the plates and electrolyte into such a chemical condition, that an electromotive force (electrical pressure) will be produced when this change is completed. This action is termed "charging," and is the process of converting electrical energy into chemical energy.

The cells can then be connected to an external circuit, such as lamps, etc., and an electric current will flow through the circuit. This is termed "discharging," and is the process of converting chemical energy into electrical energy.

In other words, **after "discharging," the storage-battery cell can be "recharged,"** whereas, with a primary cell, fresh solution or new elements must be provided in order to obtain electric current again, after it has discharged.

On "discharge," electric current from a storage cell always flows externally, from the positive (+) terminal, through the circuit to the negative (−) terminal, and **internally** from the negative (−) plate to the positive (+) plate.

---

[1] Those who desire to go deeper into this subject should see the advertisement in the back of this book describing a good book on the Storage Battery.

[2] Called "gravity cell" because the two fluids separate from each other by gravity.

[1] A book dealing exclusively with the Storage Battery can be secured of A. L. Dyke, Granite Bldg., St. Louis, Mo. Price $5.

The object of this explanation is to point out how the acid passes to the plates when discharging, forming **lead sulphate** ($PbSO_4$), which covers the plates, and to show how, if **left** in this condition, the lead sulphate which is in fine crystalline form, would, in time, act on the plates to such a depth that it would recrystallize into larger and harder crystals which are difficult and sometimes impossible to change back again to lead peroxide and lead sulphate. This is one of the most dangerous of storage battery diseases. It results not only from the battery being left for a long period fully discharged, but also from other causes, as explained under "Sulphation of Plates."

It is quite in order, however, during the discharge process, for the lead sulphate to form on the plates, but the plates should not be **left** in this condition, which can be avoided by immediately recharging. If the discharging continues after the voltage of a cell drops below 1.8, an excessive formation of sulphate will result.

Even though a battery is charged and not used, it should be charged at a low rate occasionally, as a charged battery will, in time, become discharged; and when discharged, the action is to form lead sulphate over the active material. The result will be that this sulphate will finally have the same action as stated above, on a discharged cell.

The active material is what was formed on the plates when under the process of "pasting" and "forming," which is lead (Pb) on the negative plate, and lead peroxide (PbO_2) on the positive plate.

Action of a Charged Cell

A fully charged cell on open circuit is shown in Fig. 22. For the purposes of illustration, only two plates are used, a positive (+), and a negative (−).

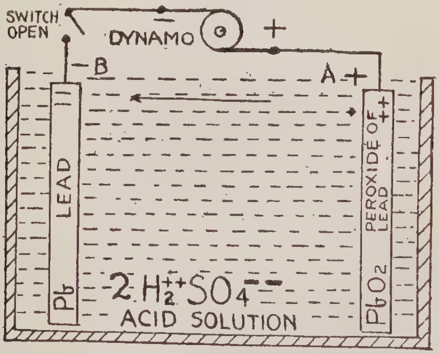

Fig. 22. **A charged cell on open circuit.** Note that the acid is in the solution and not in the plates. The active material on the negative plate is Pb, and on the positive PbO_2. The active material is not now covered with lead sulphate, as the SO_4 is in the solution.

When a cell is in a charged condition, the plates are not covered with lead sulphate ($PbSO_4$), as the SO_4 is then in the solution, which forms the electrolyte, which in turn consists of chemically pure sulphuric acid (H_2SO_4) diluted with pure distilled water, thus giving $H_2SO_4+H_2O=2H_2+SO_4$.

This acid was driven out of the plates when charged, and if a hydrometer is placed in the solution, it will be found that the solution is dense or thick and that the hydrometer will not sink as deep into the solution. The specific gravity would therefore be higher, and the specific-gravity reading will be between 1.280 and 1.300 when the solution is fully charged.

Another point, while on the subject of solution: Inasmuch as chemical changes take place, it is clear that if water is used which has metal in it, for instance, water taken from a metal roof, or if the water is not distilled, this would cause a different chemical action, injurious to the plates.

The positive plate (Fig. 22), which is supposed to be in a fully charged condition, is in the original condition as when formed, and has an active material of lead peroxide (PbO_2) in its grid. It is of a **dark-brown color.** Thus it is in a charged and healthy condition.

It is in a **diseased** condition when it fails to throw off all of the lead sulphate ($PbSO_4$) when being charged (the lead sulphate having been diffused over the active material when it was discharged).

The negative plate has thrown off the lead sulphate with which it was covered when discharged, during the process of charging, and is now a finely divided, spongy, **gray-colored,** soft lead plate (Pb).

Action of Cell When Discharging

Note that when the cell is discharging (Fig. 23), the current flows out of the (+) plate, through the motor, lamps, or other apparatus, into the (−) plate, through the electrolyte to the (+) plate.

Let us assume that the plates were in a fully charged condition, as in Fig. 22, when the circuit was closed, that is, the negative Pb, the positive PbO_2, and the solution H_2SO_4.

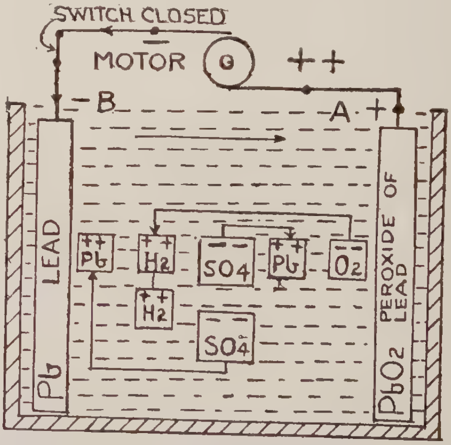

Fig. 23. **Discharging.** Note that the acid is going into the plates and will form lead sulphate ($PbSO_4$) and cover over the active material (Pb and PbO_2) on the plates. The solution will finally lose its acid and become water.

Refer now to Fig. 23. The active material (Pb) of the **negative plate** is combining with the acid (SO_4) of the electrolyte, and is converting the active material on the negative plate into lead sulphate ($PbSO_4$).

The **positive plate** active material (PbO_2) is combining as shown: the Pb with SO_4, and the O_2 with $2H_2$, and is thus being converted into lead sulphate ($PbSO_4$). See footnote below relative to the "ionic principle."[1]

---

[1] **The ionic principle** recognizes the law that every substance as well as liquids is made up of positive (+) and negative (−) electricity, and that if separated by chemical action, the positive will attract the negative. Note that when water is divided into its two parts, as hydrogen (H_2) and oxygen (O), the hydrogen particles are (+) and the oxygen particles are (−).

Action of a Fully Discharged Cell

A fully discharged cell is shown in Fig. 24. The active material on the negative lead plate (Pb) is now covered over entirely with lead sulphate ($PbSO_4$).

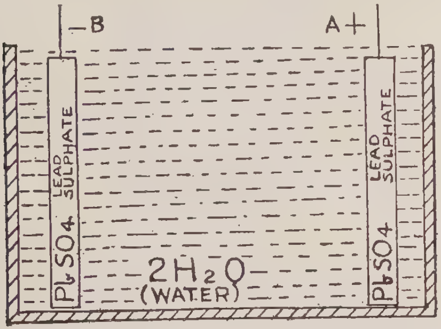

Fig. 24. **Fully discharged.** Note that the acid (SO_4) is out of the solution and into the plates, thus having combined with the lead of the plates (Pb) and having formed lead sulphate ($PbSO_4$) over the active material on both plates. The solution is now water, and is not dense.

As the acid has gone into the plates, this now leaves water around the plates, as solution. This accounts for the fact that a storage battery will **freeze quickly** when in a discharged condition.

If a hydrometer is now placed in the solution it will sink deep, as the water, without acid, is not as dense as with acid. The nearer a cell approaches a discharged condition from a charged condition, the less will the density become, until it approximates the density of water. When fully discharged the specific gravity will be about 1.150. The starting and lighting battery should be recharged before it is discharged this low.

Action When Charging a Fully Discharged Cell

A fully discharged cell just starting to be charged is shown in Fig. 25. The active material (Pb) on the negative plate is covered with lead sulphate ($PbSO_4$). The active material (PbO_2) on the positive plate is also covered with lead sulphate.

The passing of "direct current" through the cell, from the (+) terminal of the dynamo to the (+) positive plate, through the cell, to the (−) negative plate, to the (−) terminal of the dynamo (generator) causes the lead sulphate to be carried from the plates to the solution.

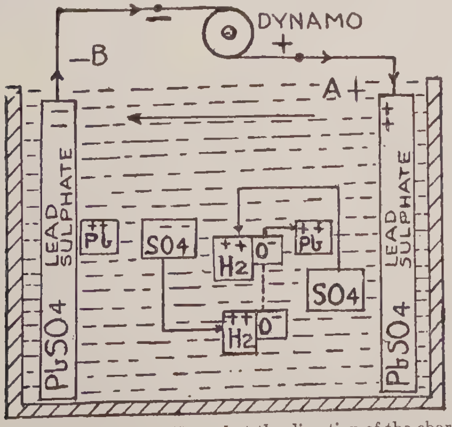

Fig. 25. **Charging.** Note that the direction of the charging current is as indicated by the arrow, or the reverse of that when discharging, as in Fig. 23. The lead sulphate ($PbSO_4$) which formed over the active material in the lead plates when discharging is now being driven off by the charging current, and the SO_4 is combining with the water. Thus the solution is gradually increasing in density or specific gravity. When fully charged the plates and solution will be as shown in Fig. 22.

Inasmuch as **the lead sulphate** ($PbSO_4$) merely covering the plates is quite accessible, it **is driven off with slight difficulty,** and the voltage rise in the cell during this period is very slight.

Note that the acid (SO_4) is passing from the plates on each side, and is combining with the H_2O (water).

As the charging continues, the lead sulphate which is buried deeper into the plates is more difficult to drive out with the charging current. The cell voltage is gradually rising.

After all lead sulphate has been removed from the plates, continued charging decomposes the water into hydrogen and oxygen which passes off in the form of gases. The voltage of the cell is then approximately 2.5 volts.

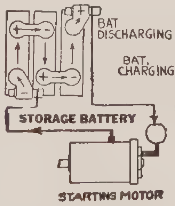
As the charging continues, the lead sulphate in the interior of the plates is more difficult to reach by the charging current, and the voltage of the cell rises as high as 2.65 to 2.70 volts.

If the charging is continued further, the temperature of the cell will rise and hydrogen and oxygen gases will pass off freely and thus the charging current is wasted and **the cell is heated.**

When the cell is fully charged, the conditions will be as shown in Fig. 22. The acid will be in the solution as $2H_2SO_4$, and the active material Pb, on the negative plate, and PbO_2 on the positive plate, will be exposed to the action of electrolyte.

Paths of Current Outside and Inside Storage Battery Cells

The external circuit of a battery discharging is as shown in Fig. 26: from the (+) terminal of the battery to the starting switch, to the starting motor, to the (−) terminal of the battery.



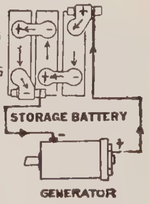


Fig. 26. Battery **discharging; external circuit.**

Fig. 27. Battery **charging; external circuit.**

The external circuit of a battery being charged is as shown in Fig. 27: from the (+) terminal of the generator, to the (+) terminal of the battery, through the battery, to the (−) battery terminal, to the (−) terminal of the generator.

Internal Circuit of a Cell Being Charged

The internal circuit of a battery cell being charged is shown in Fig. 28. We will assume the cell is an

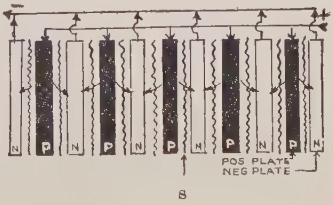

Fig. 28. **Charging the cells; internal circuit.**

11-plate cell, with 5 positive (+) plates (**P**), and 6 negative (−) plates (**N**). Note the separators (**S**) between the negative and positive plates, and note also that the negative plates are on the outside.

Each of the negative (−) plates are connected together, and each of the positive (+) plates are connected together; thus we have a positive (+) terminal and a negative (−) terminal to each cell.

The separators are placed between the negative and positive plates to insulate them from one another. The separators are porous and thus do not prevent the electrolyte or electric charges from acting on the plates, but merely serve to keep the plates from touching. In time, the separators rot, break, or become clogged, and permit the plates to touch. This causes an internal short circuit, which produces heat, and heat causes the plates to expand and to press against or through the separators more firmly.

Note in Fig. 28 that when the cell is being charged, the positive (+) current from the (+) side of the charging circuit flows into the positive (+) plates of the cells, to the negative (−) plates, and out to the (−) side of the charging circuit.

Internal Circuit of a Cell Being Discharged

The internal circuit of a battery cell being discharged is shown in Fig. 29. Note that the current path is in the opposite direction to that shown in Fig. 28, when the cell is being charged.

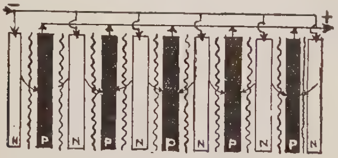

Fig. 29. **Discharging** the cells; **internal** circuit.

As the cell discharges, the active material on the plates is changed. The spongy lead (Pb) in the negative plate, and the lead peroxide (PbO_2) on the positive plate, are gradually changed to lead sulphate ($PbSO_4$). The acid in the electrolyte also passes to the plates as the discharge progresses. As the pores of the plates thus become filled with the sulphate, the **free circulation of acid into the plates is retarded;** and since the acid cannot then get into the plates fast enough to maintain the normal action, the battery becomes less active, as is indicated by the **drop in voltage,** or a discharged condition.

Voltage Drop of a Cell

Drop in voltage: Each of these actions tends to produce internal resistance, until finally a point is reached where the plates are fully coated, or changed to lead sulphate ($PbSO_4$), and where the acid is almost entirely out of the electrolyte.

The internal resistance is then so great, that the voltage is affected until it has dropped to about 1.6 if fully discharged. A cell, however, should not be discharged below 1.8 volts, and should be recharged immediately, otherwise it will be difficult for the charging action to throw off the lead sulphate from the plates, which was formed on them during the discharge action.

Electrolyte test: As the acid is withdrawn from the electrolyte during the discharge action, and replaced in the electrolyte during the charging action, it is clear that the most reliable test for determining the charged or discharged condition of a cell is to take a hydrometer reading of the cell, as explained on page 531.

Voltage of a Charged and Discharged Cell

When the battery is fully charged and before the charging circuit is opened, the voltage of each cell will be about 2.5 to 2.7.

When opening the charging circuit, the voltage of a cell drops to approximately 2.1 volts.

If the battery is then discharged at a continuous normal rate, it will gradually drop to 2 volts, which voltage will be maintained until it is about one-half discharged. From this point on, it will drop more rapidly to about 1.6 volts. The voltage of the cells, however, should not be permitted to drop lower than 1.8 volts per cell.

If the discharge rate is heavy, the voltage will drop much more rapidly. The reason for the drop in the voltage is explained on pages 522, 542.

If a high discharge rate is given, as when using the starting motor, the heavy discharge is only momentary. The result will be that the voltage will drop, probably to 1.8 to 1.6, at, say, a 200-ampere discharge, but will regain its normal voltage quickly when the circuit is opened—that is, if the battery is not already more than half discharged when the high rate of discharge is applied. See also pages 542, 545.

INTERNAL TROUBLES OF STORAGE BATTERIES

Some of the common troubles that a storage battery is heir to, are:

1. Sulphation of plates.
2. Buckling of plates.
3. Sediment.
4. Overheating.
5. Separators.
6. Short circuit of plates.

There are, of course, many other troubles, as enumerated in the "Digest of Storage-Battery Troubles," but those mentioned above are the most common, and usually account for the necessity of repairing a battery. The meaning as well as the causes are given below, and also in the "Digest of Storage-Battery Troubles." Tests are given elsewhere. See Index.

Sulphation of Plates

When cell plates are sulphated, it means that both plates are covered with lead sulphate ($PbSO_4$), the condition in which they are when discharged. This sulphation can act on the plates to such a depth that ordinary charging will not cause it to separate from the plate. In such a case, the battery will not hold a charge or give very much of a charge for any length of time, depending on the depth to which the plate is sulphated.

A sulphated plate has the appearance shown in Fig. 30. A white chalky substance forms on the negative plate which is a non-conductor and insoluble. This is usually caused by leaving a battery in a discharged condition for a long period of time and without water over the plates.

The remedy is to charge and discharge several **times at a low rate.** Owing to the sulphate on the

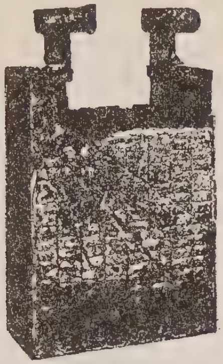

Fig. 30. A sulphated plate.

plates, the chemical action which takes place is very slow. The sulphate covers the active material, and thus only a small current can be absorbed by the active material; and **if charged at a high rate,** the water will be decomposed and form gas and give the impression that the battery is fully charged. (The active material referred to is Pb on the negative plate and PbO_2 on the positive plate, which is covered over with sulphate.)

It is more difficult to restore the negative plate than the positive plate. Only long-continued slow charging will tell. See Index under "Sulphated plates, how to restore." If this does not remedy the trouble, the plates should be examined; most likely new plates are necessary.

Sediments

Any impurities that the water contains are left behind in the cells by the evaporation of the water, and thus they settle to the bottom of the cell jar.

Mud and sediment will accumulate in the bottom of the battery and will eventually accumulate to such a height as to cause an internal short circuit of the plates, if any other than distilled water is used. The paste, or active material, falling off the plates will also result in the collection of sediment.

When cleaning the sediment from a jar, it is generally wise to replace the separators at the same time. The need for cleaning is usually indicated by lack of capacity, excessive evaporation of the electrolyte, and excessive heating when charging.

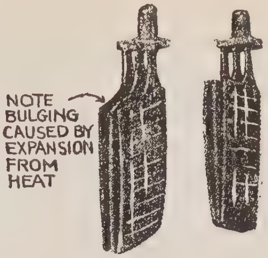
TESTS FOR INDIVIDUAL CELLS WITH TEST LIGHT

Fig. 31. Common battery troubles and a simple test.

Buckling or Warping of Plates

There is a tendency for the plates to shed the paste after it hardens on the grid, called "buckling" of the plates, meaning to distort, or get crooked, from sudden high discharges. Other causes will often result in the active material (paste) loosening and falling out of the grids to the bottom of the jar, and causing a "short circuit" from one plate to another.



NOTE BULGING CAUSED BY EXPANSION FROM HEAT

Fig. 32. Buckled plates.

Some of the causes are: Dead short circuit, as between starting motor and battery, thus causing overheating; overcharging, and at an extremely high rate, thus overheating; violent discharging and short circuits inside of the battery, which also produces excessive heat.

When the battery does not hold its charge, it is usually due to one or more defects internal of the battery, as just described, and each cell should be tested.

It will thus be observed that heating is the principal cause of buckling of the plates. Heat causes the plates to expand, and if heat is excessive and continued for a long enough period, the plates will assume a shape as shown in Fig. 32, which will cause the plates to cut through the separators.

As a plate discharges, lead sulphate is formed on it, and thus occupies more space than the active material on it. If it expands equally, it will do no harm, but if the battery is over-discharged or charged at a very high rate, the active material will expand and heat, because the portion of the plate on which there is least sulphate will carry most of the current and thus overload this section of the plate. The result is excessive heat which results in expansion and "buckling."

Plates which are not buckled too badly can be straightened by putting them in a press.

Overheating

Overheating caused by overcharging may occur if the regulation system goes wrong and permits the generator to deliver excessive current.

It is well to feel the battery occasionally, particularly the lead links and cover, after a long, hard drive. Should you suspect overheating, remove the vents from the cells and insert a thermometer, of the type made for insertion into liquids, into the electrolyte of each cell.

The battery temperature should never be allowed to exceed 110° F. Garage men who make a practice of charging batteries in their plant should enforce this rule rigidly.

Overheating should be avoided, because it expedites evaporation of water from the electrolyte, causes deterioration of plates and separators, and tends to buckle the plates. Overheating of one-half the battery should be guarded against.

Sometimes heat will be produced at the connectors, where they are welded to the posts of the plates, owing to improper welding. This, of course, would then necessitate re-welding, and would be external of the cell.

Separators

The purpose of separators is explained on page 542. Where a high rate of discharge is required from a battery, as with a starting motor, a freer and more rapid circulation of the electrolyte with the active material on the plates is necessary.

If a battery is used solely for low rates of discharge, as for ignition, then thick plates and **perforated hard-rubber separators** are generally used, which give a very long life to the battery.

Where a very high discharge is required at times, which in many instances may be over 200 amperes, then, as stated above, the rapid circulation of the electrolyte can better be accomplished through the **pores of certain woods.** The thin plates are used and many of them, in order to give sufficient plate area, and thus the action of the electrolyte on the plates is more rapid.

Various kinds of wood, and various methods of treating wood separators are employed by different manufacturers of storage batteries for starting, lighting, and ignition purposes combined. Those woods which are porous and will withstand the chemical acid are such woods as cypress, white cedar, California redwood, Douglas fir, poplar, basswood, cherry, etc.

The Exide battery uses a grooved specially treated cypress wood separator of a very porous nature. The Eveready battery uses cherry wood. The General storage battery uses California redwood. The Willard battery uses separators made of rubber fabric pierced by hundreds of cotton threads. The electrolyte is carried through the thread from one side to the other by capillary action.

When wood is used for separators, it is specially treated after sawing and grooving. The separators are placed in a warm alkaline solution of about 3 per cent caustic potash. This neutralizes the acetic acid which wood contains (and which if permitted to go into the cell would tend to dissolve the lead and cause it to crumble), and also removes resin from the pores. The pores must be fully open in order that the acid can act through them.

The alkali is removed by soaking for about two to three days, and then washing in running water. The separators can then be used. If separators are not used after treating, then place them in a weak acid solution of about 1.025 or 1.050 sp. gr. The separators have a tendency to expand in the solution, and therefore, if they are not kept wet, they will shrink.

When new separators are received, they should be soaked for about five days in a solution of electrolyte of about 1.250 sp. gr., so that they will expand to the proper proportions outside of the cell instead of allowing them to expand in the cell. Separators are the weakest part of the battery.

If the pores of wood separators clog from dirt, impurities in the water, or lead sulphate, this will prevent the electrolyte from circulating and the separators should be replaced with new ones.

Battery Internal Short Circuits

Battery short circuits may be external or internal.

External battery short circuits may be due to acid on the top of the battery forming an electrolyte between terminals as at (A) (Fig. 31); to battery terminals being sulphated, or in contact with the top of the metal battery box, or to the battery wire connections being acid-soaked.

Internal battery short circuits may be due to the internal condition of the battery, such as plates warped or buckled, or a collection of sediment at the bottom of cells due to disintegrating plates, although the latter is rare because of the height of the plates above the bottom of the jar (see **A**, Fig. 31). The usual cause is broken or rotted separators, which permit the plates to touch.

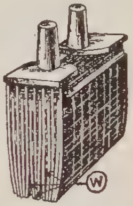


Fig. 33. The arrow points (W) show how broken down wood separators allow a plate to bend and to touch, causing a **short circuit of the plates.** Buckled plates usually cause this trouble, and too much acid rots the separators.

When one plate touches another inside of a cell, as at (W) (Fig. 32), it causes an internal short circuit. Owing to the fact that the cells are connected in series, the other cells will then send a current through the shorted plates in a reversed or discharged direction, and the negative plate (Pb) will have a coating of the active material (PbO_2) of the positive plate formed over it, and the positive plate will become a negative plate, through the reversal.

This action also occurs when the terminals of a battery are reversed with the charging current. Most of the generators, however, on automobiles of the present-day type of construction will reverse their polarity to that of the battery.

Internal short circuits, if of long standing, will necessitate new plates and separators. If the short circuit is not serious, the plates can be cleaned and new separators can be put in.

If a battery is charged in the wrong direction for a period of time with the terminals reversed, or long enough to change the positive plates to negative and negative to positive, new plates and separators will usually be required. Sometimes batteries can be reversed by long-continued charging in the right direction. In fact, batteries have been used with plates reversed, while others in the same condition would fail to hold a charge at all.

In time, even if batteries are kept in good condition, age will tell on them, and the positive plates will begin to crumble. The active material on the negative plates will lose its porous, spongy lead formation and become hard (porosity is very important in battery plates so that acid can circulate through the plates as well as through the separators).

From 15 to 24 months is the average life of a battery used for continuous daily starting purposes and general use (150 to 250 amperes discharge), as starting work is very hard on any battery.

INSTRUCTION No. 48

TESTING STORAGE BATTERIES: Voltmeter Tests; Cadmium Tests; High-Amperage Discharge Tests

TESTING A STORAGE BATTERY WITH A VOLTMETER

A battery should never be discharged completely. As we have already stated, when testing with a hydrometer 1.150 is the limit for batteries used for ignition and lights, and 1.225 for starting motors.

A voltmeter can also be used to test the battery, but bear in mind that the test is not practical unless it is made **when the battery is discharging or charging.**

No cell should ever show less than 1.8 volts per cell, or 5.4 volts for a 6-volt battery (readings taken when battery is discharging or charging). The normal voltage of the battery is 2.2 volts per cell when doing no work, which, if the electrolyte be 1.250 sp. gr., is usually lowered to about 2.1 volts, because of internal resistance.

The storage battery, unless worked below 1.8 volts, **has a recuperative power** of rising from 1.8 volts to the normal 2.1 or 2.2 volts within a few minutes after the discharge current has been discontinued. This act has often led many users astray as to their opinion of the condition of their cells.

For instance, suppose one to be out with his car, and the spark is not sufficiently strong to give satisfactory ignition of the gases; he stops to locate the defect. Usually the first thought is: Are the batteries right? The voltmeter is taken and put to the cells, and because they show a reading of 2.0 to 2.1, they are deemed all good.

As a matter of fact, if the reading had been taken while the battery was discharging, the voltmeter would probably have read 1.8 volts or perhaps less per cell. In this way it often occurs that much time is lost in going over the car looking for the defect, while all the time it has been the batteries which have innocently showed 2.0 volts, because they were standing idle.

The voltmeter can also be used to determine the positive and negative poles of the battery. Touch the voltmeter terminals instantaneously across the circuit. If the needle runs upward in the normal direction on the scale, the voltmeter is properly connected and the wire which touches the positive meter terminal is thus identified as positive. If the connections were reversed, the needle would kick off the scale, indicating that the positive terminal of the voltmeter should be connected to the other wire.

Note: Never connect an ammeter to the terminals of a battery, unless a shunt is used.

The specific gravity test with a hydrometer is the method generally used to determine whether a storage battery is charged or discharged. Provide yourself with a hydrometer to enable you to test the gravity of your electrolyte periodically, and you will avoid a great deal of trouble.

It may be said that the condition of the specific gravity is the pulse of the cell, and certainly it is the one means of ascertaining the exact condition of health of the cell or battery.

The voltmeter is generally used by battery repairmen, and is very necessary under certain conditions, if properly used, for testing for a defective battery, or for grounds and short circuits, etc.

The voltmeter can also be used to test a battery for its charged or discharged condition. When a charged battery is discharging it will give, say, about 2 volts per cell until 50 per cent of its capacity is used, and then gradually drop to 1.8 volts per cell. Therefore a meter reading in one-tenth part of a volt will give an accurate test if the battery is on discharge, telling the condition between the 2-volt drop and 1.8-volt drop in fractions of a volt.

The voltmeter, however, is more often used to test the condition of the individual cells.

When to Test

A voltmeter is used to test a battery when it is being charged, in combination with a hydrometer test (see pages 547, 531).

A voltmeter is also used to test for defective cells, as explained below.

As previously stated, a battery is usually tested with a hydrometer in order to show if it is charged or discharged, but sometimes, the hydrometer reading will show 1.275 or 1.300, which, supposedly, represents a charged condition. Yet the battery fails to hold its charge. In this instance, it is necessary to use a voltmeter to determine the cause which is usually found to be internal of the cell.

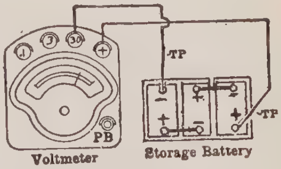

Fig. 1. Testing a 3-cell, 6-volt battery with a voltmeter.

The first step is to test the entire lot of cells, after determining that the battery has been charged and that the electrolyte reads from 1.275 to 1.300. Use the 30-volt range (model 280 Weston instrument as an example), and make connections as shown in Fig. 1. The test should be made with the battery discharging at a normal rate, say with the lights on.

A 3-cell, 6-volt battery (as in Fig. 1) should test 2 volts per cell, or approximately 6 volts for the three cells.

If the test shows the proper voltage and the specific gravity is 1.275 to 1.300, then the fact that the battery does not hold its charge is due to outside causes, such as loose connections, grounds, etc.

If the test shows a decided drop in voltage and yet the battery is known to have been charged, then the trouble is internal of the battery, probably in one or more cells.

If all cells do not come up to test, then test each cell of the battery separately, in order to find, on normal discharge, which cell is defective.

There are three methods used for testing battery cells:

1. With a low-reading voltmeter.
2. With a cadmium voltmeter.
3. With a high-amperage discharge test.

Example of Testing Individual Cells of a Storage Battery with a Low-Reading Voltmeter

The Weston model 45 voltmeter, designed especially for battery testing, will be used as an example.

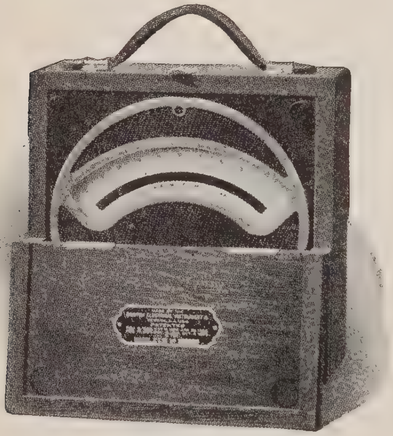

Fig. 2. Weston model 45. Low-reading battery-testing voltmeter.

This instrument is a direct-current permanent-magnet moving-coil voltmeter, having a range of 0.2–0–3.0 volts, intended for testing individual cells. It will test for low readings and also make the cadmium test.

The scale (Fig. 3) has 160 divisions, each division having a value of 0.02 volt. When reading this instrument, look directly down upon the scale, so that the image of the pointer in the mirror exactly coincides with the tip of the pointer itself. Slight deviations in the zero position of the pointer are corrected by means of the zero adjuster screw.

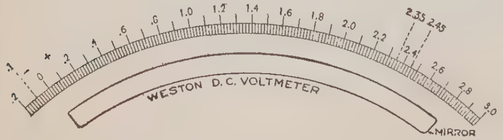

Fig. 3. Scale as used on the Weston model 45 battery-testing voltmeter. Approximately half actual size.

Note. The 2.35 and 2.45, as also (–) and (+) and .1, are not actually shown on the scale. These figures have been added here in order to show the points generally used for cadmium tests, as explained farther on.

Open-Circuit Cell-Voltage Test

This test consists of measuring the voltage of each cell of the battery **without any current** being passed into or taken from the battery.

The purpose of this test is to find out if the cells are in a **charged** or **discharged** condition.

Procedure: Connect the cable (Fig. 4) having the plain spike terminal (T) to the binding post of the voltmeter marked (+).

Connect the cable having the combination spike (T1) and cadmium (C) to the (–) binding post.

Press the plain spike terminal (T) into the (+) terminal of a cell and the combination terminal (T1) into the (–) terminal of the same cell. Be careful to penetrate into the metal of the cell terminals. Test all cells in the same manner.

Note. This test is for the open-circuit voltage of the cell. Although the cadmium stick (C) is attached to the spike (T1), it is not in use.

The voltage indicated should be 2 volts or a little higher. If it is 1.8 or lower, the cell should be tested under load, as explained under the following heading.

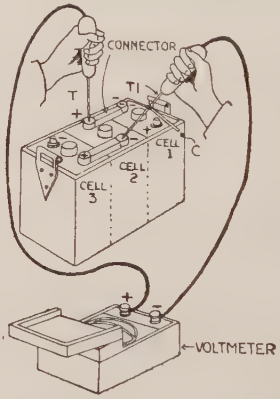

Fig. 4. Open-circuit voltage test of cells.

Testing the Voltage of Cells with Current Flowing

Purpose of the test: In the paragraph preceding, the statement was made that if 1.8 volts, or lower, was indicated the cell should be tested under load. The object of this would be to find out if the fact that the cell tested only 1.8 was due to a **discharged** condition or to a defect internal of the battery cell.

Procedure: When this test is to be made on a battery of the automotive type, connect a "resistor" across the terminals of the battery, as shown in the illustration (Fig. 5).

This **resistor**[1] can be readily made by winding about 9 feet of No. 16 soft-iron wire in the form of a helix with the convolutions separated so as to prevent touching, and is for the purpose of having the battery on **discharge** during the test.

With the resistor in place, as in Fig. 5, the current is flowing through it, and the battery is discharging. Press the spike (T) into the (+) terminal of the cell under test, and the spike (T1) into the (–) terminal of that cell. Make this test on all cells.

---

[1] See page 554, explaining how to make a "heavy discharge tester" which can be used in place of this resistor.

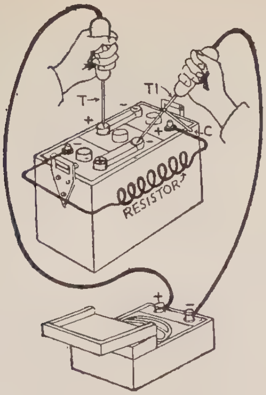

Fig. 5. Voltage test of cell with battery discharging.

If the tests on all cells of the battery show approximately the same voltage, the battery is in a **discharged** condition.

If any cell has a voltage which is lower than that of the others by a relatively large amount, it is quite possible that **the plates of that cell are defective** and should be carefully examined. This is usually done by opening the cell.

By making a cadmium test, the condition of the plates can be ascertained without opening the cell, and furthermore, the cadmium test will indicate if it is the positive or negative group of plates which are defective, as will be explained farther on.

Specific Gravity Test of Electrolyte

The test just described was to ascertain if the cells were defective or discharged. It was pointed out, that if one cell shows a voltage relatively lower than the others, it was probably defective internally, and the proper test then to make would be the cadmium test. If, however, the tests show approximately the same voltage (1.8) or less, then all cells are probably discharged. The test to make in such a case is the specific-gravity test.

After determining the cell voltage with current flowing (as in Fig. 5), and ascertaining that the battery is in a **discharged** condition, the electrolyte should then be tested with a hydrometer, as described on page 531. When using the hydrometer caution should be exercised to draw only enough solution into the tube to float the hydrometer freely, and never to put electrolyte taken from one cell into another cell. Care must also be taken not to cause air bubbles in the cell, as these are very difficult to remove and will often result in loss of electrolyte.

A fully charged battery will have an electrolyte gravity of from 1.275 to 1.300.

A discharged battery will test only 1.150 to 1.175.

If the gravity test is low, charge the battery until the hydrometer does not show any further increase in the gravity. Then repeat the test with current flowing.

If there are no defects in the cells, the voltage with current flowing will approach a value of 2 volts per cell.

If, however, the voltage drops considerably, the plates are likely to be defective.

CADMIUM TEST OF A STORAGE BATTERY CELL

Let us assume that when the test was made, as in Fig. 5, the voltage of one cell was lower than that of the others by a relatively large amount. Let us assume also that after making the specific-gravity test with the hydrometer after the battery was put on charge, the voltage dropped considerably. The indications then point to its being a defective cell internally.

The cadmium test should then be made in order to find out which group of plates are defective: whether **it is the negative or positive plates of the cell.**

The cadmium test is never made with a battery on open circuit. It is always made when the battery is **on charge or discharge.** An explanation of the principle of the cadmium test is given farther on.

Cadmium Test with Battery on Charge

Procedure in the cadmium test: Charge the battery until its voltage and specific gravity attain constant values, and, while on the finishing rate of the charge, make the test.

Connect the plain spike (T) cable to the (+) binding post of the voltmeter (Fig. 6), and the one with the cadmium stick to the other binding post.

Testing the positive group of plates of a cell: Insert the cadmium stick into the vent hole of the cell to be tested, taking care that it does not touch the plates. Press the plain spike terminal into the (+) terminal of the cell under test, and, with the "finishing rate" of charging current passing into the cell, observe the reading of the voltmeter.

Before taking the reading, the cadmium stick should be kept in the electrolyte until the voltage reading has become constant.

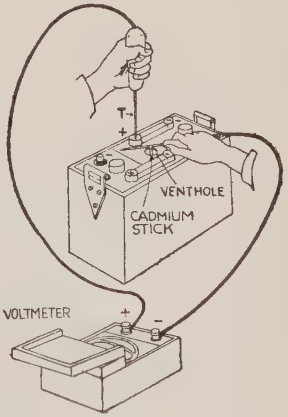

Fig. 6. Cadmium test of a cell.

If the positive plates are in good condition, the reading will be between 2.35 and 2.45 volts.

If the reading is less than 2.35, it is probable that the positive plates are defective.

Testing the negative group of plates of a cell: Transfer the plain spike terminal to the (—) terminal of the cell. The reading this time will be to the left of the zero on the scale of the instrument.

A fully charged negative group in good condition should be between 0.1 and 0.2 volt, to the left of zero (0).

If the reading approaches zero, or if it is **to the right of zero,** the **negative plates** are probably **defective,** or are in a sulphated condition requiring an extended period of charging to put them back in a healthy condition.

If the test on both the positive and negative plates gives readings which approach zero, the battery is short-circuited.

In general, it is understood in the case of a battery **on charge,** that if the cadmium test to the **negative plates** does not give a **minus** reading, the battery is not up to capacity, but a minus reading is not necessarily proof that the battery is up to full capacity. This can be determined by making **a discharge test.**

Cadmium Test with Battery on Discharge

Procedure: The battery should be discharged at its normal discharge rate until the voltage per cell is 1.8 volts with current flowing. Keep a record of the time in hours required to do this. Then with a discharge current of 5 amperes flowing, the cadmium test should be repeated.

The reading to the **positive plates** should be about 2.05 volts, and to the **negative plates** about +0.25 volt, or to the right of zero (0).

If the reading to the positive plates is much below 2 volts, it is probable that the positive group is defective.

If the reading to the negative group is greater than +0.25 volt, it is probable that the negative group is defective.

When the readings indicate defective plates, it is advisable to make a thorough inspection of the plates.

Upon reaching the voltage of 1.8 volts per cell, the battery should have given its rated ampere-hour capacity. This is determined by multiplying the ampere discharge rate by the time in hours. If the full ampere-hour capacity has not been given, the battery is lacking in capacity, and it is probable that one or both groups of plates may be defective.

When the cadmium readings show the plates to be in a fully charged condition, the density of the electrolyte should be determined. This should be between 1.275 and 1.300. If it is not, the electrolyte should be made to have the correct density.

If the density indicates a fully charged cell but the cadmium test does not show fully charged plates, the charge should be continued to see if the cadmium readings will become what they ought to be. If not, the plates are probably defective.

Remarks on Cadmium Tests

The cadmium test is usually made when a battery is tested with a hydrometer and the tests show that the battery is fully charged, but when a battery is put into service the voltage drops rapidly and the battery fails to deliver its capacity. If the battery voltage failed merely because the battery was discharged after delivering its normal capacity, then there is no need of making a cadmium test. The battery in this instance needs recharging, simply.

If, however, as mentioned above, the hydrometer tests show the battery to be charged, but that when put into service it fails to maintain its charge for its rated capacity, and the voltage drops rapidly on normal discharge, this condition is probably due to defective plates. The cadmium test will determine which set of plates are defective, or which set fails to hold its charge.

The cadmium test is also made when a battery on charge does not attain its proper voltage (2.6) per cell, and its specific gravity will not rise to a normal reading of 1.280 to 1.300 sp. gr.

The cadmium test is usually made when the battery is still on the charging line. The charging rate should be that recommended by the manufacturer, which is the "finishing rate." The battery should be charged until the voltage and specific gravity attain a constant value, and will rise no higher.

Voltmeter Used with a Cadmium Test

Parts of the cadmium outfit are more fully explained on page 550.

The voltmeter used for making cadmium tests should be a low-reading voltmeter with an additional reading to the scale on the **left of zero.**

Cadmium reading scale of voltmeters: On some cadmium-test voltmeters the scale is marked especially for cadmium readings, as discussed on page 550.

The scale used on the Weston model 45 (Fig. 2) voltmeter, is shown on page 546.

The scale used on the Weston model 280 combination volt-ammeter (Fig. 15, page 468) does not show the cadmium reading which has been added to the scale.

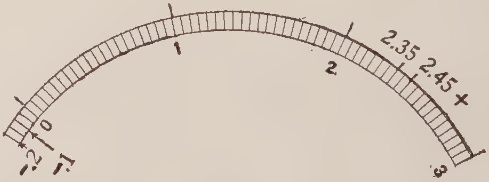

Fig. 7. The scale which is now used on the Weston model 280 volt-ammeter.

The illustration (Fig. 7) shows the scale now being fitted to this instrument, by which it is possible to make cadmium readings. The scale has 60 divisions from 0 to 3, each division being .05 of a volt. Four divisions to the left of "0" have been added for the cadmium negative readings, which are .05 of a volt each, or .1 volt for two divisions.

Cadmium Test-Points and Test-Cables

The cadmium test-points and test-cables for use with the Weston models 45 and 280 are shown in Fig. 8.

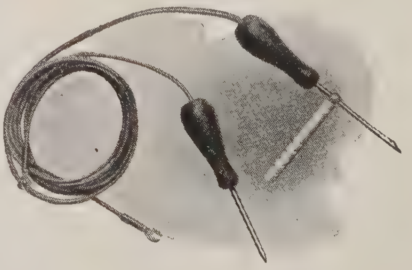

Fig. 8. Cadmium test-points and cables.

They consist of two flexible rubber-covered cables **6 feet long,** having fork terminals on one end. One of the cables is provided with a plain spike terminal, and the other cable with a combination spike and cadmium stick terminal. The cadmium stick is provided with a perforated insulating covering to keep the stick from coming in contact with the plates of the cell. Price per pair, including the cadmium stick, as shown in Fig. 10, $5; cadmium cable, stick and point, $2.75; plain spike and cable $2.25. (These can be secured of A. L. Dyke, Electrical Department, St. Louis, Mo.)

Principle of the Cadmium Test

When making a cadmium test, the cadmium stick is placed into the electrolyte vent hole of a cell, as shown in Fig. 6, page 547. The test-point is then placed on the terminal of the (+) positive plate group, to test the positive plates (Fig. 6), and on the terminal of the negative (−) plate group, to test the negative plates. Either of these tests really makes **two distinct cells** out of the one cell.

For example, let us take two plates of a cell, as shown in the simplified illustration (Fig. 9). The test is made of the positive plate **when the battery is on charge,** and of the negative plate (Fig. 10) when the battery is on charge, that is, when the battery has about reached its charged condition and is still on the line, being charged at the finishing rate.

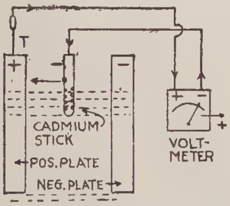

Fig. 9

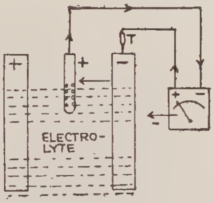

Fig. 10

Fig. 9. Positive plate test when on charge.
Fig. 10. Negative plate test when on charge.

Testing the positive plates of a cell on charge: With the prod (T) on the positive plate (Fig. 9), which is connected to the (+) terminal of the voltmeter, and the cadmium stick in the electrolyte, which is connected with the (−) terminal of the voltmeter, the cadmium acts as a negative (−) plate. Thus **the voltage would be taken of the positive (+) plate,** and the voltmeter needle will read in its normal, or right-hand direction, because the current is flowing through it from the (+) plate, to (+) of the meter, from (−) of the meter, to (−) of the cadmium.

Testing the negative plates of a cell on charge: If we now place the prod (T) on the negative (−) plate (Fig. 10), then the cadmium acts as a (+) plate. Thus **the voltage would be taken off the negative plate,** but the meter needle would read in a reverse, or left-hand direction (if charged), because the cadmium stick, which is now acting as a (+) plate and from which the current first flows to the meter, being connected with the (−) terminal of the meter, will cause the voltmeter to read in the reverse direction, not only on this voltmeter but on any other. Hence the addition to left of (0) on scale of a voltmeter (Fig. 3, page 546, and Fig. 7).

When the positive and negative plate tests are made, as described in the foregoing explanation (Figs. 9 and 10), the test is being made when the cell **is on charge.** Therefore, when a cell is being tested while on charge, and is charged or almost charged, the negative plate readings should be on the **left** or (−) side of (0) on the scale of the meter.

By adding the readings of the positive plate and of the negative plate, when a cell is being tested on charge as described above, the sum should be the voltage of the cell, because, when tests were made, as in Figs. 9 and 10, the cell was divided into two parts.

The object of making the test is to determine whether the positive plates test up to the standard as they should, when the cell is supposed to be charged, and whether the negative plates are up to standard voltage. If either of them fail to come up to this standard, then they are probably defective, if the electrolyte tests as it should.

The standard voltage of the positive plates (when charged) should read approximately from 2.35 to 2.45 volts, and that of the **negative plates** should read from .1 to .2 of a volt (to the left, or (−) of the scale), if in good condition.

Thus, if the two voltage readings are added together (2.45+.2=2.65), we have 2.65 volts as the total voltage of the cell, or a fully charged cell.

Suppose, however, that a cadmium test was made after the battery was put on the charging line, yet the cells are not charged, being nearer a discharged condition than a charged condition. In this instance, the negative plate reading would probably be on the right, or (+) side of (0) of the scale; and therefore the negative plate readings when on the (+) side of (0) are **subtracted or deducted** from the positive plate readings, which should give the total voltage of the cell. See an example of a test of this kind in the table, on page 551.

As another example, let us use two plates of a cell, as shown in the simplified illustrations (Figs. 11 and 12). The tests are being made when the battery cells are **discharged** to 1.8 volts and while the battery is being discharged at 5 amperes.

When making this test, the battery is first discharged at its normal rate, until the voltage drops to 1.8 volts. During the discharge, the battery is closely observed to see if it gives its rated capacity during the time it is discharging.

A cadmium test of a discharged battery is usually made if a battery fails to give its rated ampere-hour capacity, for if it is in good condition, it should do so.

The ampere-hour capacity or discharge rate of a battery is usually stamped on the nameplate of the battery. For example, if a battery had an "ampere-hour capacity" of 80 ampere-hours, and the "discharge rate" was 10 amperes, it would discharge at 10 amperes for 8 hours, gradually dropping to 1.8 volts, at which time it is discharged, and, if in good order, has delivered its full capacity.

If the battery is known to be fully charged and the electrolyte tested to 1.275 to 1.300, yet in an appreciable difference in time it drops to 1.8 volts before it has delivered its rated capacity, this may possibly be due to the condition of one of the group of plates, positive or negative, or of one or more cells, which discharged first. The purpose of the test **on discharge** is to determine if it is the negative group or the positive group which are defective, or which failed first. If one or the other fails to come up to the **standard voltage** under certain conditions, as outlined above, then the group (positive or negative) which differs greatly from the standard is the one at fault.

The cadmium test is then taken, after the cell is discharged to 1.8 volts and with the battery discharging at 5 amperes, in the following manner:

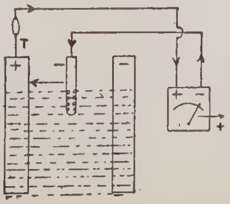

Fig. 11

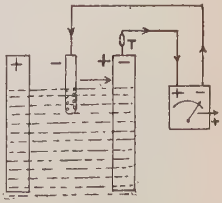

Fig. 12

Fig. 11. Positive plate test when on discharge.
Fig. 12. Negative plate test when on discharge.

Testing the positive plates of a discharged cell: With the prod (T) on the positive (+) (Fig. 11) the cadmium now acts as a (−) plate. Therefore the test is of the positive plate. When the battery is discharged and is discharging at 5 amperes, the reading of cadmium to positive (+) plate should show about 2.05 volts, if the plates are in good condition.

Testing the negative plates of a discharged cell: With the prod (T) on the negative plate (Fig. 12), the cadmium acts as a (−) plate and the negative plate acts as a (+) plate (when discharged). Therefore the test is of the negative plate, and the reading should show about +0.25, or to the right of (0) on the scale (Fig. 3, page 546). When a discharged cell is tested while on discharge, the negative plate readings will be on the right, or the (+) side of (0). Therefore the negative plate reading is deducted from the positive plate reading, which should give the voltage of the cell being tested.

For example, suppose the reading of the cadmium to the positive (+) plate (Fig. 11) is +2.05 volts, and the cadmium reading for the negative plate (Fig. 12) is +0.25 volts. The difference would be: 2.05−0.25=1.80 volts, or 1.8 volts, which is the voltage of a discharged cell in good condition and the voltage the cell should test if the voltmeter is placed on the cell terminals.

THE AMBU CADMIUM-TEST VOLTMETER

This instrument has a **specially designed scale** which is easy to read. Explanations are given below.

Readings on the Scale of the Voltmeter

This special voltmeter (Fig. 13) has the (0) line near the left end of the scale. The scale is marked especially for cadmium tests.

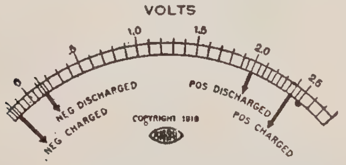

Fig. 13. Ambu special cadmium scale.

To the left of the (0) line is a red line marked "NEG. CHARGED." This line indicates the reading of −0.175, which should be obtained when testing **new negative plates which are fully charged,** that is, when making a cadmium test on the negatives, the pointer should move to this red line. If the pointer does not move as far as the red line, the negatives are not fully charged.

Similarly, there is a red line at +0.175, marked "NEG. DISCHARGED"; at +2.00 marked "POS. DISCHARGED"; and at +2.42 marked "POS. CHARGED."

Old cells will give readings which are not quite as high as those indicated by the red lines.

Any accurate voltmeter, which gives readings up to 2.5 volts in divisions of .05 volt, can be used, but the advantage of this instrument is in the scale prepared especially for cadmium-test readings.

Cadmium Stick and Test-Points

Cadmium is a metal. It looks like zinc, but is pure, because there is no other substance mixed with it.

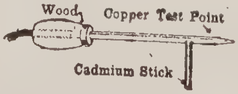

Fig. 14. The test-point, with the cadmium stick riveted to it. The cadmium is the part which is inserted in the electrolyte. It is always connected with the (−) side of the voltmeter.

A cadmium testing outfit[1] consists of two copper test-points, one of which has a stick of cadmium, about 3½" long and ¼" in diameter riveted to it, as in Fig. 14, and a special-reading voltmeter.

Why a Cadmium Test Is Necessary

The condition of a storage battery is usually ascertained by taking a specific -gravity reading of the electrolyte, with a hydrometer, a reading of 1.275 to 1.300 being usually considered as indicating a fully charged cell. While specific-gravity readings with a hydrometer should always be made, yet they should not be relied upon entirely.

For instance, a battery which gave entirely satisfactory hydrometer tests may show a rapid drop in voltage when in use, yet this condition could not be foretold by hydrometer readings alone, because the hydrometer readings would not tell us the condition of either the positive or negative plates, and it is their condition which determines the amount of energy in any battery.

Voltmeter Tests of Cells

We may also take a voltage reading of all cells of the battery, as in Fig. 15, while the current is being drawn from the battery which gave satisfactory hydrometer readings. This would tell us if the plates were not in good condition, but it would not tell us which set of plates was at fault, because the voltage reading includes all positive and negative plates, as in Fig. 15.

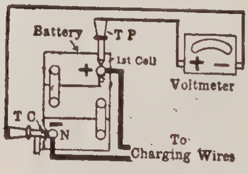

Fig. 15

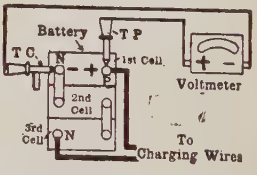

Fig. 16

Fig. 15. Testing the voltage of all cells of a battery, when the battery is on charge, and preliminary to taking a cadmium test.

Fig. 16. Testing one cell of a battery when on charge, and preliminary to a cadmium test.

If we took a voltage reading of one cell of the battery, as in Fig. 16, while the battery is on charge, it will be readily seen that the test includes both positive and negative plates. Suppose the battery will not take a full charge, which set of plates is defective: the positive or the negative?

Therefore, to determine the condition of the positive and negative plates separately, we must make a test between each set of plates and some neutral substance. Theoretically, a number of substances could be used for the neutral substance, but for practical reasons cadmium is used.

---

[1] Can be secured of A. L. Dyke, Electrical Department, Granite Building, St. Louis, Mo. See advertisement at the back of this book.

The cadmium test can be made while a battery is on charge or when it is being discharged. As a rule, the test is made only near, or at the end of a charge, in order to determine if both positive and negative groups are taking the charge properly.

How to Test a Battery on Charge

The charging current must be passing through the battery at a normal rate when the test is made, and the needle of the voltmeter should be exactly on zero—this can be set with the zero adjustment. The best time to test is at the finishing of the charge. Then proceed as follows:

First measure the voltage of one cell, by holding one of the test-points on the positive (+), and the other on the negative (−) terminal of the cell, as in Fig. 16.

If the cell is fully charged, the reading of the voltmeter will be from 2.5 to 2.6 volts, depending on the age of the battery; a new battery giving a higher reading than an old one.

Cadmium Test of Positive Plates When on Charge

Test the positive plates of one cell, by inserting the cadmium rod on test-point (TC) in the electrolyte at vent (V) of the cell, as shown in Fig. 17, being sure that the cadmium does not touch the top of the plates (a rubber tip at the end of the cadmium stick is provided on the Ambu set, to avoid any probability of touching it).

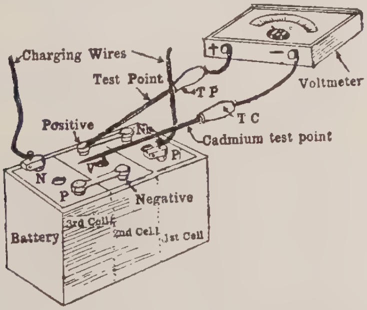

Fig. 17. Making cadmium test of the positive plates of one cell of the battery. Each cell is tested in the same manner.

Allow the cadmium to remain in the electrolyte for several minutes, until the electrolyte has no further effect on the cadmium. Then hold the pointed end of the other test-point (TP) on the **positive cell terminal.**

If the positive plates are fully charged, the voltmeter reading will be, to the right of line (0) (Fig. 13), at least 2.35 and possibly 2.42 or even 2.50, if the battery is new. Should the reading be less than 2.35, then **the positive plates are not fully charged.**

Continue the charge, and if the positive plates will not then give a reading of at least 2.35, the **positive plates are defective.**

Cadmium Test of Negative Plates When on Charge

Test the negative plates by placing the test-point (TP) on the negative terminal of the cell, as shown in Fig. 18.

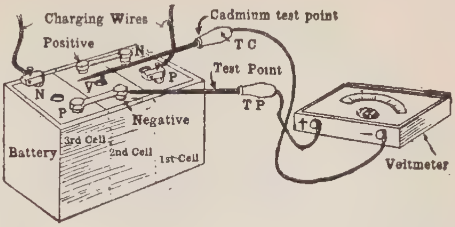

Fig. 18. Making cadmium test of the negative plates of one cell of a battery. Each cell is tested in the same manner.

If the negative plates are fully charged, the voltmeter reading will be from −0.175 to −0.2, that is, the needle will move to the left (or [−] side) of (0) on the scale (Fig. 13).

Should the reading be very nearly zero, or if the needle swings to the right (or [+] side) of the (0) (Fig. 13), **the negative plates are not fully charged.**

Continue the charge, and if the negative plates will not give a reading of from 0.175 to 0.2 volts to the left of the (0) line on the scale, then **the negative plates are defective.**

Test the positive and negative plates of the other cells of the battery in the same manner.

If the positive and negative readings, taken when charging a battery at finishing rates, or when a test is made of a battery almost charged, are added together, the sum should be the voltage of the cell, that is, when the negative readings are on the left, or (−) side of (0) on the voltmeter.

Example of Cadmium Test-Readings of a Battery

The following table furnished by the Ambu Co., gives the voltmeter and cadmium readings taken at hourly intervals on a battery during the time when it was being charged at a normal rate. A healthy battery should not depart widely from these readings.

Hours on charge	Reading across cell-volts	Reading positive pole to cadmium-volts	Reading, negative pole to cadmium-volts
0	2.10	2.25	+ .15
1	2.17	2.27	+ .10
2	2.19	2.28	+ .09
3	2.21	2.29	+ .08
4	2.23	2.31	+ .08
5	2.24	2.32	+ .08
6	2.25	2.33	+ .08
7	2.30	2.35	+ .05
8	2.48	2.43	− .05
9	2.60	2.50	− .10

(+) in front of the figures means that the reading is on the right or (+) side of "0" of voltmeter.

(−) in front of figures mean the reading is on the left or (−) side of "0" of voltmeter.

Explanation of Readings Given in the Table

Whether the cadmium readings should be added to or subtracted from each other depends entirely on the question whether the negatives give a positive (+) or negative (−) reading.

If they give a positive (+) reading, the cell voltage is the difference between the readings, while if a negative (−) reading is obtained, the cell voltage is the sum of the readings.

With a battery on charge, the negatives will give a negative (−) reading as they approach a state of charge. While the cell is still in a discharged condition, the negatives will give a positive (+) reading, even though the cell is being charged.

If a charged battery is put on discharge, the negatives will give a negative (−) cadmium reading until the cell approaches a discharged condition, and will then give a positive (+) reading.

Note that we have previously stated that when a cell was fully charged the voltage of cell should be 2.5 to 2.6, measured while the cell is on charge.

In the table above, the battery was put on the charging circuit when the voltage of the cell was 2.10 (or 2.1) volts as shown, which practically represents a fully discharged condition, as the voltage was measured while the cell was on charge. If the cell voltage were measured on discharge, it would be about 1.8 volts. Therefore, when the positive plate reading was made, it showed 2.25 volts, and thus positive plates are practically in a discharged condition. The negative plate readings showed + .15, meaning that the needle moved to the right or to the (+) side of zero, which it should do if the negative plate is discharged.

Whenever the needle of the voltmeter moves to the right, or the (+) side of (0), when making a negative plate test, then the plate is not charged; and by subtracting the negative readings from the positive readings, the difference will be that of the cell voltage.

For instance, note the first line of the table: The positive plates read +2.25 volts and the negative +.15 volts. The difference between +2.25 and +.15 =2.10, which is the cell voltage.

Whenever the needle of the voltmeter moves to the left, or (−) side of (0), in making a negative plate test, then we know the negative plate is either near charge, or charged, and by **adding** the negative readings to the positive readings, the sum should be that of the cell voltage.

For instance, refer once again to the table, and note the line where the battery has been on charge for 8 hours. The positive plates read 2.43 and the negative −.05, meaning that the needle of the meter is now reading on the left of (0). Therefore by adding 2.43 and .05=2.48, we have the actual voltage of the cell.

After 9 hours, the positive plates read 2.50 and the negative plates −.10. Therefore, by adding 2.50 and .10=2.60 (or 2.6), we get the true voltage of the cell. The plates and cell are fully charged.

How to Test a Battery on Discharge

The battery should be discharging for this purpose, and to this end it may be connected to a number of lamps which will draw about 5 amperes from it. The test should be made after the battery has been discharged to 1.8 per cell. Then make the cadmium test.

Test the positive plates on discharge in the same manner as before mentioned when testing a battery on charge.

If the positive plates are discharged, they will give a reading of 2.00 to 2.05 volts.

If the hydrometer test shows that the battery is discharged, and the positive plates give a reading greater than 2.05, they are not discharging properly, or else there is an incorrect amount of acid in the electrolyte.

Test the negative plates on discharge in the same manner as before mentioned when testing a battery on charge.

If the negative plates are discharged, they will give a reading of about 0.175 to the plus side, or **right** of the (0) line on the scale.

If the negative gives a reading between (0) and 0.175, but less than 0.175, they are not discharging properly.

The difference between the positive and negative readings gives the total voltage of a cell, when tested on discharge, or when the reading of negative plates is on the **right,** or (+) side of (0) of the voltmeter.

What to Do if Cadmium Tests Show Defective Plates

Usually, when the cadmium tests show that either positive or negative plates are not taking a charge satisfactorily, it is only necessary to continue the charge until the proper readings are obtained.

If the specific gravity of the cell is not from 1.275 to 1.300 when the cadmium tests show that both positives and negatives are fully charged, some of the electrolyte should be removed and replaced by pure distilled water, or by 1.400 specific gravity electrolyte, as the case may require.

If the specific gravity reading is too high, add the distilled water.

If the specific gravity reading is too low, the 1.400 specific gravity electrolyte should be added until the gravity is from 1.275 to 1.300.

Should the specific gravity reading indicate that a cell is fully charged, that is, if the hydrometer tests give readings from 1.275 to 1.300, but the cadmium tests indicate that both sets of plates are not fully charged, continue the charge to see if the proper cadmium readings can be obtained.

If it is impossible to obtain the proper cadmium readings on one or both sets of plates, these plates are defective.

If the operation of the battery on discharge is satisfactory, the only effect of the defective plates will be to cause the battery to lose its charge more quickly than normal, and thus require frequent charging.

If the operation of the battery on discharge is not satisfactory, however, the battery should be opened, and the defective plates repaired, or new plates put in.

Pointers to Remember When Making Cadmium Tests

1. **Remember that current must be passing through the battery** when you make the cadmium tests.
2. **The temperature of the electrolyte** should be about 70° F. when cadmium tests are made, if accurate results are desired.
3. **Do not send out a new battery** unless the hydrometer readings are from 1.275 to 1.300, until the positive-to-cadmium tests give at least 2.40 volts, and the negative-to-cadmium tests give about 0.175 volts.
4. **Do not scrape off the coating of sulphate** which forms on the cadmium.
5. **Do not allow the cadmium to become dry** after you have made tests with it. Keep the cadmium immersed in a glass of pure distilled water, or dilute the electrolyte.
6. **Be sure to get good contact** when you hold the sticker on the battery terminal. Bear down on the handle so that the point of the sticker digs down into the terminal.
7. **If both positive-to-cadmium and negative-to-cadmium readings are very nearly zero,** the cell is short-circuited and must be inspected for excessive sediment, or defective separators.
8. **The end of the cadmium rod must not be allowed to touch the tops of either set of plates,** as this would give worthless readings.

THE HIGH-AMPERAGE DISCHARGE TEST

The high-amperage discharge test is a valuable aid in determining whether batteries or individual cells require repairs or not, particularly in cases where the hydrometer readings give false indications, as for instance, if acid has been added instead of water. The high-amperage discharge test **must be used in conjunction with hydrometer readings.**

When making a high-amperage test, the actual voltage of the cells is not so important as how they **compare** with each other. It may be used to test both **incoming and outgoing batteries,** and the method of using it depends upon whether the battery is coming in or going out. This test also indicates how **battery performs** when the starter is in use.

Advantages of Testing a Battery at a High-Amperage Discharge

This test is useful for determining the following:

1. The condition of the connections: if loose or poorly burned.
2. The condition of the separators.
3. The condition of the positive and negative plates.
4. Prevents charging a defective battery which will not hold its charge.
5. Whether or not there are internal short circuits.

There are various methods employed for making a high-amperage test, some of which are shown on pages 552–554.

In either case, **the test consists of** discharging the battery at a fairly high amperage and taking the voltage reading of each cell while discharging.

A suitable current rate for this test is approximately 28 amperes for the number of positive plates in each cell for the usual types of automobile starting and lighting batteries. For example, take an Exide 3-XC-13 battery, which has 13 plates per cell (7 negative and 6 positive plates). The required amperage discharge would be 6×28=168 amperes, which would be the approximate discharge rate of entire battery.

Hold the current for about 10 or 12 seconds, and then take the individual cell voltage readings.

Test for Battery Coming in for Charging or Repairs

First take a hydrometer reading of each cell.

If the readings are within 25 points of each other, and all are below 1.200 (1.130),[1] most likely all the battery needs is a bench charge (see page 573), with a possible adjustment of the strength of the solution.

If the readings are above 1.200 (1.130)[1], or one cell differs from the others by 25 points or more, make the discharge test, and if the voltage readings are within 0.10 (.1) volt of each other, the battery needs a bench charge with an adjustment of the strength of the solution, or else replacement of a leaky jar.

If the voltage readings differ by 0.10 volt and the battery is pretty well charged, there is something internally wrong with the cell having the low reading, provided it has not been short-circuited in service. It should be opened and examined.

With a discharged battery, the difference in voltage will be greater, depending on the extent of discharge, and only experience can guide the battery man in drawing correct conclusions.

Test for a Battery after Charging and when Ready for Service

Just before putting the battery into service, make the test as a check on the internal condition, particularly if the battery has been repaired or has stood for some time since being charged. (It is assumed that the battery has the strength of solution properly adjusted.) **The battery should not show more than 0.10 volt difference between any two cells,** and no cell should read less than 1.7 volts at a discharge of from 150 to 225 amperes.

If every cell reads below 1.7, it is probable that the battery is not completely charged.

If one cell is more than 0.10 volt lower than the rest, that cell still needs attention.

Trouble Causes as Determined by a High-Amperage Discharge Test

1. **When each cell shows 1.7 volts or more, and the hydrometer test shows 1.200 or more** (at 60° or 70° temperature) then the cell is in proper condition.
2. **When any cell shows less than 1.7 and the hydrometer test is below 1.200,** the cell is either discharged or defective. Charge the battery carefully and test again. If the voltage still drops on any cell and the gravity of that cell came up on charge to 1.275 or 1.300, either the trouble is due to separators whose pores are clogged up, or which have never been properly treated to make them porous, or it is due to the plates themselves being too hard.

When the plates are too hard, they may be softened by charging and discharging the cell five or six times. If this does not improve the capacity so that the cell stands up under test, the cell should be opened and the separators changed.

If, however, the gravity of the cell did not come up on charge to 1.275 or 1.300, and the cell does not stand up to 1.7 volts on testing after charging, the cell should be opened at once, as it is defective internally.

3. **When one or more cells show a voltage of less than 1.7 volts and the hydrometer shows a gravity reading of more than 1.200,** it is due to troubles in the battery or the specific gravity of the electrolyte is too high (too much acid). Recharge the battery and test again, and lower the electrolyte density by using a separate jar for it, if necessary.
4. **When the voltage varies more than a fraction of a volt in each cell,** during a test of a fully charged battery, then the trouble is probably in the interior of the battery. Be sure that all connections are burned well, as the trouble may be in the connector instead of in the battery.
5. **When testing a fully charged battery at this high discharge** for about 10 or 12 seconds, if any of the cell connections heat, it indicates poorly burned connectors.
6. **When testing with a voltmeter,** a battery which is supposed to be fully charged, **if any cell should cause the voltmeter to read in the reverse direction,** it may be due to a fully discharged cell or to internal trouble, such as separators or sediment. Recharge and test again.
7. **When a cell bubbles too freely and froths when being discharged,** it is due to internal troubles. Recharge and test again. If it still froths, open the cell and look for defective plates, or for a short circuit internally, or for badly sulphated plates.

A low-amperage discharge test means that the capacity of the battery is tested at a low rate of discharge, usually 8 or 10 amperes, until discharged from a fully charged condition. The purpose is to determine the capacity of a battery at low rates, as, for instance, for lighting service.

The high-amperage discharge test is usually sufficient and can be given for as long a period as 15 minutes. If a battery is up to capacity at this 15-minute rate, it will practically be sure to give its capacity at a lower rate of discharge.

However, the high-amperage discharge test of a battery does not always mean testing for capacity. It may mean simply finding out how the voltage of the battery stands up at a high-amperage discharge, and this discharge is not carried on until the battery is fully discharged. A battery might have hard plates and give a fairly satisfactory high-discharge test for a minute or two and then fall down, whereas, if it were up to capacity, it would hold this discharge for 5, 10, 15, or 20 minutes according to what the discharge rate was.

---

[1] The reading in parentheses applies to batteries used in tropical climates.

The voltage at which a battery is considered discharged during a discharge test is higher for the low-amperage discharge test than for the high-amperage discharge test, being 1.7 for the low-amperage discharge, and as low as 1 volt on a heavy high-amperage discharge test.

How to Make a High-Amperage Discharge Tester[1]

A very convenient outfit for making high-amperage discharge battery tests on the individual cells without using the resistor referred to in Fig. 5, page 547, is illustrated in Fig. 19. Two spikes are arranged in a handle so that the distance between them will be the distance between the positive and negative terminals of a cell.

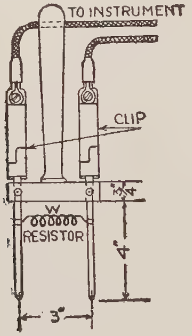

Fig. 19. Construction of a heavy-discharge tester.

Cables are attached to the spikes which are connected to the binding posts of the voltmeter. Between the spikes is connected about 1 foot of ⅛" nichrome wire (W) (Fig. 19) to form the load resistor.

When the spikes are firmly pressed into the cell terminals, the voltmeter will indicate the cell voltage under current flow.

For the convenience of those who desire to purchase such an outfit, instead of making it, A. L. Dyke, Electrical Department, St. Louis, Mo., can supply the Weston model 453 Heavy Discharge Battery Tester, either with or without a voltmeter, mounted on the prod.

Instructions for Using the Weston Model 453 High-Amperage-Discharge Battery Tester

To ascertain the actual condition of a storage battery of the automotive type it is desirable to test the voltage of each cell of the battery while a relatively heavy discharge current is flowing. A comparison is then made of one cell with another.

To use the tester, press the points of the prod into the cell terminals with sufficient force so that the reading of the voltmeter does not increase if further pressure is applied. Test each cell, one at a time, and note the reading obtained on each one. For a battery which is not defective, the readings should be very nearly the same on all of the cells.

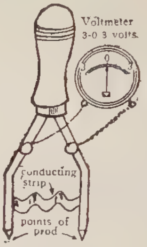

Fig. 20

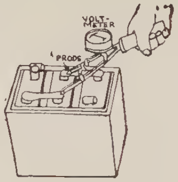

Fig. 21

Fig. 20. Weston heavy-discharge battery tester with voltmeter separate.

Fig. 21. Weston heavy-discharge battery tester with model 301 voltmeter.

When the reading on a cell differs by 0.1 volt or more from the reading on another cell of the battery, the one giving the lower reading should be carefully examined for defects.

If no reading is indicated, then that cell is in bad condition.

If readings are alike at first, and then drop appreciably, the indication is that the cell is short-circuited. If the tests on standard size automotive battery such as is used on starting, lighting and ignition systems show **cell voltages of less than about 1.4 volts,** the battery requires charging.

The resistance of the conducting strip between the legs of the prod is very closely equal to 0.01 ohm. It is designed to carry 200 amperes at a potential of 2 volts. The actual current taken from the cells when making these tests will vary with the capacity and condition of the battery. Its approximate value can be obtained by multiplying the voltmeter reading by 100. For example, if the voltmeter reading is 1.8 the approximate current passing through the conducting strip will be 180 amperes.

The passing of current through the conducting strip will cause the strip to heat, but this in no way affects the operation or reliability of the outfit. It is well, however, to keep the tester across the cell only long enough to procure the desired reading, as prolonged discharging of the battery at the high rate of current flow may harm an otherwise good battery.[1]

The F. B. Battery Tester[2]

The instructions with this tester read as follows: **Press the two tester-points firmly on the two terminals of one cell,** as shown in the illustration, being sure to make a good contact. Test each cell separately in this manner. (See Fig. 22.)

The tester will light either red or green. If red, it indicates that the condition of the battery is too low to operate properly in service, and it must be taken out and filled with distilled water and charged. If the light shows **green,** it indicates that the battery is in a **well-charged condition** and needs no further attention other than probably to be well filled with distilled water.

When the tester-points are touched to the battery terminals, the battery discharges at a 500-ampere rate through the heavy resistance of the tester, and the voltage across the points falls to a certain value, depending upon the condition of the battery.

---

[1] From instructions furnished with the Weston model 45 battery testing voltmeter described on page 546.

[1] Price without meter, $8.50; price with voltmeter, $18.00. Can be obtained of A. L. Dyke, Electrical Department, Granite Building, St. Louis, Mo.

[2] Manufactured by F. B. Electric & Mfg. Co., Detroit, Mich. Can also be secured of A. L. Dyke, Electrical Department, Granite Building, St. Louis, Mo., price $15.00.

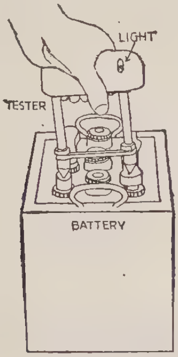

Fig. 22. F. B. Battery tester.

If the battery is in good condition, the voltage will be maintained at a point high enough to force sufficient current through the electromagnetic mechanism of the tester to cause it to operate and light the green lamp.

If the battery is in poor condition, the voltage falls to such a point that it will fail to operate the indicating mechanism, in which case the red lamp will light.

Home-Made Carbon High-Amperage-Discharge Tester

A home-made discharge tester is shown in the illustration (Fig. 23), consisting of an asbestos-lined box 4″ wide by 6″ long. It is sufficiently deep to take a lot of old electric light carbons to a depth of about 12″.

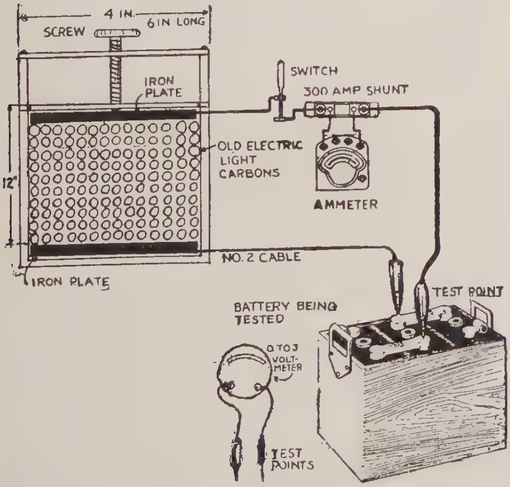

Fig. 23. A home-made carbon heavy-discharge tester.

An iron plate with one connection is placed at the bottom for the carbons to rest on. Another iron plate is placed above, with a screw arrangement for tightening or loosening the pressure of the top iron plate on the carbons.

Note. The resistance can be increased by placing brass plates about ½″ thick between the iron plates and the carbon sticks.

The exact number of carbons to use can be determined by experiment.

When connection is first made, start with no pressure, then gradually increase until the desired amperage discharge is obtained.

With a light pressure, the resistance is greater, hence a lesser discharge.

As the pressure is increased, the resistance is less, because better contact is made; therefore, the discharge rate will be greater.

This outfit will give from 5 to 500 amperes. It is not advisable to pass more than 300 amperes, at the most, through it, as it will get very hot.

Ammeter: A suitable shunt (of not less than 300 amperes) should be used with the ammeter (model 280 Weston shown).

Voltmeter: Can be a separate meter, as the model 301, or the voltmeter connection on the model 280 can be used. The voltmeter is placed **across** the circuit, and the ammeter with shunt in **series** with the circuit.

Test-points can be made as explained on page 464.

Heavy cable, about No. 2, should be used.

Home-Made Resistance High-Amperage Discharge Tester

A method of using iron wire resistance instead of carbons is shown in Fig. 24. The size of the iron wire and the length of the coils are given in the illustration, as: 4 coils of 33 ft., No. 16 iron wire; 3 coils, 71½ ft., No. 8; 6 coils, 57½ ft. No. 8.

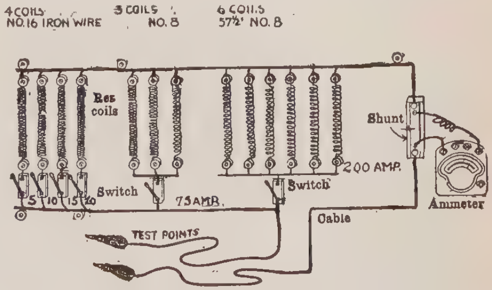

Fig. 24

The model 280 Weston combination volt-ammeter is shown connected in the circuit with a 300-ampere shunt.

The test-points are connected with the battery in a manner similar to that by which the test-points of the carbon principle are connected.

The rate of discharge can be made 5 amperes by closing the first switch to the left; the next switch will add 5 amperes more, making 10 amperes, and so on, until all switches are closed, at which time a 200-ampere discharge will be given.

The coils will get very hot, and should be protected with asbestos.

INSTRUCTION No. 49

A DIGEST OF STORAGE-BATTERY TROUBLES; EXTERNAL AND INTERNAL: Pointers; Care of a Storage Battery

A DIGEST OF BATTERY TROUBLES (EXTERNAL)

Battery troubles can be classified under three headings:

1. Failure of generator to charge battery.
2. Battery will not hold charge.
3. Battery voltage drops immediately after charging.

1. Indications of a generator not charging the battery can be observed on the ammeter, as explained on page 471.

The cause may be attributed to generator troubles, to defective cut-out (points not closing), to open circuits in the line, or to ground or terminal connections of the battery. Often poor connections at battery terminals and grounded wire will result in dim lights and weak current supply. Always clean battery terminals with a file when connecting the battery. Sulphated or **corroded battery terminals** are also a common cause of a battery not getting a full charge.

For **tests**, see pages 482–489.

2. Indications of the battery not holding its charge are: slow cranking of starting motor; dim lights when the battery supplies current; missing of ignition.

Cause (a): The car is not run enough in the daytime without lights, or at high enough speed for the generator to charge the battery and replace the current that is taken from it when the lamps are burning with the engine idle or running at very low speed. Or the car may be run mostly at low speeds.

There is more trouble from discharged batteries in winter than in summer, owing to the fact that engines are usually more difficult to start and the battery is used more. Consequently the generator does not have an opportunity to put back the current taken out—especially if the car is run more at night with the lights on.

The engine crank is more difficult to turn over on cold days after standing a long while, since the oil is heavy and congealed, and unvaporized gasoline is present.

Keeping battery charged: Keep the engine tuned up so that it starts on the second or third turn. This minimizes the amount of current used in starting, and, remember, this is very large. **Be economical with lights.** Use headlights only when absolutely necessary. **Determine the car speed at which the cut-out relay makes connection with the battery,** and operate the car as much as possible above this speed.

If you drive much in a congested city district and stop your engine many times, you will find that your battery can be kept more nearly charged by changing gears in traffic whenever necessary, instead of trying to do it all on high gear. The reason for this is that by changing gears you boost your engine speed so that the battery is charged, while if you try to pull slowly on high you get down to a speed at which charging stops, because of the opening of the cut-out.

Remedy: Have battery recharged from an outside source. Use the starting crank as often as possible. Use the starting motor as little as possible. Use dimmer lights instead of headlights, thus saving on the current consumption. Provide a good "choker" or primer, which will start the engine quickly.

Cause (b): The output of the generator may not be properly adjusted, as for instance, the third brush. Or the third brush, or the main brushes may not be seated properly.

Cause (c): A ground in the car wiring: With the engine idle and all switches "off," disconnect the battery wire and touch it lightly on the battery terminal a few times, as shown in Fig. 5, page 453. If there is a spark produced there is a ground in the wiring between the battery, the cut-out, and the generator.

Remedy: See Index under "Testing for grounds." This may be done as follows: At night, or in a dark garage, turn on all the lamp switches, but remove the bulbs from the sockets and disconnect the battery ground wire at the ground plate. Then strike the bare end or terminal of the ground wire against the ground plate; if sparks are noticed, there is a ground in the wiring, which should be looked for and removed.

Cause (d): Cut-out is not operating properly. Examine the cut-out and see that it is properly connecting and disconnecting the generator circuit (see page 351). The cut-out switch should be in the open position when the engine is not running, or should stay in the closed position when the engine is running above "cut-in speed." If the switch does not close, the windings may be defective, or there may be oil on the brushes or the commutator of the generator, or one of the brushes may be worn too short, or may not be seating properly.

Cause (e): A constantly discharged battery can also be caused by an overload on the starting or lighting system.

Quite often extra large lamps, or additional electrical devices, or a short circuit in the electric horn, will cause undue waste of current. Replace by lamps with a lower candle power and use the least number possible. Spotlights are handy, but consume current. Use the headlights.

Cause (f): A constantly discharged battery, if not caused by lack of sufficient charging current, or open or grounded circuits, is then to be attributed to internal troubles of the battery, such as weak electrolyte, water below the level of the plates, internal short circuits, defective separators, buckled plates, or connectors not properly welded to the battery plate posts. The battery jar may also be leaking.

3. Indications of the battery voltage dropping immediately after charging are generally noticed by the starting motor turning over very slowly and the lights becoming unusually dim. The voltage, even with a good battery, will drop probably to 1.8

volts when about 200 amperes are drawn from it for the starting motor, but if it drops to much less than this, when it is known to have just been fully charged, then the car trouble is probably internal.

Causes: Internal short circuit of one or more cells; grounded starting switch; poor or loose connections at the battery terminals, ground connection or connectors; electrolyte below the level of the plates.

Tests: The battery should be given a "high-rate discharge test."

If trouble should develop, as shown by the engine not cranking properly, lights burning dimly, or "missing" of the engine when the battery is used for ignition, look for the cause as indicated below.

1. Make sure that **all connections are tight** and that all contacts are clean.
2. **Take a hydrometer reading** of each cell. If the battery is found to be exhausted (gravity 1.150 or thereabouts), give a special charge from an outside source. See that the electrolyte is above the level of the plates.
3. **If, after having been fully charged, the battery is soon exhausted again,** there is trouble somewhere else in the system, or the battery is defective internally. In this case a "high-rate discharge test" and a "cadmium test" should be made.
4. **The wiring may have become grounded** to the frame of the car, and cause a leakage of current which in time may completely discharge the battery.
5. **If a broken jar or short-circuited cell** is indicated (gravity considerably lower than in other cells), have the battery repaired.

When lamps burn dimly, turn on all the lamps and read the voltage with a low-reading portable voltmeter of each cell or of the battery (see pages 545, 546, 483, 470).

If the voltage per cell is 2 volts or thereabout, the trouble is in the connections.

If cell voltage is low (1.8 volts or lower), the trouble is in the battery.

When the lamps burn brightly, but the engine will not crank, notice when attempting to start the engine whether the lamps become very dim or go out; if they do, the trouble is in the battery.

If they continue to burn brightly, the trouble is in the motor or motor circuit.

Causes of a Battery Becoming Discharged through Lack of Care and Attention

1. **Frequent starts** with but short runs.
2. **Insufficient input** to the battery on account of short runs at low speed.
3. **Use of headlights** while standing at the curb.
4. **Ignition switch left on** the battery overnight.
5. **Unnecessarily high candle-power lamps,** including spotlight.
6. **Lamps left burning** overnight.
7. **Moving car in garage or elsewhere on the power** from the battery.
8. **Prolonged attempt to start** in cold weather without priming and without warm water in the radiator.
9. **Prolonged attempt to start without investigating engine troubles,** such as:
    - Poorly adjusted carburetor.
    - Dirty or cracked spark plugs.
    - Gummed and sticky valves.
    - Carbon.
10. **Starting and lighting system:**
    - Worn generator brushes.
    - Sticking of points in automatic cut-out.
    - Loose belt (leather).
    - Loose connections.
11. **Loose connections,** generator, motor or battery terminals, fuse box, ground wire, switch or spark plugs.
12. **Grounds,** due to loss of wire insulation through chafing.
13. **Corroded battery terminals.**
14. **Infrequent testing** and water filling of battery.

Battery Box Acid-Soaked

Grounds quite frequently result from old battery boxes which have become thoroughly soaked with acid, as a result of the covers not being sealed properly, split covers, overfilling with water, or boiling when being charged at too high a rate. This acid forms an electrical path between the terminals of the battery, through the damp box to the metal frame on which it rests.

A test can be made by disconnecting the terminals of the battery and connecting a voltmeter between one terminal and the metal frame. If there is any indication at all, examine the battery box and see if it is damp or soaked.

See also, page 484 for testing with a 110-volt test-light.

The remedy would be to place dry wood between the box and metal frame; clean the battery thoroughly and paint it with acid-proof paint.

DIGEST OF STORAGE-BATTERY TROUBLES (INTERNAL)

Sulphation

Indication: Gravity cannot be brought up by charging.

Causes: Overdischarge; standing in discharged condition; raw acid added to replace evaporation; electrolyte level low; short circuits and grounds; local action.

Remedy: Give a long 24-hour charge at a low rate. If this fails, replace the elements; balance the electrolyte in each cell, and charge for a long period.

Local Action

Indication: Gravity will drop rapidly after a charge, owing to internal causes.

Causes: Impurities in electrolyte; active material loose in grids.

Remedy: Disassemble and wash the plates, and put in new separators and electrolyte. Put in new plates if the active material is loose.

Lack of Capacity

Indication: Battery will not hold charge.

Causes: Excessive use of lights or starter; external short circuit; local action; internal short circuit; cracked jar; sulphation; clogged separators; rotted separators; sediment.

Remedy: Use lights and starter less. Dismantle, and clean out the sediment, and put in new plates and separators if necessary, and if the battery does not come up and hold the charge on as long, charge at a slow rate.

Internal Short Circuit

Indication: The gravity of an internally short-circuited cell will always be low, as it is discharged internally, owing to internal causes.

Causes: Rotted separators; sediment; buckled plates.

Remedy: Disassemble and clean; replace the separators and plates if necessary. Plates may be pressed back when buckled, in some cases.

Constant Low Gravity

Indication: When gravity is 1.210, the battery is about half discharged.

Causes: Using starter too much; sulphation; short circuits and grounds; stopped electrolyte—replace with water; cracked jar.

Remedy: If below 1.200, remove and charge from outside source. See "Sulphation"; see "Internal short circuit"; see "External short circuit."

High Gravity

Causes: Evaporation replaced with electrolyte or acid; wrong gravity of electrolyte used.

Remedy: Balance the electrolyte in each cell.

Low-Voltage Reading When on Discharge

Causes: Battery discharged. Do not permit the voltage to fall below 1.8 on discharge; internal resistance high; low-gravity electrolyte; dead cell.

Remedy: Recharge. See "Sulphation"; see "Low gravity."

Buckling of Plates

Causes: Sulphation; overheating.

Remedy: See "Sulphation."

Terminals Corroded

Cause: Slopping.

Remedy: Use ammonia wash, or soda.

Separators in Wrong

Cause: Flat side of separators in contact with positive plate or inserted with grooves horizontal.

Remedy: Insert properly. If the plates are damaged, replace them.

Separators Rotted

Causes: Overheating: gravity too high; buckling.

Remedy: See "Overheating"; see "High gravity"; see "Buckling."

Separators Clogged

Cause: Impurities in pores of separators.

Remedy: New separators. Wash battery out.

External Short Circuits

Causes: Circuit grounded or shorted; battery terminals shorted; battery box acid-soaked.

Remedy: Trace circuit.

Lights Dim, Weak Starter

Causes: Discharged battery; loose connections; dead cell or cells.

Remedy: Test and charge battery. Tighten connections after cleaning. Test with hydrometer and cadmium voltmeter.

Electrolyte Level Low

Causes: Evaporation; slopping; broken jar.

Remedy: Replace evaporation with distilled water. See that the battery is properly sealed. Replace the jar.

Negative Plates Harden

Never allow negative plates to dry unless all acid has first been removed.

Cause: Plates exposed to air.

Remedy: New plates required if repeated charge or discharge fails.

Active Material on Plates Soft

Cause: Overcharge.

Remedy: Press back, but better put in new plates.

Battery Frozen

Causes: Battery discharged; water added without charging.

Remedy: New plates.

Broken Jar

Causes: Vibration; battery dropped or set down hard.

Remedy: New jar.

Active Material Shedding

Causes: Overdischarge; overcharge; buckling; short circuits and grounds; overheating.

Remedy: See these headings.

Overdischarge

Indications: Gravity less than 1.150 and voltage less than 1.8 on discharge.

Causes: Faults in electric system; improper operation of system.

Remedy: Use caution in using starter, lights, etc. See if the generator is properly charging the battery.

Overcharge

Indications: Buckled plates; shedding of active material; overheating. Gravity will be about 1.275.

Causes: Car used mostly during the day and on long runs; generator regulator out of adjustment or third brush adjusted for too high a charge.

Remedy: Burn lights part of the time. Test output.

Internal Resistance High

This will result in overheating and loss of capacity.

Causes: Sulphation; clogged or reversed separators; low gravity.

Remedy: See these headings.

Overheating

Causes: Charging rate too high; discharge rate too high; high internal resistance; short circuits and grounds; dead cell; excessive temperature of atmosphere, and high charging rate.

Remedy: See "Sulphation"; "Separators"; see other headings in this Digest. Use the battery sparingly on warm days and also on extremely cold days.

LOCATING BATTERY TROUBLES WITH A HYDROMETER

Low gravity in all cells: If the starter occasionally fails to spin the engine, and if the battery lacks energy, it may be that on testing with a hydrometer and finding the "gravity" low, say below 1.225, all that the battery requires is an extra charge. The battery may have been previously discharged to so low a state that the normal generator output has not been sufficient to restore it.

If failure, due to low gravity, recurs after this extra charge, then the generator is failing to put enough current into the battery. Or it may be that a short circuit in the wiring is causing the battery energy to be wasted. It may be that the battery box is acid-soaked.

Low gravity in one cell: If it is found that the gravity is low in any cell, say 50 points lower than in the others, then make hydrometer tests of the cells oftener to determine whether the difference in gravities of the cells is increasing.

If the trouble increases, the cause undoubtedly is that a short circuit is just beginning. Some one of the following conditions may be the cause: separators wearing through, or sediment accumulating in the bottom of the jar until it touches the plates, or a piece of metal has fallen into the cell and has bridged across the plates. Water containing certain minerals may have been put into the cell, preventing the cell from holding its charge.

The remedy is to remove the element and remedy the cause. New separators should in almost every instance be installed in all cells.

It is advisable to make a "high-rate discharg test" or a "cadmium test" before disassembling a battery.

A broken jar is sometimes the cause of constant low "gravity" in a cell. A broken jar can be detected from the fact that you will have to add water more frequently to its cell than to the others, to keep the plates covered. The leak may be between the jar walls and the sealing compound. The addition of water to replace the electrolyte lost from such a cell will naturally reduce that cell's "gravity."

Sulphation and low gravity: Suppose the gravity of a cell is persistently low and water is added often. As a result, the tops of that cell's plates may have been left exposed to the air for a period of time, and so the plate tops may have become sulphated, and the disease has proceeded downward so as to affect the plates throughout. If this evil had progressed far enough, the cell would not respond to charging, and the "gravity" would not rise. The cell would become unduly hot during charge, and would hasten the evaporation of water.

1.150 or lower: With "gravity" as low as this, the battery cannot be depended upon, even to operate the lights.

Gravity too low to read: Hydrometer readings usually run as low as 1.150. Batteries may be found with gravities too low to be measured with the ordinary hydrometer, so that you cannot fully diagnose the battery with this instrument alone. These are extreme cases, however. Possibly all they require is a thorough charge, but the special conditions of the necessary charge must be observed. Should there be sulphation—and there is likely to be if the battery has stood long in a state of low "gravity"—the rate of charge secured in the automobile would undoubtedly overheat and buckle the plates, and so injure both plates and separators.

Constantly high "gravity": While 1.285 is usually indicated as the proper top mark for full charge, a reading of 1.300 of itself need cause no alarm.

However, if a few hydrometer tests show that the battery is being charged regularly, but that for considerable periods after charging the "gravity" reaches 1.285, it is then necessary to reduce the charging rate, for the battery is getting more than enough, and this is daily shortening its normal life.

Excessive gravity: Gravity above 1.300 is certainly abnormal and indicates that the battery has been **"doped"** by the addition of excessive acid. Prompt reduction of the acid proportion is needed to save the battery's life.

STORAGE-BATTERY POINTERS

1. **Learn to prepare the electrolyte.** Use a large earthen crock or lead vessel with burnt seams. One part of chemically pure concentrated sulphuric acid is mixed with several parts of water, proportion of water varying with type of cell.
2. **Prepared electrolyte** may be bought if desired.
3. **Always pour acid into water,** never reverse.
4. **Use pure water,** either distilled or rain water.[1]
5. **Allow the electrolyte to cool** before placing in the cells. The specific gravity should be 1.200 or 25° Baume. Add distilled water if a higher reading is obtained.
6. **Grids should always be at least ½" below the** surface of the solution.
7. **Clothing** is greatly affected by acid.
8. **Ammonia** immediately applied to a splash of acid on the clothes, neutralizes the acid and prevents a hole being burned in the material.
9. **In case a drop of acid splashes into the eye,** wash well with warm water and put into the eye a drop of olive oil.

---

[1] **Distilled water:** Artificial ice is not always made of distilled water. Rain water can be used if it does not come from a metal roof or where mineral substances will get into it. Distilled water can usually be obtained at drug stores or battery supply houses. Filtered water will not do. See also page 584.

10. **Avoid the use of an open flame** in a room where a storage battery is being charged, or in which it has been left for some time, as an explosive mixture of air and hydrogen may be formed.

11. **Storage batteries are rated in ampere-hours,** this being based on the steady current the battery will discharge. A battery that will discharge at 5 amperes for 8 hours without the voltage falling below 1.75 is rated as a 40-ampere-hour battery. This does not mean that 40 amperes would be the output of the battery if discharged in one hour. The ampere-hour capacity decreases with the increase in current output.

12. **The current in charging** should be kept within the maker's specified limit. One authority advises for rapid charging, covering a period of three hours, 50 per cent, 33 per cent and 16 2/3 per cent of the total current for each consecutive hour.

13. **The e.m.f. of the charging current at starting the charge** should be about 5 per cent higher than the normal e.m.f. of the battery. After a few minutes, this voltage may be 10 or 15 per cent higher than the normal battery e.m.f. However, the battery is kept in the best condition by using a constant charging current, and, if necessary to maintain this, the voltage may be raised to 25 per cent higher than the normal battery voltage.

14. **Be sure that the positive pole of the charging mains** is connected to the positive side of the battery.

15. **To determine the polarity,** hold the two wires in a glass of acidulated water or electrolyte, keeping them at least ½″ apart. Gas will collect most at the negative lead.

16. **A cell is fully charged:** (a) if, with a constant current, the voltage and specific gravity do not change in one hour; (b) when the plates decidedly increase the quantity of gas given off; (c) when the specific gravity measures 1.275, and the voltage from 2.5 to 2.7; (d) when the negative plate assumes a light-gray color and the positive plate turns a dark brown.

17. **Never adopt the method of putting a wire across the positive and negative terminals,** to see if there is any "spark." It is almost a dead short circuit, and if the cell be of a small capacity of, say, 30-ampere-hour, and the wire No. 16 copper, the current may be anything from 30 to 100 amperes for a fraction of time, which, when calculated, is a very appreciable amount of the total capacity, if only for a second of time. It is also very detrimental to the cell, assisting the disintegration of the plates or active material thereon.

18. **Lead cells** for starting and lighting purposes should not be discharged below 1.8 volts.

19. **Excessive boiling** will loosen the active material.

20. **If the cells are hot while charging,** reduce the charging current.

21. **If a battery is not in use,** give it a short charge once a month.

22. **If white sulphate is formed on the grids,** it may be reduced by charging at a high rate for a few hours and overcharging at a low rate for two or three days.

23. **Continued sulphating** will buckle the plates, as will also too rapid discharging.

24. **A cell that has been short-circuited** should be disconnected from the battery and charged and discharged several times separately.

25. **Manufacturers furnish directions for keeping batteries when not in use.** One way to do this is to charge the battery fully, then siphon the electrolyte out of the jars, to be kept until used again. The plates must then be removed and stored. See "Storing batteries."

26. **Never allow the cells to stand in a discharged condition,** as it becomes very difficult to get them properly charged if they are left standing any length of time, unless great care is taken during the succeeding charge.

27. **If the terminals begin to corrode,** use vaseline.

28. **Voltage readings** should be taken only when charging or discharging.

29. **Do not let the battery get too warm;** its temperature should never exceed 100° F.

30. **Use only distilled water to replace losses from evaporation.** Add acid only in special cases.

31. **Each time you charge,** bring the gravity up to maximum, or charge until it has remained constant, for at least one hour in every cell.

32. **When charging the battery,** put in at least 20 per cent more current (ampere-hours) than is taken out, and at every third charge give it a 50 per cent over-charge, at the finish rate for the general good of the battery.

33. **Voltage readings are only approximate.** Gravity readings give correct indications.

34. **Keep the box containing the battery perfectly dry.** If any acid is spilled into the box, wipe it off carefully with a piece of waste dipped in ammonia water.

35. **When charging at the finish rate,** or 24-hour rate, leave the battery on until bubbles begin to rise in the electrolyte, and then for at least one hour longer.

36. **Never add acid or electrolyte to the cells** except to replace loss from spilling.

37. **In cases where the specific gravity will not show** any rise during or at the end of its charge, it indicates a short circuit, and the cell has not received its charge.

38. **In cases where the specific gravity comes up to 1.250 at the end of its charge, but falls to a** lower figure during a period of idleness or standing for say twenty-four to forty-eight hours, this also indicates a short circuit, or else local action (or internal discharge), due to contamination of the electrolyte.

Don'ts and Do's—Read Carefully

Always disconnect the wire from the generator terminal before disconnecting the battery, and reconnect the battery before reconnecting the terminal. Otherwise the lamps may all be burned out if the engine should be started.

Don't use a piece of wire instead of a fuse.

Don't short-circuit your battery with a pair of pliers or a screwdriver, to see if it is charged.

Don't advance the spark, but retard when you start with a starting motor, with the throttle partially open.

Don't use emery paper on your commutator; use fine sandpaper.

Don't forget to see that your ignition switch, spark lever, and gas lever are all in their proper positions, before depressing foot switch to start engine.

Don't fail to push down the button of the foot switch to its limit.

Don't continue to crank your engine, if ignition does not take place after a few revolutions. There is something wrong with your ignition system, or the carburetor. Look for the trouble. Just turning over the engine will not help matters, but it will exhaust your battery, if continued for any length of time.

Don't allow connections on generator, battery, or motor to become loose.

Don't blame the generator for every trouble you may have. As a matter of fact, 90 per cent of all troubles originate in switches or wiring connections, or at the lamps, which are necessarily small and more or less liable to imperfect contact or short circuit.

Don't forget that it requires twenty times as long to restore current to the battery as it takes to start the car. In winter, it is sometimes advisable to use the starting crank to save the battery current.

Don't put oil or grease on the commutator of the generator or motor.

Don't tighten up on the silent chain drive unless the slack becomes excessive from stretching. The chain must be run with a reasonable amount of slack to prevent noise and wear.

Don't fail to lubricate the silent chain drive at frequent intervals. Noise will be eliminated and wear reduced. Keep the chain and sprockets clean, and free from dirt.

Don't run your car, if for any reason the battery is disconnected from the circuit, unless you have disconnected the chain driving the generator, or the generator itself has been removed, or the field-circuit is opened. See also page 366.

Dont' forget to examine your battery at intervals of about two weeks, and make certain that the electrolyte covers the top of the plates in each cell.

Don't allow your battery to become loose in its box or container. Strap or wedge it tightly in position, and make certain that the terminals cannot come into contact with anything which may cause a short circuit.

CARE OF A BATTERY IN SERVICE

The care of a battery in service, or where there is a generator on the car to recharge it, is summed up in the four following rules, which, if observed with reasonable care, will result in the best service being obtained:

1. **Add nothing but pure water to the cells,** and do it often enough to keep the plates covered.
2. **Take frequent hydrometer readings.**
3. **Give the battery a special charge whenever the hydrometer readings show it to be necessary.**
4. **Keep the filling plugs and connections tight, and the battery clean.**

Adding Water

Water must be added often enough to keep the plates covered. If the plates are exposed for any length of time, they may be seriously damaged.

The length of time a battery can go without the addition of water will depend upon the season of the year, water being required more frequently in summer than in winter.

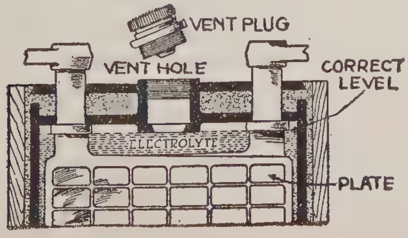

Fig. 1. Section of cell, showing correct level of electrolyte.

The best plan is to make it an invariable rule to remove the filling plugs once each week and to add water if the level of the electrolyte is below the bottom of the filling tube.

Never bring an open flame, such as a match or candle, **near the battery.**

Always add the water regularly, though the battery may seem to work all right without it.

In freezing weather, when necessary to add water, always do it just before running the engine.

If temperature is extremely low, start the engine so that the **battery is charging before adding water.**

The reason for this is that water, being lighter than electrolyte, **will remain on the surface and will freeze** in cold weather. If the engine is run, however, the gassing, owing to the charging current, will thoroughly mix the water with the electrolyte; also the motion of the car when running will have a similar effect. Thoroughly mixed electrolyte will not freeze solid, except at very low temperatures. See page 531.

The reason why the solution (electrolyte) falls below the top of the plates is that when the battery is being charged it gasses or bubbles. This action changes some of the water into gas, which escapes, or evaporates. Thus the water evaporates when the battery is in service, and the acid does not. Therefore it will be necessary to replace the water—but don't add too little, and don't add too much. Many a case of apparent leak has been blamed to an over-indulgence of water.

Replace evaporation, but do not add enough water to any cell to raise the electrolyte above the indicated level.

Electrolyte Level

Note that for each battery there is a well-defined level, up to, or nearly to, which you should endeavor to keep the surface of your electrolyte, but above which you must never raise the level of the solution when you add water to your battery.

In the U. S. L. type EDC battery, for example, the level is 1 inch above the plate tops. In the type

EL the level is ⅝ of an inch. In many other types of U. S. L. batteries the electrolyte level is ½ inch above the plates.

Not only should the electrolyte level be at the same height in all cells, but **there should be the same amount of acid in the electrolyte in each cell.** Therefore always restore the electrolyte from the syringe, when testing, to the cell from which it was taken.

Before water is added to the cells, take a hydrometer reading of each cell to see whether all cells are equally healthy. No cell can live unto itself—if it goes wrong, it affects the others.

How to add water: Remove the filling plugs by turning to the left, and if the level of the electrolyte is found to be below the bottom of the filling tube, add water by means of the hydrometer syringe (Fig. 2) or a very small pitcher, until the level begins to rise in the tube.

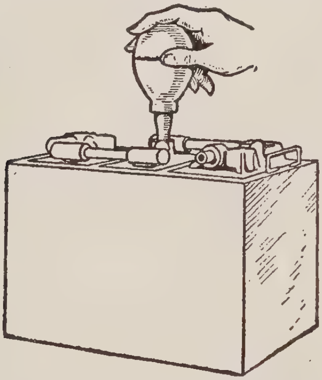

Fig. 2. Adding water to a storage-battery cell.

After adding water, be sure to replace the filling plugs and tighten by turning to the right. **If the filling plugs are not tightened, the electrolyte will flood out of the battery and cause damage.** Also wipe off the top of the battery.

Kind of Water

The water used must be of reasonable purity, as the use of impure water, if persisted in, will injure the plates. **Distilled water,** melted artificial ice, or rain water collected in clean receptacles is recommended.

Water collected in rain barrels from **metal roofs** would contain a trace of the mineral—therefore avoid it.

Nothing but pure water must be put into the cells. If acid of any kind, alcohol, or in fact anything but water, is added to the cells, it will result in very serious injury to the plates and may ruin them.

There being no loss of acid, **it is never necessary, during normal service, to add any acid to a battery.**

If electrolyte has been spilled from the battery by accident, the loss may be replaced with electrolyte. See pages 585, 530.

Finding Level of Electrolyte

A method recommended by the U. S. L. Battery Co., is shown in Fig. 3.

Unscrew the vent from its well, push a glass tube (Fig. 3) with both ends open, straight down, as shown, through the well and against the tops of the plates. Then close the top end of the tube with your thumb and remove the tube with the top end still closed. The height of liquid in the tube equals the height of the electrolyte level above the tops of the plates. Be sure to restore the electrolyte to the cell from which it was taken. If you persistently take electrolyte from one cell and put it into another, you will gradually get your cells unbalanced. Be sure to test the levels in all cells.

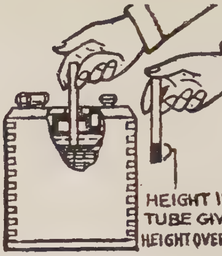

Fig. 3. Testing the level of electrolyte in a cell.

Miscellaneous

Take frequent hydrometer readings, for they show whether the battery is receiving sufficient charge.

Care of battery case: If water or electrolyte is spilled upon the battery or in the compartment, wipe dry with waste. If electrolyte is present in any quantity, use waste moistened with weak ammonia in order to neutralize the acid in the electrolyte. Do not allow electrolyte to collect upon the woodwork, as it will cause deterioration.

Once a week, when adding water, inspect all the battery connections and make sure that they are tight and clean. **A loose or dirty connection** may cause trouble when least expected.

Care of connections: If signs of corrosion of any brass or copper parts should appear, clean the parts thoroughly with weak ammonia and apply vaseline. Don't fail to examine the ground connection of the battery (see page 428) for the result of an open circuit.

Connections throughout the system must be examined periodically and kept tight and clean. Sometimes a connection, even if tight, will give trouble, due to foreign matter such as paint or varnish on the contact surfaces. This must be removed with a file or sandpaper. The connections to the generator and the grounding connections to the frame of the car must not be neglected.

Locating Battery Trouble in Service

1. **Take a hydrometer reading in each filling tube** of each cell (see page 531 on how to use a hydrometer). If all readings are within 50 points of each other and all below 1.200 (1.130)[1], give the battery a bench charge, following the instructions on page 573. Locate the cause of trouble and remove it.

If the readings are all above 1.200 (1.130)[1], or if one cell differs from the others by 50 points or more, make the high-rate discharge test.

If the solution is too strong, it indicates that acid or electrolyte has been added to the cell.

If it is too weak, the cause is sloppage of the battery solution and replacement with water, or else a broken, cracked, or leaky jar, or internal trouble.

2. **Just before replacing the battery in service,** make the high-amperage discharge test, **to be sure** the battery is in good condition.

---

[1] Applies to tropical climates.

3. **Hydrometer readings less than 1.225** (1.155),[1] but more than 1.150 (1.080)[1], indicate a battery less than half charged. If the car is equipped with an electric starting motor, use lamps and starter sparingly until readings become more than 1.250 (1.180)[1].

Readings less than 1.150 (1.080)[1] indicate complete discharge. In such a case the battery should be removed and given a bench charge.

If readings in one cell differ from the others by 50 points or more, it indicates loss of electrolyte, wrongful addition of electrolyte, or internal trouble in the battery.

If the car is laid up, put the battery into proper storage.

4. **Go over all connections.** A loose or dirty connection is often the cause of trouble. If the connections between battery and cable terminals are not kept well coated with vaseline, they may corrode, causing a poor connection, or else opening the circuit altogether. If the connector is causing the trouble, remove it and clean the parts thoroughly with weak ammonia. Then remove all dirt, apply vaseline, tighten the connections perfectly, and give the whole connection a heavy coating of vaseline.

5. **There may be a leak or ground in the wiring.** Test for this by turning on all lamp switches and then removing the bulbs from the sockets. Disconnect one of the cables at the battery, and in its place tightly hold a file against the battery post, making sure there is good electrical contact between the file and post. Then rub the cable terminal along the file; if sparks are noticed, there is a ground in the wiring, which must be looked for and removed.

6. **If the engine will not crank,** turn on the lights and attempt to start in the usual manner. If lights become dim, the battery is in poor condition and should be given a bench charge and the cause of trouble should be investigated and removed. If lights continue to burn brightly, the trouble is elsewhere than in the battery.

7. **If the generator of the starting system is not in proper adjustment,** the battery will not be kept supplied with the proper amount of current. If the supply is insufficient, the battery will become discharged; if it is too much, the battery solution will become hot (110° F.). The generator should be readjusted to deliver more or less current, as the case may require. On all cars, the generator is originally adjusted to supply an amount of current which experience has shown to be the most satisfactory for average running conditions. If the car is run only at nights, more current is naturally required because the lights use a large part of the current which would otherwise go to the battery. If long daylight runs are the rule, the opposite is true, because then almost all the current goes into the battery.

When a Battery Needs Recharging

On systems where a storage battery is kept charged by a generator run from the engine, the system is supposed to be automatic, but for various reasons the generator may not keep the battery charged, or the battery itself may be defective and so will not hold a charge for any length of time. The indications would be a **weak starting motor, or dim lights.** The battery, however, in this case ought not to be allowed to become weak.

There are several causes for a battery becoming discharged: in fact, so many that it is advisable to refer to the "Digest of Battery Troubles" (page 556).

The usual and common causes are failure of the battery to receive sufficient current from the generator, or permitting the level of the electrolyte to fall below the level of the plates (see "1. Examine battery," page 478).

When the battery is used in connection with a charging generator system, the system is so designed and adjusted that the amount of charging current received by the battery from the charging generator (dynamo) should about compensate for the discharge current used when starting the engine, or when lighting the lamps from the battery. At medium or high speeds, the current for lamps does not come from the battery, but from the dynamo.

It sometimes happens, owing to conditions, such as excessive use of lamps, especially when the car is driven at low speed, or when the car is driven mostly at night, with all the lights on, that the current is taken up by the lights and the **battery receives but a small portion of the current from the generator,** or that when the weather is cold, the starting motor is used more than usual.

In cases of this kind, the **output of the generator should be increased,** if not already up to its capacity, and the least amount of current possible should be used.

It is advisable to see that a **primer is used in order that the engine may start easily.** Be sure that the battery is kept charged, even though it be necessary to have it charged at an outside source occasionally, as a full voltage of the battery is also required for good ignition, which is also necessary in starting an engine. By this means, too, **current is saved.**

To tell when a battery needs recharging, there are two methods: (1) Test the battery with a voltmeter when it is discharging, as when all lights are on. Test each individual cell, and if any is as low as 1.8 volts during discharge, the battery needs recharging. (2) Test with a hydrometer, as directed on page 531. This latter test is the one used most.

See page 545 under **"The first step is to test the entire lot of cells."** See also, "Digest of Storage-battery Troubles," page 556, and also page 478.

---

[1] Applies to tropical climates.

INSTRUCTION No. 50

STORAGE-BATTERY CHARGING EQUIPMENT

STORAGE-BATTERY CHARGING EQUIPMENT

Kind of current: For charging a battery only **direct current** can be used.

Connections: Connect the positive (+) wire of the charging circuit with the positive (+) terminal of the battery and the negative (−) terminal of the battery with the negative (−) wire of the charging circuit.

Storage batteries are usually connected in series when being charged. This subject will be dealt with farther on.

Finding polarity: To determine which is the positive and which is the negative terminal of a charging circuit, the best plan is to use a voltmeter and place it across the line. If the meter needle moves to the right, the wire connected to the (+) terminal of the voltmeter, which is usually marked, will indicate the (+) or positive wire. The same test can be made on storage-battery terminals. If the charging circuit is 110 volts, the voltmeter should have a corresponding capacity. If a voltmeter is not at hand, there are several simple methods which can be resorted to, as shown in the illustrations below.

Storage-battery terminals are usually marked "+" and "−" or "Pos." and "Neg." The storage battery positive (+) terminals can also usually be determined by their dark color whereas the negative (−) is of a light color.

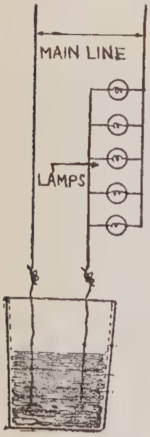

Fig. 1

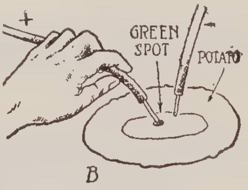

Fig. 2

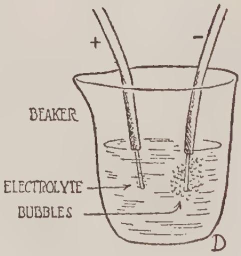

Fig. 1A

Fig. 1. To find the **polarity of charging wires,** or of any direct current source, dip the ends of the wires into a glass of water in which a teaspoonful of salt has been dissolved, care being taken to keep the wires at least one inch apart. When current is on, fine gas bubbles will be given off from the **negative** wire.

Another method is to use a beaker (see **(D)** (Fig. **1A)**, in which a small amount of electrolyte is added to water. The negative pole will have the most gas bubbles around it.

Fig. 2. A potato can be used as shown in the illustration.

The charging wires from a rectifier, if connected wrongly (use a regular dash-type ammeter), will show 30 amperes. If connected correctly, they will show about 6 amperes.

Charging Methods

As already stated, only direct current can be used to charge storage batteries. There are **several methods** of doing this, which are classified as follows:

1. From a 110, a 220, or a 500-volt **direct current** power and lighting line.
2. From an **alternating** current power and lighting line, by the use of a **motor-generator.**
3. From an **alternating** current power and lighting line, by means of a **rectifier.**

Charging Resistance

Charging resistance is a suitable apparatus inserted in series with the charging circuit. By varying the resistance, the current can be regulated.

Resistance may consist of **lamps** or of **resistance** wire.

An Explanation of Resistance

Resistance can be in the form of a bank of lamps (Fig. 6), of resistance wire (Figs. 3 and 4), of water (Fig. 5), of carbon and other resistance metals. Lamps or resistance wire is generally used, the latter being termed a "rheostat."

Principle of a Rheostat

By way of illustration, we will use a wire resistance unit (Fig. 3). German silver, nichrome, iron wire (some others also), offer resistance to the flow of electric current. The **smaller the wire,** for the same amount of current, the **greater the resistance.**

If, for example, a coil of iron wire of 1/32″ diameter and of sufficient length is wrapped around an insulated cylinder, such as porcelain or stone and connected to a 110-volt circuit, by connecting one wire, say, from the (+) side of the 110-volt circuit to **(X,** Fig. 3), the current would then flow down the rod **(T)** to the sliding contact **(C).**

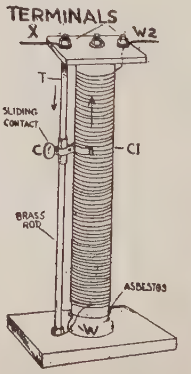

Fig. 3. Principle of a rheostat or resistance unit

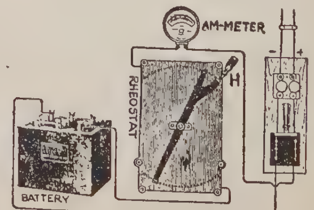

Fig. 4. A rheostat of standard construction

If one terminal of the battery is then connected with (W2), which is one end of the wire coil (C1), and the other battery terminal is connected with the other, or (—) side of the 110-volt circuit, this would form a circuit, and the amount of resistance wire in the circuit would depend upon the position of the sliding contact (C).

By moving the sliding contact (C) down, **more** resistance is thrown into the circuit; by moving it up, **less** resistance will be in the circuit. This is the principle of a rheostat, and is similar to that of "resistance units," as used for charging batteries, which will be discussed farther on. In some instances an ordinary stove pipe, covered with asbestos and wrapped with iron wire has been used.

A rheostat of a more modern construction is shown in Fig. 4. The principle is similar to that shown in Fig. 3, except that the construction is different. It consists of wire resistance mounted on the back of a slate base. The resistance can be iron wire, German silver, nichrome, or any other kind of resistance wire.

The amount of resistance which can be cut into or out of the circuit is regulated by movement of the handle (H), and it serves the same purpose as the sliding contact (C) in Fig. 3.

A rheostat might be termed a device for absorbing some of the electrical pressure.

For example, suppose you desired to charge a 6-volt storage battery from a 110-volt circuit. It would be necessary to absorb approximately 104 volts in some sort of resistance or rheostat.

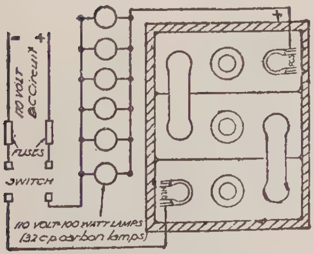

Fig. 6. A lamp bank resistance

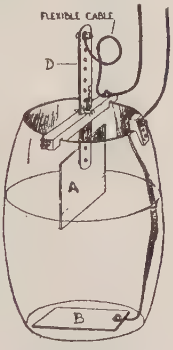

Fig. 5. A water rheostat

Principle of a Water Rheostat

A simplified illustration (Fig. 5) gives the principle of a water rheostat. A 5-gal. stone jar is partially filled with salt water (or acidulated water), with one metal contact (B) in the bottom, and the other (A), which is a sheet, immersed more or less in the barrel. The movement of (D) regulates the resistance, i.e., the nearer the plates are together the **less** the resistance; the farther apart they are the **greater** the resistance.

The construction and action of an acidulated water rheostat is as follows: Let us suppose that current is to be taken from a 500-volt direct current, to pass 3 to 9 amperes; use a 5-gallon stone jar and mix 1 part sulphuric acid with 3 gallons of water. Use two plates of lead or soft metal as electrodes, the main requisite being that they have sufficient area to keep the heating effect down as low as possible. Current applied at one terminal leaves the plate and passes through the water to the other plate. One of these is made stationary and the other movable, and the resistance is regulated by changing their relative distance apart. The farther they are apart, the greater the resistance. During the action of the rheostat, the water is decomposed into its natural elements, oxygen and hydrogen, and the loss must be made up occasionally by the addition of more water.

The prime object of a rheostat is to cut down the voltage.

Charging a Battery from a 110-Volt Direct-Current Circuit Using Lamp Resistance

The amount of resistance to use depends upon conditions as will be explained.

If only one battery is to be charged from a direct-current circuit, the most convenient resistance is a combination of lamps of proper size and rating. An arrangement for charging from a 110-volt circuit is shown in Fig. 7.

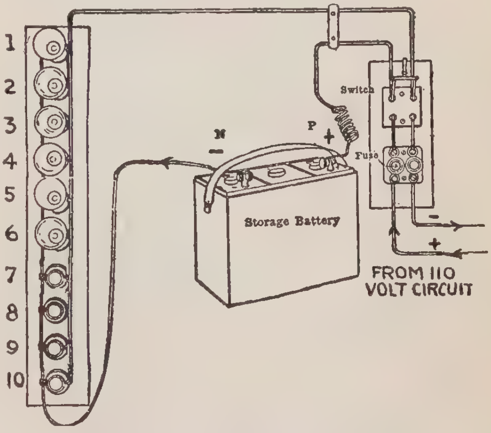

Fig. 7. Diagram of connections for charging one 6-volt battery from a 110-volt direct-current line. Note that the bank of lamps is arranged so that any number of lamps from 1 to 10 can be screwed into or taken out of the sockets. 110-volt, 100-watt, 32-c.p. lamps which draw 1 ampere each are used above. Remove the filler plugs to permit frequent hydrometer readings during charging and also for gases to escape.

The lamps used are carbon filament lamps rated at 110 volts and of 32 candle power. As shown, they are arranged parallel with each other and the combination is in **series** with the battery.

The amount of current or amperes passing to the battery will be determined by the number of lamps used, the watt capacity of the lamps, and the method of connection.

A 32 c. p. 110-volt, carbon filament lamp will pass approximately 1 ampere and is a 100-watt lamp. Watts are found by multiplying the voltage of the circuit (100 volts used instead of 110, which is near enough in this instance) by the ampere capacity, as 100 volts × 1 amp. = 100 watts.

A 16 c. p. 110-volt carbon filament lamp will pass ½ ampere and is a 50-watt lamp.

With the arrangement shown in Fig. 7, **each lamp will allow 1 ampere** of charging current to pass through the battery, so that the number of lamps will depend upon the charge rate of the battery.

Fig. 7 shows six lamps screwed into sockets, which will, therefore, allow **6 amperes** to flow (suitable for a Type XC-13 Exide battery, as shown in the "bench charge" table, page 573).

If 32 c.p. lamps are not available, then use 16 c.p. carbon filament lamps. When using the 16 c.p. lamps it will be necessary to **double** the number, because a 16 c.p. lamp, being a 50-watt lamp, draws but a ½ ampere at 110 volts.

If tungsten or other high-efficiency lamps are used, more will be required than if carbon filament lamps are used, because they draw less current.

Charging a Battery from a 220-Volt Direct-Current Circuit

If a battery is to be charged from a 220-volt circuit, it will be necessary to place two 32 c.p., 110-volt lamps in series, as shown in Fig. 8, because, as the voltage increases, the amperage decreases. Therefore if two 32 c.p., 110-volt lamps are placed in series, the two lamps would draw 1 ampere.

If there are four of these series groups connected in parallel, as shown in Fig. 8, then there would be 4 amperes passing to the battery; if five groups, 5 amperes; if six groups, 6 amperes, and so on.

If two 16 c.p., 110-volt lamps are placed in series, instead of two 32 c.p. lamps, then the two in series on a 220-volt circuit would draw a ½ ampere. Therefore, in order to draw 4 amperes to the battery, it would require eight groups connected in parallel.

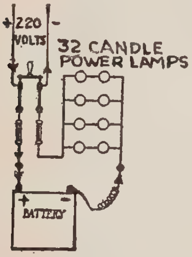

Fig. 8.

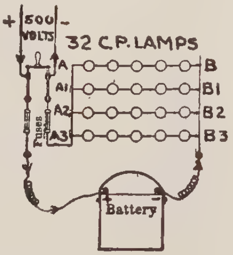

Fig. 9.

Charging a Battery from a 500-Volt Direct-Current Circuit

To charge a battery from a 500-volt direct-current circuit, use 32 c.p., 100-volt lamps. In order not to burn out the lamps, place five in series, as (A) to (B) (Fig. 9).

The five lamps, however, owing to the series connections, will allow but one ampere to pass. In order to pass **two amperes,** another group of five are placed in a parallel or multiple connection as at (A1) to (B1). For **three amperes,** another row from (A2) to (B2) would be necessary; for four amperes, another row (A3) to (B3). If **five amperes** were desired, **five more lamps,** connected as in Fig. 9, would have to be used.

Lighting a Garage with the Charging Current

A current economy in charging storage batteries can be effected by utilizing the current that is ordinarily consumed by the lamp resistance shown in Figs. 7, 8, and 9, while lighting the garage at the same time. The banks of lamps can be placed separate from where the charging is being done, if the correct size of wire is used.

Use of the Ammeter and Voltmeter when Charging

The ammeter can be connected in series with the charging circuit and will indicate the amperes flowing to the battery.

The voltmeter must not be placed in series. It is generally used to test the voltage of the battery during charge or discharge, by placing its terminals across the battery terminals from time to time during the charge or discharge.

A hydrometer is used repeatedly during the time a battery is on charge, as it is important to observe the specific gravity during the charge. Directions for using the voltmeter and hydrometer during the charging of a battery are given farther on.

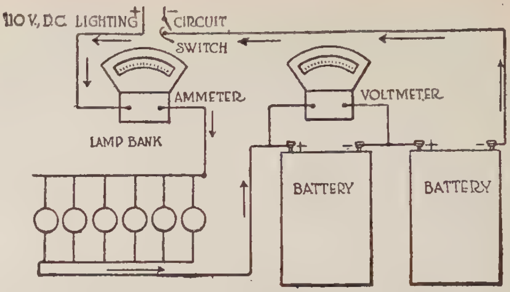

Fig. 10. Method of connecting voltmeter and ammeter when charging.

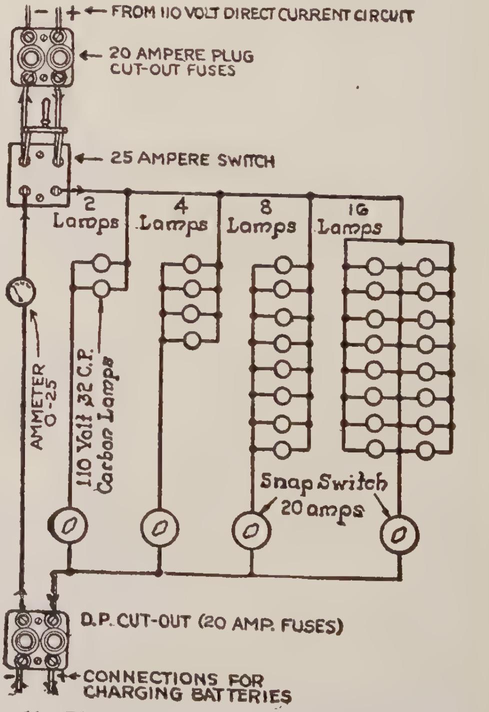
A 2 to 30-Ampere Lamp-Charging Outfit

If the number of batteries to be charged varies from time to time, the lamp bank shown in Fig. 11 is very convenient when charging from a 110-volt direct-current source.

Thirty ordinary lamp sockets are mounted to a board (Fig. 11) and wired up to snap switches in groups containing two, four, eight, or sixteen lamps. A suitable main switch, fuse cut-out, ammeter, and terminal block complete the connections.

With this equipment, from one to twelve 6-volt batteries can be charged in series at one time. Different combinations of switches on and off permit regulation of the current through the batteries.



- + ← FROM 110 VOLT DIRECT CURRENT CIRCUIT

D.P. CUT-OUT (20 AMP. FUSES)
← CONNECTIONS FOR CHARGING BATTERIES

Fig. 11. Diagram of connections for charging one to twelve 6-volt batteries from a 110-volt direct-current source, using lamps.

Construction and connections of Fig. 11: A base of hard wood and No. 12 wire is used. Various charging rates can be had by switching on banks of lamps instead of unscrewing lamps. Note that banks of 2, 4, 8, or 16 32 c.p. lamps can be used singly, or **all together,** which would make **30 amperes** total. Each 32 c.p. 110-volt lamp gives 1 ampere.

To obtain 20 amperes, switch on the 4 and 16 bank: for **10 amperes,** switch on the 8 and 2 bank; for **5 amperes,** put 2, 16 c.p. ½-ampere lamps in 2 bank, which would give 1 amp., and use this with the 4 bank.

The ammeter indicates the quantity of current in amperes passing to the battery. It can be connected in series, as shown in Figs. 11 and 10. An ordinary dash-type ammeter can be used if the rate of charge is not over the capacity of the meter. If in connecting the meter the hand points in a wrong direction, reverse the connections to the meter.

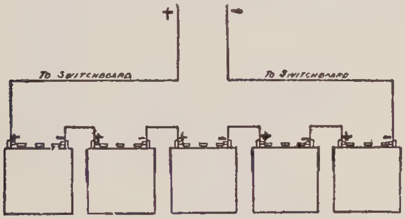

Fig. 12. Method of connecting batteries in series to be charged. If there is a 12-volt battery in series with the 6-volt batteries, consider it as two 6-volt batteries. If an 18-volt battery is in series, consider it as three 6-volt batteries.

Table Giving the Amperage or Rate of Charge Used When Charging from 1 to 11 Batteries

Place the batteries in "series," as in Fig. 12. Then use the number of lamps as indicated in the table below. We are assuming that the charging circuit is a 110-volt direct-current circuit.

Number of Batteries	No. of 32 c. p. 110 v. Lamps at "start" and amp's.	No. Lamps for "finish" rate
1	10L—10a	3L
2	10L— 9½a	3L
3	11L— $9\frac{4}{10}$a	3L
4	12L— $9\frac{6}{10}$a	4L
5	13L— 9¾a	4L
6	15L—$10\frac{2}{10}$a	4L
7	17L—$10\frac{4}{10}$a	5L
8	19L—10⅜a	6L
9	21L— $9\frac{9}{10}$a	6L
10	25L—10a	8L
11	30L— $9\frac{9}{10}$a	9L

L designates lamps in circuit and **a**, amperes passing to battery.

It will be observed that, **to charge more than one battery, more lamps are used** in order to obtain the same amperage rate of charge, or nearly the same. This is due to the fact that as each battery is connected in series with another, the battery voltage is increased .

When charging several batteries, the practice is to charge at 6 amperes during the day and 3 amperes at night. This permits watching during the day and avoids overheating at night.

The table given above is figured for a discharged 90 to 100 ampere-hour 6-volt starting and lighting battery.

If smaller batteries are on the line, or if some are **partially discharged,** charge at the 24-hour rate until smaller ones or partially discharged ones are charged, then remove them.

Resistance Units Instead of Lamps for Charging Batteries

Instead of lamps, "resistance units" of approximately 35 ohms resistance and 3.3 amperes capacity each may be used. or as shown in Fig. 13. This equipment will occupy less space than the lamps and serve the same purpose, each resistance unit replacing two lamps.

Instead of either a lamp resistance or unit resistance panel, a special form of **rheostat** may be used. The size and type depend upon the conditions.

When ordering a rheostat, it will be necessary to give the following information:

1. The voltage of the charging mains.
2. The number of cells to be charged in series.
3. The lowest and highest current rate desired.

Resistance of some sort must be used when charging batteries, except where the voltage of the charging mains is exactly the voltage required to charge the battery or batteries. Within certain limits, a motor generator set can be regulated to deliver the voltage required. Where much charging is done, a motor generator set is more economical in operation than a charging resistance.

When resistance, or a rheostat, is used instead of lamps, the resistance should be such as to produce, when carrying the proper charging current, a voltage drop equal to the difference between the voltage or pressure of the charging circuit and that of the battery being charged.

Example of a Charging Battery Using Resistance Units, and Method of Construction

The **parts necessary** to construct this 5-battery charging outfit are:

1 Double-pole single-throw switch.
2 10-amp. plug cut-outs (fuses).
1 Ammeter, reading 0 to 30 amperes.
40 ft. of No. 16 rubber-covered flexible wire.
1 Resistance unit with two taps.
1 Resistance unit with nine taps.

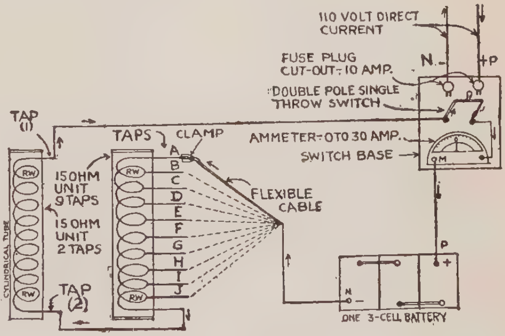

Fig. 13. Resistance charging circuit.

Construction: The resistance units can be obtained of the General Electric Co., of Schenectady, N.Y., or Ward-Leonard Co., Bronxville, N.Y. They are merely coils of wire (spiral resistance wire) wound on cylindrical tubes over asbestos and baked on the cylinder. The tubes are encased in porcelain and measure approximately 22″ long and 2″ diameter.

Taps: There are two taps from each single resistance unit in the left-hand coil of Fig. 13. The coil in the center of Fig. 13 has 11 taps or connections. Each resistance unit in this illustration has 15 ohms capacity, and is known as the 15E form P (General Electric Co. designation).

These resistance units are inexpensive, costing in the neighborhood of about two dollars each.

Charging: Batteries are referred to generally, as 3-cell, 6-volt batteries. If a battery has 6 cells, it is treated as two 3-cell batteries; if it has 9 cells, it is treated the same as three 3-cell batteries, etc.

To figure the amount of resistance necessary to charge 1 to 5 batteries, that is, 3-cell batteries, on a 110-volt direct-current line, note the following:

Resistance is always referred to as so many "ohms." If one 3-cell battery is to be charged at a 3-amperage rate, figure the resistance necessary to put it in series with the battery as follows: **N×SV =TV,** in which **N** stands for number of cells, **SV** stands for single voltage, or the voltage of one cell, and **TV** stands for total voltage. Substituting figures for the symbols (letters), we have: 3 cells (N) ×2.1 volts (SV)=6.3 volts (TV); i.e., the total voltage required for a 3-cell, 6-volt battery at the beginning of a charge is 6.3 volts, and **the resistance to use for a 3-ampere charge is:**

$$\frac{110\text{v}-6.3\text{v}}{3\text{ amp.}}=34.6\text{ ohms}=\text{resistance required.}$$

Arrived at as follows: 110—6.3=103.7÷3=34.6.

If two 3-cell batteries are to be charged at a 3-ampere charge, multiply the 6.3v in the foregoing example by two—for instance:

$$\frac{110\text{v}-12.6\text{v}}{3\text{ amp.}}=32.5\text{ ohms}=\text{resistance required.}$$

If three 3-cell batteries are to be charged at a 3-ampere charge, multiply the 6.3v in the first example by 3; if four 3-cell batteries are to be charged multiply by 4, etc.

If battery is to be charged at 5 amperes, divide by 5, instead of by 3. For instance:

$$\frac{110\text{v}-6.3\text{v}}{5\text{ amp.}}=20.7\text{ ohms}=\text{resistance required.}$$

To charge two 3-cell batteries at 5 amperes:

$$\frac{110\text{v}-12.6\text{v}}{5\text{ amp.}}=19.5\text{ ohms resistance required, etc.}$$

To increase the amperage of a charge, to say, 10 amperes per hour, divide by 10 instead of by 3 or 5 amperes, and cut out enough units to give the required resistance necessary.

To operate on a higher voltage than 110 volts, as explained in the example above, say, 220 or 500 volts, in order to find resistance necessary, use 220 or 500 instead of 110 volts, as used in the examples.

How to charge: The two resistance units (Fig. 13) at the left and center of the diagram, give 15 ohms each, or a total of 35 ohms (actual addition shows 30 ohms, but will give 35). One of the units (that in the center of Fig. 13) has 11 taps, so that the entire 11 resistance coils (RW) can be thrown into the circuit, or only part of them, as shown in the diagram. The resistance unit (at the left of Fig. 13) is connected at all times, and is 15 ohms. The other 15 ohms in the center can be subdivided:

By merely connecting the wire from the battery (—negative) to (A), all resistance (30 ohms—will give 35) is in the circuit. When connected with (J) only the resistance in the unit at the left of Fig. 13 is in circuit. The table (Fig. 14) will explain how and why the resistance units are added or cut out.

By following the arrow points on the diagram, from the + P wire, over the switch from the main wire, the circuit can easily be traced. The dotted lines represent the connections at different taps on the center unit of Fig. 13.

Number to Charge of Batteries 3-cells	To Charge Batteries at 3 Amps.		To Charge Batteries at 5 Amps.	
	Ohms of Resistance Necessary	Tap to Which to Connect Battery—	Ohms of Resistance Necessary	Tap to Which Connect Battery
1	34.6	A	20.7	F
2	32.5	B	19.5	G
3	30.3	C	18.2	H
4	28.3	D	16.9	I
5	26.2	E	15.7	J

Fig. 14. Table showing ohms resistance required for battery charging, using resistance as in Fig. 13.

When connection is at (A), this gives the least current, as the entire 30 ohms is in circuit. When at (F), 22½ ohms resistance is in the circuit.[1]

The ampere current flowing may be read on the ammeter. The actual current will depend upon the number of batteries in series, as in diagram (Fig. 15). If the current obtained at (A) is not sufficient, then cut out resistance by connecting with (B) or (C), and so on, each giving a greater current than the one preceding, the maximum being at (J).

Fig. 15. Method of connecting more than one battery to charge. Note that batteries are connected in series—the positive pole of one battery to the negative pole of another, etc. Letters (B), (C), (D), and (E) refer to taps. (M) refers to the connection on the ammeter. Thus "B to M" would include all resistance, except coils (A).

As the batteries become charged, the rate will become less, but may be increased again to 3 amperes, by proceeding with the next operation of cutting out resistance. Charge until the specific gravity has reached a maximum and remained there for five hours. This is the standard, indicating completion of charge. The cells should gas at the same time. If they do not, the maximum gravity has not been reached.

The important point to watch in charging is, not to let the temperature of the cell get above 110° F. If it does, the charge must be temporarily stopped, until the cell cools down, and then be continued at a lower rate. But be sure to charge until the specific gravity has remained at a maximum for five hours. In case one battery becomes charged first, it should be taken out of circuit and the remaining batteries charged at 5 or 6 amperes until charge is completed.

Charging Batteries from an Alternating-Current Circuit Using a Rectifier

Alternating current flows alternately in opposite directions, and is used to a great extent for house lighting. Only **direct current,** which is constant, or a continuous current, is suitable for charging storage batteries.

---

[1] If each unit (Fig. 13) is 15 ohms, the two would represent 30 ohms, and when the tap is made at (F) this would cut out one-half of the resistance of the center unit of Fig. 13, leaving 22½ ohms in the circuit. Although the table (Fig. 14) calls for 20.7 ohms at (F), this would be near enough for practical purposes.

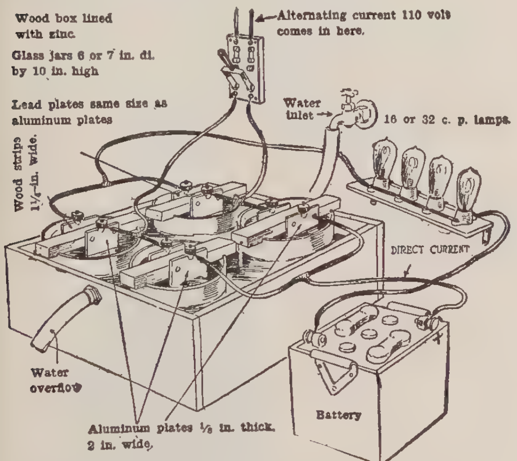
Alternating current can be rectified so that it will flow in one and the same direction. It can then be used for charging storage batteries. A device for such a purpose is called a **rectifier.**

There are several types of rectifiers, as follows:

1. Chemical rectifier.
2. Mercury arc rectifier.
3. Synchronous commutator type.
4. Tungar rectifier.
5. Vibrator type.

Chemical Rectifier

A chemical rectifier is not very efficient and is seldom used. There is a tendency for liquid in jars to get hot and boil if too high a current is passed through it, otherwise water is not necessary (see Fig. 16).



Wood box lined with zinc
Glass jars 6 or 7 in. di. by 10 in. high
Lead plates same size as aluminum plates
Wood strips 1½-in. wide.
Alternating current 110 volt comes in here.
Water inlet
16 or 32 c. p. lamps.
DIRECT CURRENT
Water overflow
Battery
Aluminum plates ⅛ in. thick, 2 in. wide.

Fig. 16. A home-made chemical rectifier.

The amount of charging current is regulated by using 16 or 32 c.p. lamps. One-half of 1 ampere will pass through a 16 c.p. lamp and 1 amp. through a 32 c.p. lamp. Therefore the more lamps, the more amperes flowing. About 2 amperes or four 16 c.p. lamps is best with this outfit, which of course would require a long time to charge a 100-ampere-hour battery if the latter is entirely exhausted.

The solution consists of a concentrated solution of common baking soda in pure water. (*Motor Age.*)

Synchronous Type Rectifier

The synchronous commutator type of rectifier is merely an alternating-current motor with which a commutator is used to change the alternating current to direct current.

Vibrator Type Rectifier

The vibrator type of rectifier is divided into two classes: one, whereby the storage battery being charged determines the polarity of the charge, and the other, whereby a permanent magnet determines the polarity of the charge.

With this last-mentioned type and previously mentioned rectifiers, it is **important that positive and negative poles of the battery be connected** to the positive and negative poles of the rectifier.

On one other type of vibrator rectifier, which is similar to that shown in Fig. 17, but minus the permanent magnet, there is **another winding on the electromagnet,** which is "shunted" across the battery terminals and which takes the place of the permanent magnet.

With this type it does not matter which of the terminals connects with the battery, as the voltage from the battery will set up its polarity in the electromagnet. The disadvantage, however, is that if the battery is almost totally discharged there will not be sufficient voltage to excite the electromagnet which should determine the polarity of the charge.

Vibrator Type of Rectifier with a Permanent Magnet

The vibrator type of rectifier transforms the alternating current from 110 volts to 10 or 12 volts. The current then passes through an electromagnet, the amount of current to operate the vibrator being regulated by resistance (RE) (Fig. 17).

The purpose of the electromagnet, vibrator, and permanent magnet is as follows: If the alternating current flowing through the electromagnet is 120-cycle waves per second, the core (N) of the electromagnet would change its polarity with each cycle wave.

If, however, some means were employed to **cut out 60 of the cycle waves,** and utilize only **one-half of the waves,** or only every other cycle wave which **flows in one direction,** and which would be a direct flow of current, then the vibrator would close the circuit to the battery at (VS), and charge the battery.

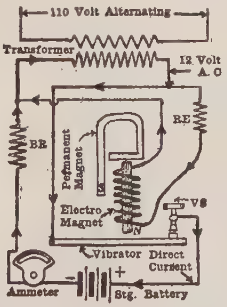


Fig. 17

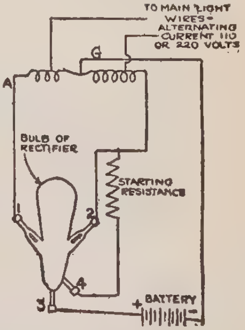

Fig. 18

Fig. 17. Vibrator type of rectifier.

Fig. 18. Mercury arc rectifier for 60, 50, 40, 30, or 25 cycles, 110 volts.

This is made possible by placing a "permanent magnet" at the end of the electromagnet, as shown in Fig. 17, which keeps the electromagnet core definitely (N) and (S). During the time the 60-cycle waves per second are flowing one way, or in harmony with the permanent-magnet polarity, the vibrator "cuts in" the battery, and during the time the 60-cycle waves flow in the other direction, the vibrator is not attracted by the core (N), because current is flowing in an opposite direction to the polarized magnet core, and magnetism is not set up.

A spring, not shown, is attached to the vibrator which is adjusted to hold the vibrator away from the core (N) until current flowing in harmony with the permanent magnet polarity, both combined, draws the vibrator to the core. The resistance **(BR)** is used to limit the amount of charging current to the battery, say 6 amperes.

Positive and negative wires must be connected correctly, but on another type of vibrator rectifier, as explained above, this is not necessary.

This kind of rectifier (Fig. 17) and most other rectifiers of this type are only suitable for charging one 6-volt battery at a 6-ampere rate, or a 12-volt battery at a 3-ampere rate.

The Mercury Arc Rectifier

The mercury arc rectifier (Fig. 18) is used considerably for charging electric vehicle batteries. A maximum of 30 amperes is the average. A large glass tube contains mercury in its base. Graphite terminals (1) and (2) are the "anodes." Terminal (3) is the "cathode" for negative wire, there being only one. (G) is the transformer. A small electrode (4), connected to one side of the alternating current, is used for starting the arc across the mercury.

Tilting the tube causes a mercury bridge between the terminals and produces an arc when the tube is turned in a vertical position.

When the current alternates, first one, and then the other "anode" (1) and (2) becomes positive, and a continuous flow is towards the mercury "cathode" (3), thence to the battery, back to the opposite side of supply.

The Tungar Rectifier

The Tungar rectifier (Fig. 19) consists of a hot argon low-pressure gas-filled bulb (**B**) (Figs. 19, 20), with a "cathode" (**F**) (tungsten filament) and an "anode" (**A**), a transformer (**T**) for exciting the filament, a rheostat (**R**), and the load which is shown as a storage battery. The connections in Fig. 19 show the half-wave rectifier in its simplest form.

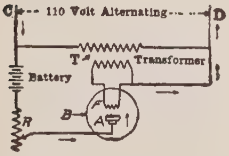

Fig. 19

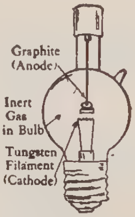

Fig. 20

Principle: Assuming an instant when the side (**C**) of the alternating-current supply is positive, the current follows the direction of the arrows through the load, rheostat, bulb, and back to the opposite side of the alternating-current line. A certain amount of alternating current, goes through the transformer (**T**) to excite the filament, the amount depending on the capacity of the bulb.

When the alternating-current supply reverses, and the side (**D**) becomes positive, the current is prevented from flowing. In other words, the current is permitted to flow from the "anode" (**A**) to the "cathode" (**F**), or against the flow of emitted electrons from the cathode, but it cannot flow from the cathode to the anode with the flow of electrons. This type of rectifier is extensively used.

The General Electric Co., Schenectady, N.Y., supplies a Tungar rectifier for public garage use. It has a charging capacity of 6 amperes and will charge any combination of 3, 4, 5, 6, up to 30 cells at 6 or 7 amperes or less from alternating current. Smaller outfits are made for private garage use. Booklets numbered as follows will be sent to readers of this book who are interested: Large outfit, booklet B-3487; for private garage use, booklet B-3532. Address General Electric Co., Schenectady, N.Y.

The Motor-Generator Set, for Charging Batteries

Only direct current can be used to charge storage batteries, but in most towns and cities only alternating current is available.

There are three methods of charging batteries where only alternating current is available:

1. **By the use of a rectifier,** as explained.
2. **By the use of an electric motor operating on alternating current and driving a dynamo or** generator which will generate "direct" current, from which current the battery is charged. This motor and generator is then "direct connected" on one base, and called a "motor-generator set."
3. Instead of an electric motor being used to drive the generator, this **direct-current generator can be driven by belt power** from a line shaft, or gasoline engine, or other power.

Where a limited amount of battery charging is to be done, the rectifier (Fig. 17) is recommended.

Where many batteries are to be charged, motor-generator sets, shown below, are recommended

Description of a Motor-Generator Set

As an example we will use a type 6-G Valley Electric Co.'s motor-generator (Fig. 21).

Names of parts: (**M**), motor, operates from alternating current and drives a direct-current generator (G); (T), terminals; (S), motor switch; (**R**), rheostat to regulate charging current to battery; (**A**), amperemeter; (**B**), generator switch; (**C**), automatic cut-out.

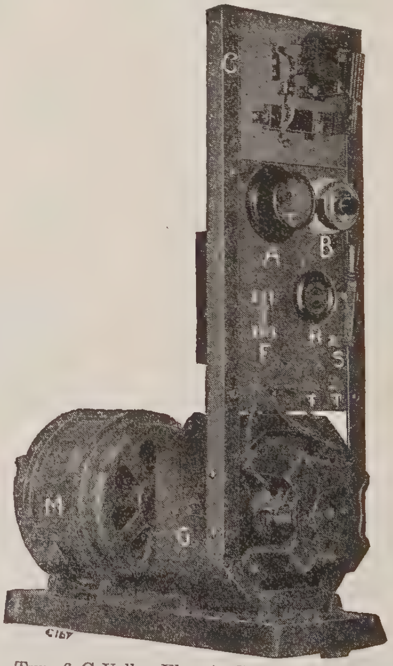

Fig. 21. Type 6-G Valley Electric Co.'s motor-generator set.

This set will charge **1 to 10 batteries in series at 8 amperes; generator, 75 volts, 8 amperes, 600** watts. This same type 6-G set will charge 20 batteries at 4 amperes, if two auxiliary rheostats are used as shown in Fig. 23.

Auxiliary Rheostat

The purpose of this device will be understood better after reading the explanation of its use that follows.

Construction: Resistance coils wound on asbestos board are placed about ¾″ apart lengthwise on the back of a slate slab. This resistance can be cut in and out of the circuit by a handle (**H**) (Fig. 23).

The ammeter (A) on the rheostat indicates the charging rate on that particular rheostat line, whereas the ammeter on the switchboard indicates the total amperes to all lines, or to 1 or 5 batteries if charged without this auxiliary rheostat. The maximum carrying capacity of the auxiliary rheostat is 10 amperes.

Refer now to Fig. 22. Note that there are ten 6-volt batteries connected in series with the type 6-G motor-generator set, **without** the use of the auxiliary rheostat. The charging rate is 8 amperes and this is the capacity of the 6-G motor-generator.

CHARGING 20 BATTERIES WITH 2 AUXILLIARY RHEOSTATS AT 4 AMPERES

Fig. 23

Now refer to Fig. 23. Note that there are two sets of ten batteries connected with two auxiliary rheostats (AUX. R1 and AUX. R2). Each set with its auxiliary rheostat, instead of being in series with the main charging line from the generator, is connected **parallel** to the line.

Therefore, instead of each set of ten batteries (Fig. 23) drawing 8 amperes, as in Fig. 22, they only draw 4 amperes, or, in other words, **the rate of charge is reduced one-half,** in order to charge as many as twenty batteries.

When charging with the use of the two auxiliary rheostats, place each rheostat handle (H) of (AUX. R1) and (AUX. R2) so that all resistance is cut out.

Then set the charging rate of the generator by moving its shunt-field rheostat (on the switchboard) until ammeter on switchboard shows 8 amperes.

Then note the reading on each of the ammeters (A) on the auxiliary rheostats. A little resistance can then be cut in or added to the line that is taking most of the current until each of the two auxiliary lines is cut down to the proper amount of current at which it is desired to charge each lot of batteries.

The highest rate at which the twenty batteries can be charged, as shown in Fig. 23, is 4 amperes.

When inquiring about a motor-generator of a manufacturer, the following information will be required:

1. The number of cells to be charged.
2. The highest and lowest charging rate.
3. The voltage of the supply mains.
4. If this is alternating current, give, in addition,
5. The frequency in cycles per second, and
6. Whether it is single phase or three phase.

How to Change the Polarity of Shunt-Wound Generator

It is possible to change the polarity of shunt-wound generators, and since this is the type of generator used for battery charging, it is well to know how to correct the polarity, which is easily done by the following method:

Cut out all the field resistance by turning the rheostat handle to "high" (the resistance of the rheostat is in series with the shunt field-circuit), and connect on a charged battery to the panel board (Fig. 22) (−) to (−) and (+) to (+). Close the battery switch, which will start the generator as a motor, and cause the ammeter to indicate "discharge"; then throw in the main line switch, and the meter will show "charge," and the polarity will be corrected. The polarity will never change while the set is operating. A change of polarity is caused by connecting the batteries wrong when the set is not running.

A Direct-Current Generator Driven by a Belt

A direct-current generator can be driven by a belt from a line shaft, engine, or any other source of power. A type 3-G generator with switchboard, cut-out, and belt pulley can be purchased (Fig. 24).

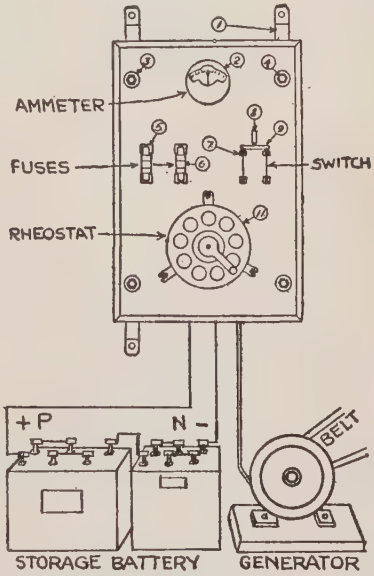

Fig. 24. **Belt-driven generator and switchboard.** **Parts:** (1) bracket for support; (2) ammeter; (3, 4) bolts; (5, 6) fuses; (7, 8, 9) double-pole, single-throw switch; (10) slate slab; (11) rheostat.

The speed of this particular type of generator is 1,800 r.p.m., and the outfit sells for $88. It is a 300-watt capacity, 30-volt 12-ampere generator. This generator will charge 6 batteries at 6 amperes if two auxiliary rheostats are used, or 1 to 3 batteries in series at 12 amperes.

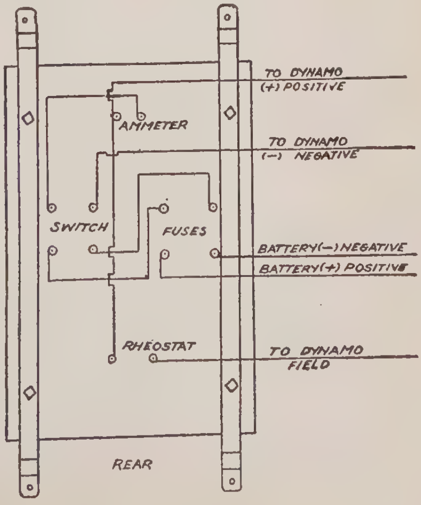

Fig. 25. Rear of switchboard showing connections.

INSTRUCTION No. 51

CHARGING BATTERIES: Putting Batteries in Storage

The different charging methods were explained in the preceding instruction. We shall now deal with the charging of the battery.

When a Battery Charge Is Necessary

A battery charge is necessary:

1. When discharged, that is, when each cell is as low as 1.8 volts and the specific-gravity reading is 1.200 or less.
2. When a battery is received new and in a dry condition.
3. When a battery is received new and in a wet condition.
4. When defective.
5. When repaired.
6. When stored.

A battery may be charged:

1. When on the car.
2. When removed from the car.

Charging and Discharging Action

There are two chief points to consider when charging a battery. In other words, the proper charging of a battery depends upon two points, namely, **gassing** and **temperature,** explained as follows:

To charge a battery, direct current is passed through the cells in a direction **opposite** to that of discharge. This current, passing through the cells in the reverse direction, will reverse the action which took place in the cells during discharge (explained under the "Principle and action of a storage battery," page 539). It will be remembered that during discharge, **the acid of the electrolyte went into and combined with the active material,** filling its pores with sulphate and causing the electrolyte to become weaker (merely water).

Action of current: Reversing the current through this sulphate in the plates restores the active material to its original condition, and **returns the acid to the electrolyte.**

Thus, during charge the electrolyte gradually becomes stronger, as the sulphate in the plates decreases, until no more sulphate remains, and all the acid has been returned to the electrolyte. It will then be of the same strength as before the discharge, and the same acid will be ready to be used over again during the next discharge. **Since there is no loss of acid, none should ever be added to the electrolyte.** There is, however, a loss of water from evaporation.

Object of charging: The acid absorbed by the plates during discharge is, during charge, driven from the plates by the charging current and restored to the electrolyte.

Gassing: When a battery is fully discharged, it can absorb current at the highest rate. As the charge progresses, the plates can no longer absorb current at the same rate, and the excess current goes to form gas. In a battery which is charged, or nearly charged, the plates can absorb current without excessive gassing only at a low rate, and a high charging rate will be almost entirely used in forming gas, resulting in high temperature and wear on the plates.

In starting and lighting systems, the aim is to provide sufficient current under average running conditions so that the battery will not be "starved," and yet that the charge will be at a rate which will not cause injurious gassing.

Normal and abnormal sulphate: The sulphating which takes place during an ordinary discharge is entirely normal. If, however, charging is insufficient, the sulphate increases and becomes hard, and the plates become lighter in color, lose their porosity, and are not easily charged; this is the abnormal condition usually referred to as "sulphated." This condition is usually the result of "starvation" of the battery.

Overdischarge: It is not **discharge** at any rate which injures a battery, but **overdischarge,** or, what in time amounts to the same thing, undercharge or "starvation."

"Starvation": If a car is so run that the battery gets insufficient charge and is "starved," it cannot be expected to do its work properly.

Overcharge: Persistent overcharging not only tends to wash out the positive active material, but also acts on the positive grids, giving them a scaly appearance.

Low temperature: Temperature has quite a marked effect on a battery. Low temperature (temporarily) both lessens the ampere-hour capacity which can be taken out of the battery and lowers the discharge voltage. It is as if the battery were numbed by the cold and unable to make the same effort as at normal temperature. The effect of cold is only temporary, the battery returning to its normal state upon its return to normal temperature, even without charge.

Starting batteries are usually designed with sufficient margin over the ordinary requirements so that they will still perform their functions under reasonably low temperature conditions. It is just as well, however, to bear in mind the effect of cold weather and to aim to keep the battery unusually well charged in winter, and not to expose it unnecessarily to low temperatures.

There is no danger of the electrolyte freezing in a fully charged cell; but in one which is over-discharged, or has had water added without subsequent charging, this is liable to occur.

High temperature: High temperature is to be avoided from the standpoint of the life of the battery; 110° F. is usually given as the limiting temperature, and even this would be harmful if maintained steadily.

Heating is ordinarily the result of charging at too high a current rate. If the temperature of the electrolyte in a battery is found to run excessively high, the system should be inspected; it may be out of adjustment and be charging the battery at too high a rate.

The effects of continued high temperature are to distort and buckle the plates, to char and weaken the wood separators, to soften and sometimes injuriously distort the jars and covers.

Charging a Battery on the Car

If a battery is charged on the car, the chief points to determine are whether it is getting too small a charge, or whether it is getting too much of a charge.

If it is not getting a sufficient charge, this is attributable to the following causes:

1. Car is run mostly at night with lights on, and does not run enough in daytime with lights off.
2. Overloading, such as additional electrical apparatus drawing on it.
3. Battery is old and probably sulphated.
4. Loose connections, or sulphated battery terminals, or ground causing leaks, the latter causing the battery to discharge.
5. Cut-out not opening and closing properly.
6. Generator third brush, or main brushes not seating properly.
7. Generator output set too low.
8. Cold weather driving caused excessive use of starter.

If it is getting too much charge:

1. The temperature of the battery is raised. The connectors will probably be found to be hot. Test the cells with a hydrometer and do not permit the temperature of the electrolyte to rise above 105°. Lower the charging rate.
2. If the charging rate cannot be lowered, then allow the lamps to burn in the daytime.

A Bench Charge (Battery Removed from Car)

A bench charge is a method of charging the battery from a source outside of the car.

If the car is not equipped with an electric generator, a "bench charge" will be required periodically, depending upon how often or how long the lighting or the ignition system has been used.

If the car is equipped with a generator, a "bench charge" will be necessary only in case of trouble, such as the battery being run down on account of the generator output being insufficient, or caused by driving too much at night with the lights on, or by excessive use of the starting motor.

Indications of the battery requiring a "bench charge" will be as follows:

1. When the hydrometer readings of the specific gravity of the cells show less than 1.200, or as great a difference as 25 to 50 points.
2. When the cell voltage falls below 1.8 volts per cell, the test being made when lights are on.
3. When the starting motor revolves, but lacks speed and power.
4. When the lights are dim while the engine is idle.
5. When the electrolyte is below the level of the top of the plates and the battery is discharged. First, fill with water.
6. When the battery is "doped," that is, when acid has been added in place of water. In this instance the battery may be discharged to where the cell voltage is but 1.8 volts per cell, yet the specific gravity readings will be 1.200 or more.

How to Give a Bench Charge

Use **direct current** only, never alternating.

Connect the battery correctly to the charging source, the positive battery terminal to the positive charging wire, and the negative battery terminal to the negative charging wire. The positive battery terminal is marked POS or (+), or is painted red; the negative is marked NEG or (−), or is painted black.

Limit the charging current to the amperes given in the table below, by connecting suitable resistance in series with the battery (see Fig. 6, page 565, showing a method of charging a 6-volt type XC-13 Exide battery from a 110-volt lighting circuit; direct-current only).

Remove the filling plugs and add distilled or other "pure" water until the level reaches the bottom of the filling tubes.

It will be necessary to take hydrometer readings while charging. If the plugs are left out or loose, the solution will flood out unless the valves (Fig. 28, page 528) are each given a quarter turn, bringing them into the position shown.

As quite a few hydrometer readings are required, turning the valves after removing the filling plugs is less work than removing and tightening the filling plugs before and after every reading, as would otherwise be necessary.

Charge at the rate shown in the following table until all cells are gassing or bubbling freely and evenly, and until the hydrometer reading of every cell goes as high as it will. Then charge for five hours longer.

If, on charge, the hydrometer reading of any cell continues to rise above 1.310 (1.240)[1], dump the solution, refill with "pure" water, and continue to charge at about two-thirds of the earlier rate until the hydrometer reading of every cell goes as high as it will. Then charge for ten hours longer.

Keep the temperature of the solution below 110° (125)[1] F., interrupting the charge if necessary.

After the charge is complete, adjust the strength of the solution to between 1.270 and 1.300 (1.200[1] and 1.230[1]) as explained under "Adjusting the strength of the solution," page 535.

Just before putting the battery back into service, make the high-amperage-discharge test, as explained on page 553.

Charging Rates

Charging rates are given by the Exide manufacturers under the head of "Bench Charge," page 573, for all ordinary charging, and under "Initial charge and repair charge," for charging both when the battery is new and when it is to be repaired.

The U. S. L. table gives an ampere-charge rate to start with, termed "starting rate," a "finishing rate," and a "24-hour rate." This will all be found in the foregoing table, page 574.

It will serve to make the table clearer if we explain some of its features. For example, under the heading, "U. S. L. Starting and Lighting Batteries—6 Volt," note that the battery number "A-313-B," meaning a 3-cell 13-plate battery (see page 523 on how to determine) has a 90-ampere-hour capacity at 1 ampere discharge. The **starting** rate, to charge this battery is 10 amperes; the **finish** at 2½ amperes.

For example: Start the charge at the "starting rate," or lower, as shown in the table, and continue the charge until the cells **gas freely.** This will ordinarily take about six hours. Then continue the charge for six hours at the normal rate (finish); see table.

A battery charge is complete when, with charging current flowing at the **finish rate** given in the tables, all cells are gassing (bubbling) freely and evenly and the gravity of all cells has shown no further rise during one hour.

The 24-hour rate is the one used for charging through the night, and cells charging at this rate may be left on continuously.

If you have no voltmeter nor hydrometer, it is possible to determine when the battery is fully charged by observing when gas bubbles begin to rise from the solution while the battery is charging at the 24-hour rate.

Procedure of Charging

Commence the charge at the current rate given under **"Starting Rate,"** (see table, page 574). Be sure that the rate is correct for the particular type of battery. Continue to charge at the maximum rate until the cells begin to gas or bubble freely, at which time the voltage will be approximately 2.5 volts per cell (7.5 volts for a 6-volt battery). When one or both of these conditions are obtained, reduce the charging current to the value given under **"Finishing Rate,"** by unscrewing the proper number of lamps (if charging with lamp resistance), and continue to charge at this rate until the cells again gas freely, and the specific gravity of the electrolyte ceases to rise, as indicated by successive half-hour readings taken after the cells begin to gas.

At the end of charge, the voltage will be approximately 2.5 volts per cell with the current flowing at the minimum rate, but on a new battery this voltage will be greater, reaching as high as 2.65 volts per cell.

The specific gravity of the electrolyte at the end of charge should be at a maximum between the value 1.275 and 1.285. Correct all specific-gravity readings for temperature as described under "Specific Gravity," page 532. Make sure that the battery is full, but do not overcharge.

The temperature of the electrolyte should not be allowed to exceed 100° F. during charge. If this temperature is exceeded, cool the battery by reducing the charging current, or by temporarily stopping the charge.

Hurrying a charge: This is not recommended, but when unavoidable, put the battery on **double** the "starting rate" given for the particular size of battery in the table on page 574.

Charging Small and Large Batteries

It is not advisable to place small batteries in series with large-capacity batteries and then give the small ones the rate of charge required for the large ones. This practice will cause the temperature of the small ones to rise more quickly than in the large ones, and will thus cause overheating.

If charging more than one size in series is unavoidable, then charge all at the rate required for the smaller battery; then when the latter is charged, take it off the line. It is best to have separate charging lines for series circuits of different sizes of batteries, for then the charging rate can be controlled accordingly.

Charging and Discharging Sulphated Batteries

With the sulphated battery, the charging should begin at about a 2 or 3-ampere rate and should not be allowed to rise beyond 5 or 6 amperes. A thermometer reading should be made often, and the temperature of the solution should never be much over 100° F. Never let it heat more than 110°.

When the cells begin to gas and give off bubbles, take the battery off the charger and discharge the battery by connecting some lamps on it or some resistance across its terminals (see tests on pages 546 and 547). Put in just enough lamps or resistance to draw a discharge current equal to 1/10 the ampere-hour capacity (if you have 80 ampere-hour batteries, discharge at an 8-ampere rate, or a 10-ampere rate); discharge the battery until each cell has a voltage of 1.7 or 1.8 volts while the battery is discharging. Repeat this process from two to three times and the sulphate will be well broken down and the battery will be in good condition. In some instances it may be necessary to charge and discharge for a week or more.

See also item 2, page 589, relative to the "water treatment" of sulphated cells.

When discharging the battery, observe as suggested above, the discharge rate and the time it requires for the battery to discharge to 1.8 volts. Multiply the two together and you have the ampere-hour capacity of the battery. Compare it with the rated ampere-hour capacity of the battery, and if your result is considerably less, the cell or cells should be opened for inspection.

If the **temperature rises** in the cells, yet **does not gas freely,** then there is trouble inside of the battery. Open it for inspection.

Charging a "Doped" Battery

Where a battery has been doped with acid, it should be given an immediate charge. Then remove some of the electrolyte and add water during the time the cells are freely gassing, while on charge, until the hydrometer test shows about 1.275 or 1.280, but do not take the hydrometer reading for at least an hour after the water is added.

The length of time to charge will depend upon the amount of acid added and the condition of the battery resulting from the acid. If the plates are not badly sulphated, a long-time charge at a low rate may bring the battery back to normal.

If the acid has caused sulphation, see above. The battery may also require new separators if the battery has been doped often (see also pages 535, 543, 544, 588).

Reversed Charge

Should a reversal occur, put the battery on charge at the 24-hour rate, and leave it on for several days. Do not take it off until its voltage and gravity have both reached a maximum, with the battery at normal temperature, 70° F.

Charging Repaired Batteries

This subject is dealt with farther on, under the subject of "Battery Repair."

What to Do when Receiving a New Battery from the Factory

Batteries are shipped from the factory either "charged" or "bone dry."

Receiving a Battery Filled or Wet

When a "charged" battery is received, it is one which has had the solution added and which has been given its initial charge at the factory. It leaves fully charged, and contains the proper amount of solution and is intended to be put into service.

Before putting it into service, however, it should be examined by testing the strength of the solution by taking a hydrometer reading (see page 531, Fig. 1) in each cell. All readings should be more than 1.250 (1.180).[1] Add distilled water through each filling tube until the level reaches the bottom of the tube (Fig. 1, page 561), and replace and tighten the plugs.

In freezing weather, charge the battery for an hour at the proper rate (see page 577), in order to mix the water with the solution.

If all cells, or some cells read less than 1.250 (1.180),[1] give the battery a "bench charge" (see page 573).

If there is not enough solution to give a hydrometer reading, and if there is no evidence that the solution has been spilled in shipment, add distilled water to the proper level, and replace and tighten the filling plugs. Then charge for an hour at the proper rate (see "bench charge," page 573). Then test the strength of the solution.

If the solution has been spilled in shipment, then use electrolyte having a strength of 1.250 (1.180)[2] instead of water to make up the loss (see "Mixing Electrolyte," page 534).

Just before putting the battery into service, make the "high-amperage discharge" test (see page 552).

Receiving a Battery Dry or Unfilled

Batteries are often shipped unfilled, or "bone-dry," as it is termed. A "bone-dry" battery is one which has never had solution added and which, therefore, has not been given an initial charge at the factory. To it is attached a tag, reading "unfilled" or "dry."

A bone-dry battery may stand a considerable length of time before being put into service, the time limit being given on the tag.

Bone-dry batteries are shipped to all foreign countries and many battery distributors order batteries dry, preferring to give them their initial charge when sold, thus preventing the deterioration that would result if a fully charged battery was kept on their shelves over a long period of time.

Care of Battery When Received Dry

1. Store it in a dry, clean location and keep the temperature above freezing and below 110° F.

2. Put it into service before the expiration of the time limit given on the tag attached to the battery. The process of putting into service will require about five days.

3. If the battery has been allowed to stand beyond the time limit, a cell must be opened up and the separators examined just before putting the battery into service. If the separators are cracked, warped, or split, the entire battery must be provided with new separators; otherwise, reassemble the cell and put the battery into service.

Putting a Bone-Dry Battery into Service

The following instructions are taken from the Exide instruction book:

1. Fill with electrolyte of the proper strength and give a long initial charge at the proper rate.

2. Remove the filling plugs and pour electrolyte of the proper strength carefully into the cells until level with the bottom of the filling tubes, using china or glass vessels or a rubber syringe. The proper strength for filling varies with the different types of Exide cells and should be as follows:

For Types JX, XC, and XE, it is 1.360 (1.260)[1]
For Types LX, LXR, LXRE, LXRV, and SX, it is 1.340 (1.260)[1].
For Types MHA, PHA, and PHC, it is 1.320 (1.260)[1].
For Type ZA, it is 1.320 (1.240)[1].
For Types KXD and KZ, it is 1.300 (1.240)[1].

If electrolyte of proper strength is not on hand, it can easily be made as explained on page 535.

3. After filling, allow the battery to stand ten to fifteen hours before starting the initial charge. It is important that the full time be allowed.

4. Arrange charging circuit.

   (a) Direct current only must be used, never alternating.

   (b) The positive terminal of the battery must connect with the positive of the charging circuit, and the negative of the battery with the negative of the charging circuit. The battery positive terminal is marked POS or (+), or is painted red; the negative is marked NEG or (−), or is painted black.

   (c) Arrange the resistance in series with the battery, so that the charging rate will be that given in the table below. Use either lamps in parallel or a rheostat for resistance.

5. Not sooner than ten to fifteen hours after filling the battery with electrolyte, add more electrolyte to restore the level, if it has fallen, and replace the filling plugs, screwing them tight. Never charge with filling plugs out or loose.

Start charging, and **continue at the amperes shown in the table** (Fig. 2) until the battery has received at least the number of ampere-hours shown. If the rate is maintained, the time required will be ninety-six hours (four days). The initial charge is not complete until the hydrometer reading of every cell goes as high as it will and then remains there for ten hours. Be sure to make the charge absolutely complete, as the entire future of the battery depends upon it.

---

[1] The readings in parentheses apply to batteries used in tropical climates. The term "tropical climates" is applied to conditions where the temperature is never low enough to freeze water—or warm climates.

[2] Applies to tropical climates.

[1] Applies to tropical climates.

6. Keep the temperature of the solution below 110° (125°)[1] F., interrupting the charge if necessary.

7. After the charge is complete, the strength of the solution should be between 1.270 and 1.300 (1.200[1] and 1.230[1]). If it is not between these limits, adjust as explained on page 536.

8. Wipe off the top and sides of the battery case with a rag dampened with ammonia to remove any electrolyte that may have been spilled.

9. Just before putting the battery into service, make the "high-rate discharge test" (page 552).

The following instructions are those on the tag of all Witherbee batteries which are shipped dry:

Remove the vent plugs and fill with 1.300 electrolyte (approximately 2½ parts by volume of distilled water and one part by volume of chemically pure sulphuric acid); allow to stand for twelve hours, adding 1.300 electrolyte, if necessary to obtain the proper level in the cell.

Then charge at the rate specified on a name plate for not less than sixty hours, or until the gravity stops rising, adjusting the gravity at the end of the charge to 1.300 sp. gr. at 70° F.

The temperature during the charge should be kept below 110° F.

While charging, add distilled water to replace any electrolyte lost by evaporation. After charging, insert the vent plugs.

Important: If the temperature exceeds 110° F. during charge, the current should be reduced and the time lengthened proportionately.

Never fill with acid, the temperature of which is over 90° F.

It is very important that the instructions be followed carefully, as too much acid or improper charging rates will ruin the plates.

TYPE AND SIZE OF CELL	Charging Rate Amperes	Minimum Ampere Hours
KZ-3 ZA-5	½	50

Fig. 2. **Table for initial charge and repair charge** of Exide batteries.

BATTERIES IN STORAGE[1]

It is necessary to put batteries into storage:

1. When a car is to stand idle for a considerable period, as when it is held for future delivery.
2. When a car is laid up for the winter.
3. When batteries are kept in stock.

Should it be "dry" storage or wet storage? That depends on the condition of the battery.

Any battery which is to be out of commission should, if possible, be put into **wet storage,** providing it will not soon require dismantling, in which case it should be put into **"dry"** storage.

"Dry" storage requires no attention during the storage period. The battery must, however, be dismantled and reassembled, and if its condition is such that this will soon be required, anyway, dry storage is obviously the better method.

Putting a Battery into Dry Storage

1. Provide a dry place for storage, free from dust.

2. Have on hand enough "pure" water to fill all the cells.

3. Empty the battery solution by tilting and turning over the battery, and immediately replace the solution with the water.

4. Allow the battery to stand filled with water for approximately ten to fifteen hours.

5. Give the battery a charge, as outlined in the first five items of "Charging a Battery after Repairing" (page 590).

6. Unseal the cells and pull out of the jars the elements complete with covers, that is, without removing the sealing nuts.

7. Remove the separators.

8. Wash the plates by dipping them several times in water.

9. Replace the separators, using new ones for the wood separators. Be sure these are thoroughly saturated (see page 588: "When New Separators Are Necessary"). Where there are rubber separators, they may be used again, if they are not broken or cracked.

10. Pour the water out of the jars.

11. Put the elements back into the jars and reseal before the negatives dry out.

12. Put a tag on each battery, giving the date put into storage.

13. Replace and tighten filling plugs.

14. Within twelve months put the battery into service, as outlined on page 576 ("Putting an Unfilled or Bone-Dry Battery into Service"). (It is preferable to do this immediately and then keep in wet storage on "trickle charge.")

15. If it is impossible to reseal the cells, proceed as in items numbered 1 to 6 inclusive (above). Then remove the wood separators and throw them away. Where there are rubber separators, replace them between the plates. Allow the plates to drain and to become thoroughly dry. Pour the water out of the jars. Put the elements back into the jars, but do not seal.

Putting a Battery into Wet Storage

1. Provide a bench or shelf in a convenient location and of sufficient size to allow a little air space all around each battery.

2. Place the batteries upon wood strips in order to keep the bottom of the batteries clear of the bench.

3. Install the necessary wiring, switches, and charging resistance, so that batteries can be easily connected up and charged where they stand on the bench.

4. Apply vaseline freely to the battery terminals and to the exposed copper wires.

5. Batteries may be kept in wet storage by means of either the "trickle charge" or "periodic charge" method.

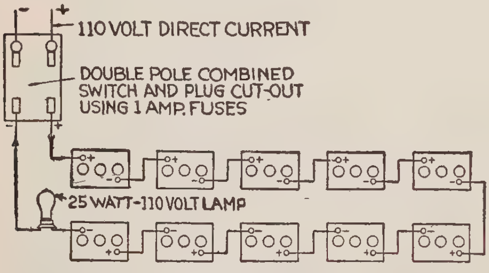
---

[1] From the Exide instruction book.

Trickle Charge

When a number of batteries are to be held in wet storage, the most satisfactory results can be obtained by **charging continuously at a very low rate,** which is so low that gassing is avoided and yet gives enough charge to maintain the batteries in good condition.

This charge is termed a "trickle charge," and in many cases will be found more convenient to arrange for than the "periodic charge." It has the added advantage of keeping the batteries in condition for putting into use at any time on short notice.



110 VOLT DIRECT CURRENT
DOUBLE POLE COMBINED SWITCH AND PLUG CUT-OUT USING 1 AMP. FUSES
25 WATT-110 VOLT LAMP
-
+

Fig. 3. Diagram of connections for "trickle charge," showing ten 6-volt type XC-13 batteries.

How to Apply a Trickle Charge

1. Give a bench charge.

2. Connect a tungsten lamp or lamps of appropriate resistance in series with the cells, across a charging system adapted for continuous charging.

Fig. 3 gives an example of connections for a "trickle charge," and the table below gives suggested lamp resistances to provide proper rates for various numbers and sizes of cells of the Exide make.

3. Every two months interrupt the "trickle charge," remove filling plugs, add water to the bottom of the filling tubes, replace and tighten the filling plugs, and continue the "trickle charge."

Type and Size of Cell		KXD-5 or 7 LX or LXR-5 SX-9 XC-9	JX-11, 13 or 15 KXD-9 or 11 LX or LXR-9 to 13 LXRE-9 or 13 SX-13 XC-11, 13 or 15 XE-13 or 15	JX-19 LX or LXR-15 or 17 LXRE or LXRV-15 or 17 MHA-11 PHA or PHC-13 XC-17, 19 or 21 XE-19 or 21
Approximate Current		0.05 Ampere	0.10 Ampere	0.15 Ampere
Number of cells. (Usually three cells to a battery)	3	5 15-watt lamps in series	3 25-watt lamps in series	2 25-watt lamps in series
	30	2 15-watt lamps in series	1 25-watt lamp	1 25-watt lamp
	45	1 15-watt lamp	2 25-watt lamps in parallel	3 25-watt lamps in parallel

Fig. 4. Tungsten lamps to use for a "trickle charge." Lamps are rated at 110 volts. Combinations given are to be used in series with batteries across a bus of 105 to 115 volts.

Periodic Charge

This is a method of wet storage in which the batteries are given charges **periodically,** and is used where it is not practicable to arrange for the "trickle charge" method.

How to Apply a Periodic Charge

1. Give a bench charge.

2. Store in a dry, clean location, and keep the temperature above freezing and below 110° F.

3. Once every month remove the filling plugs, add distilled or other "pure" water to the proper level, replace, tighten the filling plugs and charge for five hours at the proper rate given in the "bench charge table" (Fig. 1, page 573).

4. Before putting the battery into service, add "pure" water and give a bench charge.

QUESTIONS AND ANSWERS ON CONNECTING A 6 AND 12-VOLT BATTERY

Q. 1: If a 12-volt battery is connected to a 6-volt battery: positive (+) to positive (+) and negative (−) to negative (−), as in Fig. 1, what would be the voltage?

Ans.: The resultant voltage impressed on the circuit would be 6 volts in the direction of the 12-volt battery and opposed to the direction of the 6-volt battery. The 6-volt battery would be charged at 6 volts.

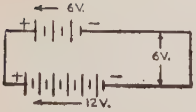


FIG.1

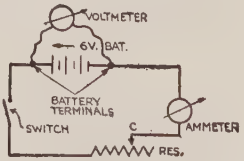

FIG.2

Q. 2: What amperage would flow to the 6-volt battery?

Ans.: This would depend upon the resistance of leads, internal resistance of the 6-volt battery, and internal resistance of the 12-volt battery.

First, it will be necessary to find the ohms resistance of the 6-volt battery; therefore we will insert a resistance wire into the circuit as in Fig. 2.

On an open-circuit test of the 6-volt battery we will assume that it tests 6.25 volts with a voltmeter across the (+) and (−) terminals with the switch open.

We will now discharge the battery by closing the switch and cutting in resistance. At (C) we will say the discharge is 302 amperes and the voltage drops to 2.98 volts.

Thus at a 302-ampere discharge the voltage has dropped from 6.25 to 2.98, or a drop of 3.27 volts. (These are only approximate figures.)

The ohms resistance would then = volts dropped ÷ amperes, or 3.27V ÷ 302A = .0108, or approximately .01 of an ohm resistance of the 6-volt battery.

We will assume, for the purpose of explanation, that the ohms resistance of the 12-volt battery is twice that of the 6-volt battery, or .02 of an ohm.

Therefore, to find the amperes that would flow to the 6-volt battery from the 12-volt battery (not considering the resistance of the leads, connections, etc., which is negligible), we will proceed as follows:

Amperes = volts ÷ resistance, thus:

$$\text{Amp.} = \frac{6 \text{ volts}}{.02 \text{ ohms (R)} + .01 \text{ ohms (R)}} = \frac{6 \text{ volts}}{.03 \text{ ohms (R)}} = 200 \text{ amperes.}$$

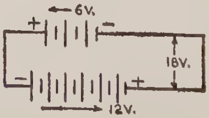

FIG.3

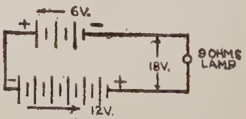

FIG.3A

Q. 3: What would be the voltage of battery if the 6-volt and 12-volt battery were connected together (in series) as in Fig. 3: (+) to (−), as shown?

Ans.: The resultant voltage would be 18 volts. in the direction of both batteries. Both batteries would discharge. If the 6-volt battery was **discharged,** it would be charged in an opposite direction, thus reverse-charging or depolarizing the plates.

Q. 4: At what ampere rate would the 12-volt battery charge the 6-volt battery if the 6-volt battery was completely discharged?

Ans.: Considering the ohms resistance as .02 ohms for the 12-volt and .01 for the 6-volt battery, it would figure approximately thus:

$$\text{Amperes} = \frac{12 \text{ volts}}{.02+.01(\text{R})} = \frac{12 \text{ V}}{.03(\text{R})} = 400 \text{ amperes}$$

Q. 5: Suppose a lamp of 18 volts, drawing 2 amperes, was placed across the circuit (Fig. 3A). What would be the ampere discharge and voltage?

Ans.: The voltage would be the same as in Fig. 3: 18 volts. The ohms resistance of the lamp would be found as follows: 18 volts÷2 ampere=9 ohms (or R). Therefore,

$$\text{Amperes discharge} = \frac{18 \text{ volts}}{.02+.01+9\text{R}} =$$

$$\frac{18 \text{ V}}{9.03(\text{R})} = 1.9933 \text{ amperes.}$$

Thus it is observed that there is quite a difference in the rate of discharge, where **batteries** are connected together as in Fig. 3, and where a **lamp** or other equal resistance is placed in the circuit.

We have assumed in these examples that the internal resistance of a battery while being charged is the same as its internal resistance while being discharged. This is not strictly true.

Q. 6: Isn't it the usual plan to connect batteries together as in Fig. 3, that is, to connect (+) to (−), and to connect several batteries together to charge them. Then how could a battery be charged in the wrong direction?

Ans.: By referring to Figs. 4 and 4A, the explanation will be made clear. In these illustrations only one set of plates is shown to make the explanation clear. One set of plates, to the right, represents the internal circuit of the 12-volt battery, and the set of plates to the left, the 6-volt battery.

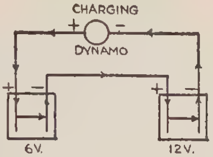

FIG.4

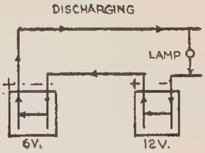

FIG.4A

Referring to Fig. 4: When batteries are being **charged,** connected (+) to (−), as shown, the current from the charging source must flow from (+) of the dynamo to (+) of the battery, and through the battery, (+) to (−), then to (+) of the next battery and (+) to (−) internally, to (−) of the dynamo, forming a complete circuit. This is as it should be.

When on a **discharge,** however, as in Fig. **4A,** note that if both batteries start fully charged, then the discharge current from the 12-volt battery would pass from (+) of the 12-volt battery to (−) of the 6-volt battery, and it is clear that the 6-volt battery would discharge in the same direction as the 12-volt battery, and depolarizing is not probable.

If, however, the 6-volt battery was **discharged,** the rule is to connect the (+) terminal of a charging source to (+) of the battery, and in this case, the direction of charging would be as in Fig. 4 (note the arrow in the 6-volt battery). However, as the (+) of the 12-volt battery (Fig. **4A**) is connected with the (−) of the 6-volt battery, it is clear that the current would flow in the **wrong** direction internally of the 6-volt battery, and the (−) plate of the 6-volt battery would become a (+) plate, and the (+) plate a (−) plate.

This is why we frequently find one cell in a battery having become depolarized, owing, probably, to internal troubles which discharged it, whereas the other cells are charged, and thus, as current is passing through this discharged cell in the wrong direction to charge it, it will be depolarized or the plates will be reversed in polarity.

Note. It is not advisable to charge a battery from another battery. The explanations given above are used for the purpose of making clear how one cell of a battery can sometimes be depolarized and then show opposite polarity from that of the other cells, if defective internally.

CONSTANT POTENTIAL BATTERY CHARGING

The method previously treated in this book might be termed a "constant current" system. It consisted of connecting a sufficient number of batteries in series to approximate a voltage of 110 or 220 volts supplied by a direct current charging line, there being an adjustable resistance so that the amperes can be properly adjusted to the battery requiring the lowest ampere charge. **The amperage is usually kept constant and the voltage varies** according to the state of charge of battery. This results in it being necessary to have the batteries on the line anywhere from 12 to 48 hours in order to charge them properly.

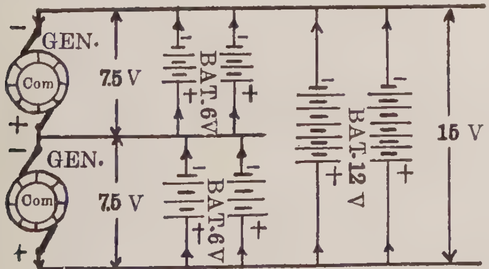

Fig. 5. Circuit of the Marshall-Chandeysson constant potential system (Marshall Electric Co., 3225 Locust St., St. Louis, Mo.).

The constant potential, or constant voltage method of charging storage batteries consists of connecting the batteries **in parallel** across the low-voltage 7½ and 15-volt circuit, instead of using a 110 or 220-volt line, and the **voltage, or potential, is held constant** regardless of load. Each battery will draw current from the constant potential bus bars in accordance with its counter-electromotive force or the amount to which the battery has been discharged. In other words, a battery fully discharged will draw more current than one which is only partially discharged. **No resistance is used.** The batteries are connected to the bus bars with as low a resistance as possible. Batteries can be charged in from 6 to 8 hours by this method.

In practice, a three-wire generator is usually employed, this generator having two commutators, one at either end of a single armature, and two separate and distinct windings, one connecting to each commutator. Such a generator will give a three-wire system, as shown in Fig. 5, the negative brush of one commutator being connected to the positive brush of the other. Such a system is capable of giving 7½ volts for charging 3-cell batteries and 15 volts for 6-cell batteries. In the smaller sizes a single-commutator, 7½ volt, two-wire generator is often used for charging 3-cell batteries. These generators are built in sizes from 125 to 200 amperes, 7½ volts rating, and also 300 amperes to 600 amperes, 7½ to 15 volt rating. Larger machines can be had if required.

The generator is shunt wound with an automatic voltage regulator in series with the shunt fields. This regulator is very sensitive in operation and insures a constant voltage at all times, regardless of load conditions. The shunt-wound generator also has the advantage that if current supply to the driving motor is accidentally shut off, the generator will operate as a motor in the same direction of rotation (on the battery current) and will not injure the batteries, whereas the compound-wound generator will reverse the direction of rotation with probable serious results.

Question 1: Why can a battery be charged at a high rate by the constant potential system, whereas by the series method it would cause heating and gassing which is injurious to a battery?

Answer: The charging of a battery by the constant potential method is tapered. The amount of current drawn by each battery will be dependent upon the condition of the batteries and how much they have been previously discharged. The ampere charge starts at a high value and tapers off rapidly as the battery builds up its counter voltage (c.e.m.f.) as it becomes charged. By the series method the current or amperage is constant, and the voltage varies and a certain amount of current is forced through a string of batteries. Under these conditions, if an accurately reading voltmeter is placed across the individual terminals of the several batteries in series, it will be found that there is quite a difference in the voltage or potential of each individual cell, this being due to the fact that some of the batteries are more run down than others. A battery that is almost charged, if in series with other batteries that are run down, will be forced to take a higher current than it should, and this current will be dissipated in heat and gassing

INSTRUCTION No. 52

EQUIPMENT FOR STORAGE-BATTERY WORK: Layout of a Shop for Storage-Battery and Electrical Work; Tools and Supplies; Charging Equipment

LAYOUT OF SHOP FOR BATTERY AND ELECTRICAL REPAIR WORK

The following layout for a storage-battery repair shop is taken from *Motor Age* and was prepared by Mr. B. M. Ikert. The layout is one that has many advantages, as will be noticed by a study of the illustration.

The space is divided into two sections (A) and (B). The dimensions are given on the illustration.

(B) shows the layout of the room for battery work, such as for charging, putting in new plates, new separators, new jars, burning-in straps, discharging and testing.

The room is 12′ x 19′ and is a part of the "Service Station," as shown on page 691.

(A) shows layout of a room for the electrical department for starting, lighting and ignition work, such as putting in new brushes, new windings, testing and repairing armatures (if the job is not too complex), undercutting mica in the commutator, recharging magneto magnets, putting in new condensers in magnetos, timers and coils, regulating the charging rate of generators, testing and repairing electric horns. Each of these subjects is explained in this book. See the Index under the appropriate captions.

Supplies should be carried in the electric department, such as lamp bulbs, spark plugs, fuses, condensers, generator and motor brushes, timer points for Delco, Atwater-Kent, and Connecticut ignition timers.

A Wiring Diagram Book for tracing circuits is very important. On the subject of electric testing instruments, see Index.

Tools and Spare Parts for Storage-Battery Work

Anyone undertaking to care for or repair batteries will in time gather together the equipment he considers necessary or desirable for the work. Many of the tools are questions of personal taste or present equipment, but there are four things absolutely essential:

1. Suitable charging equipment (see "Charging Apparatus").
2. A hydrometer syringe.
3. A battery thermometer.
4. A lead-burning outfit.

In addition, tools and equipment must be available for the following purposes, and suggestions are here given along with the list of purposes.

1. To read battery or cell voltage: a portable voltmeter, such as a Weston, model 280, or model 301, or model 45.
2. To remove connectors: a brace with 5/8″ and a 3/8″ wood bit.
3. To tighten or loosen sealing nuts: a special wrench. There are three sizes.
4. To tighten or loosen tie bolts: a screwdriver, or else a special spanner bit.
5. To unseal covers: a putty knife. See Fig. 2 (9).
6. To remove element from jar: two pairs of 6″ or 8″ gas pliers. See Fig. 2 (10).
7. To prepare surfaces for lead burning: knife, scraper, wire brush, file or end-cutting pliers.
8. To handle sealing compound: receptacles in which to heat and from which to pour.

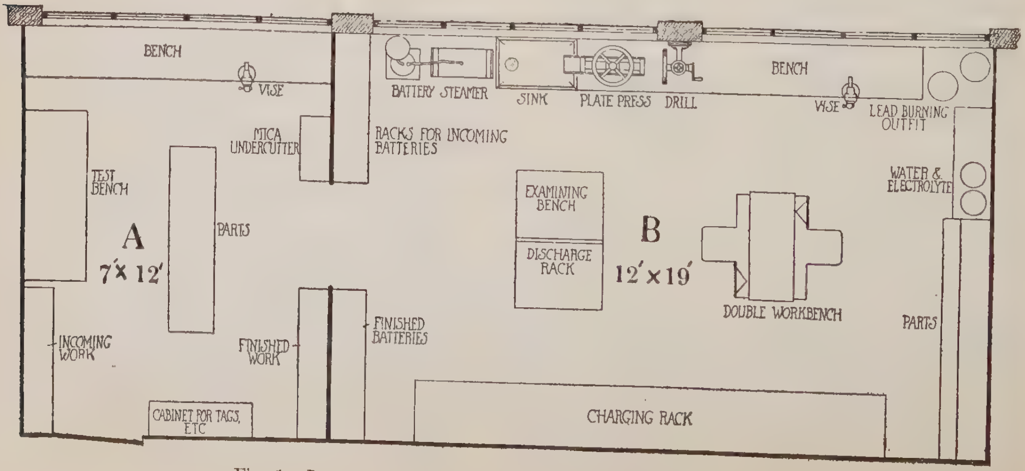

Fig. 1. Layout for a shop for battery and electrical repair work.

. To handle electrolyte: non-metallic or lead vessels for storing, mixing, and pouring; rubber gloves or fingers for protection; soda or ammonia solution for neutralizing effects of spillage or sloppage.

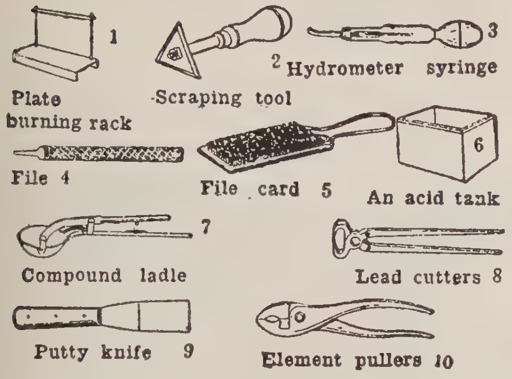

Fig. 2. Small tools for battery work, as follows:

1. **Plate-burning** rack.
2. **Scraping tool** for cleaning parts to be burned.
3. **Hydrometer syringe** for testing and mixing electrolyte.
4. **File for cleaning lead** before burning, 10″.
5. **File card** for cleaning lead from file.
6. **An acid tank,** lead-lined for mixing acid, storing and soaking separators 24″ x 36″ x 24″. Separators, when new, are usually dry and should be soaked in a weak solution of electrolyte before using.
7. **Compound ladle** for melting sealing compound.
8. **Lead cutters** for cutting excess lead and for cutting post straps to necessary size.
9. **Putty knife** for scraping sealing compound.
10. **Element pullers,** or regular gas pliers.

Rubber gloves (not illustrated).

Thermometer for determining temperature of electrolyte in cells.

Lead funnel for filling batteries with electrolyte.

Supplies, Parts, and Instruments for Battery Work

A stock of spare battery parts should, of course, be kept on hand, and with these should be included:

1. **Compound for sealing jars** and surrounding jars. This can be made of gum asphaltum 50 per cent, paraffine wax 25 per cent, and resin 25 per cent, melted together. Battery stations usually buy this compound in bulk.
2. **Solution for making battery box acid proof** (see page 585). This can be purchased at battery supply houses.
3. **Electrolyte** 1.400 or 1.300 sp. gr. test should be kept in a closed stone or glass vessel. Electrolyte is sold by manufacturers. Electrolyte is mixed with water to the density required when using.
4. **Distilled water:** A supply should be kept on hand for battery use.
5. **Extra battery connectors** should also be kept on hand, as well as other connections and parts, such as extra jars, covers, vents, separators, etc.
6. **Pure lead** (10 lbs.) for burning connections together.
7. **A 10 lb. bundle of antimony** and lead bars for burning to straps.
8. **Burning strip** for lead burning.
9. **Glass tube** for testing the acid level.
10. **Volt-ammeter** with a scale 0-30 volts and 0-3-30 amperes is indespensable to the battery repairman.
11. **Cadmium voltmeter.**

Equipment for Battery Work

The following illustrations and itemized list suggest an equipment suitable for battery work.

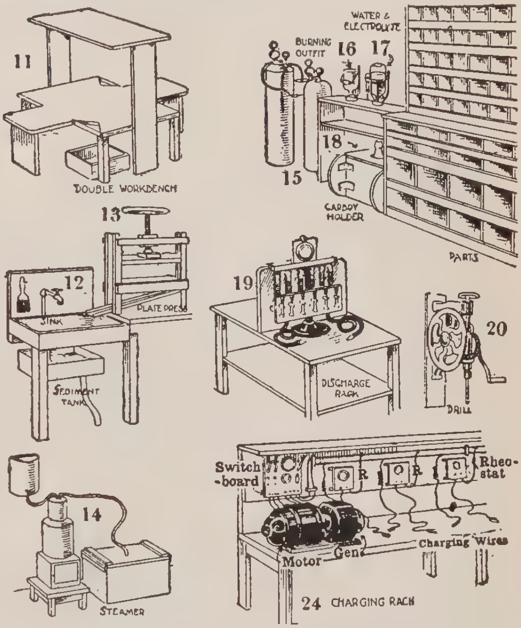

Fig. 3. Equipment for storage-battery work (suggested by *Motor Age*) as follows:

11. **Work bench** and seats.
12. **Sink** for washing plates, etc.
13. **Plate press.** In discharged negative plates the active material is bulged out and must be pressed back flush with the grids. As the acid is pressed from the plates, it flows into lead-coated troughs. Length of jaw of press, 19″.
14. **Battery steamer** for softening the sealing compound so that it can be opened.
15. **Lead-burning outfit.**
16. **Distilled water.**
17. **Electrolyte.**
18. **Carboy of acid.**
19. **Battery-discharging outfit** for discharging battery.
20. **Post drill** to drill top of connectors.
24. **Motor-generator battery-charging outfit.** A rectifier or other methods could be used.
25. **Shelf and bins** for spare parts.

LEAD-BURNING

The parts of a battery which must be burned together by melting the parts to be joined are the post-straps to the plates, connecting links to the post and terminals to the posts, and lead terminals on the battery cables.

Methods for lead-burning are as follows:

1. By an **electric arc.**
2. By **gas,** or a combination of gases.
3. By a well-tinned **soldering iron,** with pure lead as a solder.

The Electric Arc for Lead Burning

The electric arc method consists of one terminal of a spare 6-volt battery connected to the terminal to be burned on the battery being repaired. Clamp (C) (Fig. 4, page 582) is connected to other terminal of the spare battery, or on one of the connectors of the adjoining cell, depending upon whether the battery is partially discharged or fully charged. In the latter case, 3 cells will give too much voltage. The number of cells should be sufficient to heat the carbon (CR) to at least a bright cherry red while it is in contact with the joint.

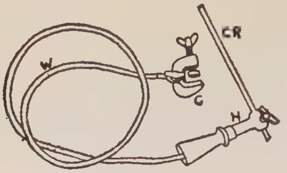

Fig. 4. An electric arc lead-burning outfit.

At the end of cable (W) a carbon holder (H) should have a piece of carbon (CR) sharpened to a long point like a lead pencil which should project not more than 3″ from the holder. When contact is made at the terminal to be burned, this completes the circuit and an "electric arc" is formed. This outfit is not meant to be used where considerable lead-burning is done.

Although this is called the "arc burning outfit," more satisfactory results can be obtained by using the carbon, after it becomes heated, like a soldering iron, without actually drawing an arc.

The carbon should be cooled off occasionally by plunging it, carbon and all, into a pail of water. After being used for a short time, it will be found that the carbon will not heat properly, because of a film of scale that will be found to have formed on the surface. This should be cleaned off with a knife, or file, as occasion requires.

As in the case of flame-burning, additional lead to make a flush joint should not be added until the metal of the pieces to be joined has melted. The carbon should be moved around to insure a solid joint at all points. The electric arc outfit can be secured of the Electric Storage Battery Co., Philadelphia, Pa.

Lead-Burning with Gas

Where there is considerable work of this sort to be done, gas or a combination of gases should be used. Different methods are explained on this page. In addition to using the flame for lead-burning, it can be used for welding light metals.

Gases which can be used, other than as stated on this page, are hydrogen and oxygen, hydrogen and compressed air. The combinations most used, however, are those shown in Figs. 5 and 6 following. The illuminating gas and compressed air can be used, but it does not give as intense or hot a flame as the combinations shown in Figs. 5 and 6.

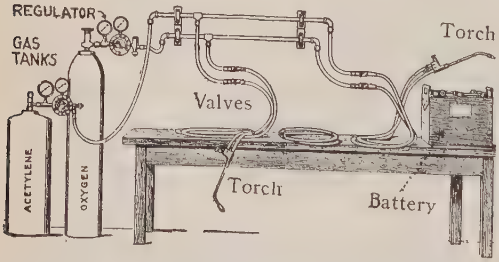

Fig. 5

Fig. 5. Imperial **lead-burning outfit for use with acetylene and oxygen.**[1] Consists of type F oxygen regulating valve with 15 lbs. pressure gauge; type 10R acetylene constant pressure regulator; 35′ 3/16″ rubber hose; bench-block with 2 needle valves; type L lead-burning torch with 4 tips; 1 wrench ($25). A torch with 4 tips, bench-block, 16 ft. hose can be had for $9, where one is already equipped with a welding outfit using oxygen and acetylene. This method gives four times the intensity of heat that is provided by the method shown in Fig. 6.

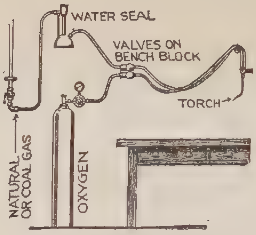

Fig. 6

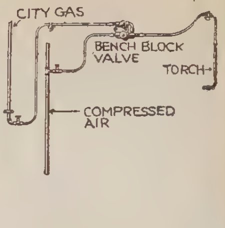

Fig. 7

Fig. 6. Imperial **lead-burning outfit for use with illuminating (hydro-carbon) gas or natural gas and oxygen**[1] in high-pressure tanks. Consists of same outfit as shown in Fig. 5, except that an Imperial hydraulic back-pressure valve and purifier for coal gas or natural gas takes the place of the acetylene regulator and type L-2 lead-burning torch is provided ($25).

Fig. 7. Imperial **lead-burning outfit for use with illuminating (city) gas and compressed air.** On account of the relatively lower temperature of this flame, this outfit works much more slowly than the others, but costs less to operate. Air pressure is obtained from a compressed-air tank which is used in most garages for filling tires. The outfit consists of a type O Imperial torch; type O bench-block; 17 ft. hose; gas shut-off cock; air shut-off cock ($12)[1].

The gases, therefore, which can be used for lead burning are:

Acetylene and oxygen.
Illuminating or natural gas and oxygen.
Illuminating gas and compressed air.

Acetylene and oxygen, as illustrated in Fig. 5, are used most.

To use gas, it is necessary to have the proper kind of lead-burning torch, and also two valves for properly mixing the gases to control the size of flame, called the "bench block." In addition, rubber hose and regulators on the gas tanks are necessary. See Index, under "Gas torches."

Soldering Iron

In the absence of a lead-burning outfit, a fairly good job can be done by using a very hot, well-tinned soldering iron, with pure lead as a solder. This however is not advised, except for temporary work.

Pointers on Lead-Burning

Cleaning surfaces: In all lead-burning, absolutely clean surfaces are essential to good workmanship. Lead is soft and very readily cleaned with a scraper or file. In the case of a battery which has had electrolyte in it, the surface to be burned should first be wiped with ammonia to neutralize the acid, and then allowed to dry before scraping.

Before starting to burn,[2] the connector or terminal should be lightly tapped to a snug fit on the post. The top of the post should be $\frac{1}{8}$″ below the top of the connector to allow space for burning. If the post is too long, remove the connector and trim off the post.

Method of burning: The top of the post should be melted first, then fused to the connector, after which lead from a piece of burning strip can be run in until the joint is flush.

The color of the flame, when using gas and air, should be greenish. If too much air is being used, the color will be blue, and the flame will gradually become invisible and deficient in heating power.

---

[1] Can be secured of the Imperial Brass Mfg. Co., 1200 W. Harrison St., Chicago, Ill.

[2] In order to avoid the possibility of an explosion of the gaseous mixture when using a flame near a battery, place the filling plugs in the battery and cover the entire battery with a wet cloth, pressing it down over the vents of the cells, except on that part on which the burning operation is to be performed. The gases can also be removed from the cells by blowing them out with compressed air.

Questions and Answers on Lead Burning with a Blow Torch

Q. 1: Can a blow torch generating 1,500° F. be used for lead burning on a storage battery?

Q. 2: If not, can a double-jet torch generating 3,000° F. be used for the burning?

Ans.: Lead melts at approximately 600° F., from which note that either of the torches mentioned produces sufficient heat for lead burning, but it is also necessary that the torch produce an extremely small and concentrated needle-point flame for successful lead burning on storage-battery work. Note therefore that heat alone is not sufficient for lead burning, but the required heat must be combined with the needle-point flame.

MISCELLANEOUS BATTERY REPAIR DEVICES

Moulds for battery parts: Junk lead can be used for making connectors, terminals, pillar posts, etc., with moulds as shown in Fig. 8.[1]

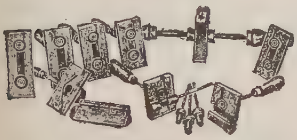

Fig. 8

Fig. 9

Battery clips: The battery clips shown in Fig. 9 are handy for snapping over battery terminals. They can be secured of the Muller Electric Co., Cleveland, Ohio.

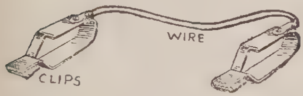

Fig. 10

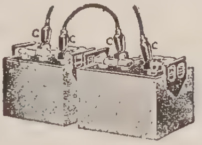

Fig. 11

Flexible service connectors: A very serviceable jumper lead or connector is shown in Fig. 10. It is handy for connecting batteries when charging, testing, etc., as shown in Fig. 11. They can easily be made by soldering cable to two of the battery clips.

Lead-Burning Rack

When burning post straps to the plates, great care should be exercised that the plates are kept a proper distance apart. The Ambu plate-burning racks are shown in Fig. 12.

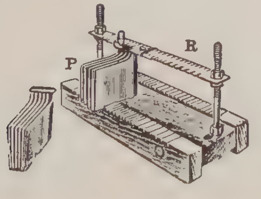

Fig. 12

In the work of burning-in plates, great care must be exercised to see that the plates are kept the proper distances apart. The Ambu plate-burning racks accomplish this work in half the time required with ordinary racks; the plates are held at exactly the correct distances apart. The single plates are set in the rack and rest in the slotted grooves of their particular size. Special fittings are used to simplify the work and to hold the plates in position. These fittings also prevent the hot lead from running away when burning, and permit of puddling the lead.

There are two types of plate-burning racks:

Type "A," the small rack, will take care of practically all 1/8″ plates, such as Exide 3XC, Willard, Gould, Philadelphia, and U. S. L. On this rack there are two slot groups, one group having slots of 5/32″ and 7/16″ between centers; the other has slots of 1/8″ and 3/8″ between centers. Price $8.00.[1]

Type "B," the large rack, is designed to care for over 95 per cent of all types of plates made. There are six slot groups on this rack, as follows: 5/32″ and 29/64″ between centers; 7/32″ and 5/8″ between centers; 5/32″ and 31/64″ between centers; 5/32″ and 7/16″ between centers; 1/8″ and 3/8″ between centers; and 3/16″ and 3/4″ between centers. Price $12.50.[1]

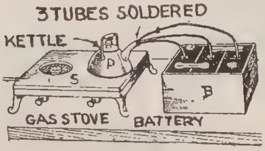

Fig. 13

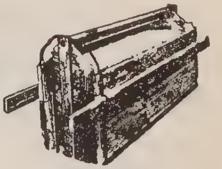

Fig. 14

Fig. 13. A home-made steam generator for softening the composition, so that the battery top may easily be removed. Consists of kettle (P), gas stove (S), and tubes. Steam is generated and passed into the cells. The acid should first be removed with a syringe.

Fig. 14. Crating a battery for shipment; note its shape in illustration. Inside diameter should be 2″ larger than the battery and the crate should be stuffed with excelsior. Label: "Handle with care—ACID."

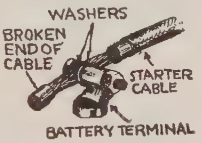

Fig. 15

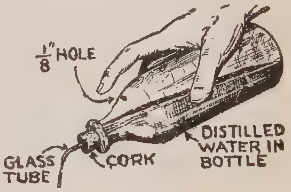

Fig. 16

Fig. 15. Method of making a temporary battery terminal.

Fig. 16. Method of refilling a battery with distilled water. Note the 1/8″ drilled vent-hole in the bottle. A glass or quill can be used for a spout.

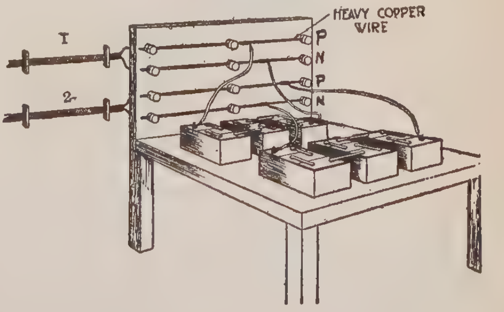

Fig. 17. Simple method of connecting many individual batteries to one pair of supply wires. (P) and (N) are large bare wires; (1) and (2) are separate circuits. Smaller leads to individual batteries can be made.[2]

---

[1] The Campbell Engineering Corpn., Kansas City, Mo., supplies moulds as shown.

[1] Can be secured of A. L. Dyke, Electrical Dept., Granite Bldg., St. Louis, Mo.

[2] From *Motor Age* and *Motor World*.

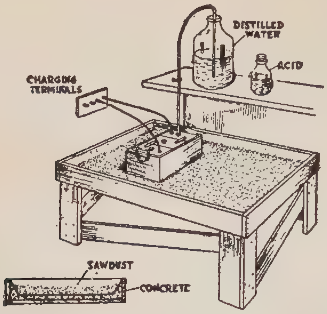

Fig. 18. **A special battery bench** with concrete basin filled with sawdust serves to make the battery work cleaner. The sawdust absorbs the acid.

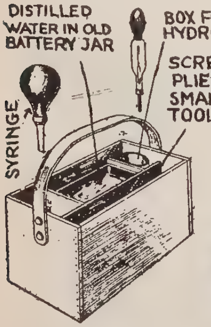

DISTILLED WATER IN OLD BATTERY JAR
BOX FOR HYDROMETER
SCREW DRIVER PLIERS AND SMALL TOOLS
SYRINGE

Fig. 19

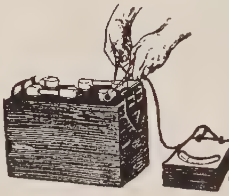

Fig. 20

Fig. 21

Fig. 19. **Battery service kit.** A rectangular box is divided into four compartments, as shown. One contains the hydrometer, in a cylindrical pasteboard box for testing; the second contains distilled water, in an old battery jar for replenishing water; a third holds a syringe for placing the water in the battery. The fourth space runs the entire length of the box, and is used for miscellaneous tools, such as screwdriver, pliers, meter, etc.

Figs. 20 and 21. **Voltmeter and copper contact, or test-points for testing voltage of cells.** The points can easily be made by using file handles and heavy copper cable ground to a point, with flexible leads wrapped around the upper part of the points (Fig. 21), and sweated on with solder.

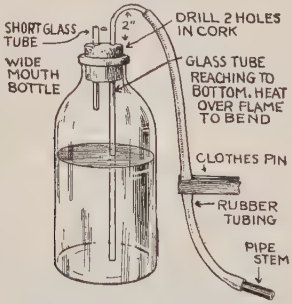

Fig. 23

Fig. 23. **The principle of the syphon** may be used in many places in repairshop work. For example, it provides a simple method of drawing distilled water for the storage batteries. A glass tube extending to the bottom of the bottle is inserted in the cork and a rubber tube is attached as shown. The end of the rubber tube must extend below the bottom of the bottle; consequently it is advisable to place it on a shelf. The tube may be made long enough to reach to the storage batteries. The flow of water is controlled by a simple spring device which pinches the tube. This may be made, or purchased at a drug store.

To put the syphon in operation it is merely necessary to suck on the tube until it is filled with water. Once this is done the water will remain in the tube and the syphon will always be ready for instant operation until the bottle is emptied. The illustration (Fig. 23) shows how to construct a syphon. This is handy for keeping distilled water ready for instant use and free from dust, etc.

The same **principle may be resorted to for drawing gasoline from a tank, oil from a crankcase, or electrolyte from a storage battery,** and is adaptable to many other uses. Of course, it is usually more convenient to drain a gasoline tank or crankcase in the ordinary way, but sometimes the syphon principle will be found quicker.

Battery Steamer and Water Condenser

Battery steamer. The tubes (P) are inserted in the cells to be opened. The steam will quickly soften the sealing compound and prepare the battery so that the elements can easily be removed. Some of the electrolyte should first be removed with a syringe so as to give the steam a chance to circulate.

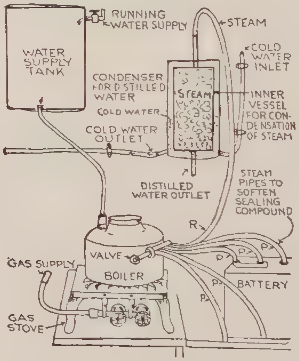

Fig. 22

Water condenser. Only pure water can be used in storage batteries. The best water to use for filling storage batteries is **distilled** water. Distilled water can be obtained at drug stores. Where considerable battery work is done it is best to have a condenser for distilling water, an example being shown in the illustration. Steam passes from the boiler through pipe (**R**), to a copper vessel, lined with bloc tin, inside of an outer vessel. Cold water circulates between the two. As steam passes into the copper vessel it is cooled (due to the circulation of cold water around it) and thus condenses into distilled water which is drawn off into an earthenware or glass vessel (not metal) at the distilled water outlet. This outfit sells for $27.50 and can be secured of American Bureau of Engineering, 2632 Prairie Ave., Chicago, Ill.

Note. All stills must be registered. Any revenue officer will register a still. This is a government requirement.

Melted artificial ice, or rain water can be used if distilled water cannot be obtained, providing it has not come into contact with metal pipes or roof. A good method of collecting rain water is directly into an earthenware vessel during a rain. The use of well or hydrant water or boiled or filtered water should be avoided as it is likely to contain iron or alkali detrimental to the plates.

MISCELLANEOUS STORAGE-BATTERY REPAIR INFORMATION

Corrosion of the terminals or other parts of the connectors should be prevented by coating them with vaseline or petroleum jelly. Sometimes they get so badly corroded that it is almost impossible to unscrew the terminals, and greasing them in this way will prevent recurrences of such trouble.

When overhauling a battery, it is a good plan to put all the connectors, terminals, and other removable pieces at the top in a strong solution of soda and hot water and to let them stay in it for about an hour, so that the solution will have plenty of time to clean them thoroughly. Then put on the vaseline, and no more corrosion should appear. In the first instance, corrosion is usually the result of overfilling the jars or spilling the solution, which in time acts upon the lead and brass terminals.

A Cracked Battery Jar

Never attempt to repair a cracked or broken battery jar, as this is impossible. When the jars get in this condition, they must be discarded as useless.

It is not very much trouble **to remove any cell from a battery,** because the makers have seen to this point. To take apart the connectors on a Willard battery, for instance, the procedure is to drill a 3/4" hole in the end of the connector, directly over the post. This hole should be drilled with any form of drill and about two-thirds through the connector, when the latter will come off readily. The connectors have to be burned back on, and more lead must be used to fill up the drilled-out hole.

To remove a cell from an Exide battery, the top nuts and connections must first be taken off, the nuts unscrewing in the regular manner (see page 586).

Celluloid jars can be repaired by making a cement of celluloid and acetone. Dissolve the celluloid in acid until it is gummy; then clean the seams and coat.

Cracked Compound

Sometimes the tar composition material that is on top of the cells cracks, and very often these become serious points of leakage of the cell solution. The best and simplest way to remedy these is to seal them together with a hot iron, such as an old cold chisel or similar tool. Press the hot iron on the sides of the crack and gradually work them together until the hole is sealed over. If more of the tar material is needed, a big lump of it can be secured from a battery supply house.

To Make a Battery Box Acid Proof

Use 6 parts of wood tar and 12 parts resin; melt them together in an iron kettle, after which stir in 8 parts of finely powdered brick dust. The surface to be covered must be thoroughly cleaned and dried before painting with this preparation, which should first be warmed.

Spilled Electrolyte

If there is evidence that electrolyte has been spilled from the cells, use electrolyte of 1.250 sp. gr., instead of water, to make up the loss.

After adding solution or water, replace and tighten the filling plugs by turning to the right, and give the battery a charge at the proper rate for the particular type of battery in question.

Never add electrolyte to a cell after the gravity has been adjusted to the proper point, unless to replace actual loss by spilling.

Prices to Charge for Battery Work[1]

Price for charging a starting and lighting battery which includes testing ....50c to $1.25

6-volt type	$ .50
12-volt type	.75
16-volt type	.85
18-volt type	1.00
24-volt type	1.25

These prices do not include changing of batteries. All changes not requiring more than 15 min., 25c. Batteries requiring more time to take out and replace will be charged for at regular labor rates.

Price per day for rental of a battery, while your battery is being charged, 10c to 25c.

Starter rental will not be installed until the generating system on the car has been tested and assurance is given that the battery will receive proper charge while the car is in use. A deposit to cover rental batteries is required.

Price for testing the electric system, other than disconnecting and connecting battery, per minute................1c to 2c

Price for repair work, per hour..................60c to $1.00

Notice: Storage batteries left over 30 days will be considered abandoned, and will be junked without recourse.

The foregoing is taken from a printed placard on the wall of a leading storage-battery repair shop.

Where to Obtain Supplies

It is best to order plates and parts of the manufacturer of the battery. Names of some of the concerns who handle supplies are:

General Storage Battery Co., St. Louis, Mo. (supplies and parts of all kinds).

Witherbee Storage Battery Co. (supplies in general), 643 E. 33rd St., New York.

Storage Battery Supply Co. (supplies in general), 239 E. 27th St., New York.

Address of Storage-Battery Manufacturers

Electric Storage Battery Co. (Exide), Philadelphia, Pa.
Witherbee Storage Battery Co., 643 E. 33d St., New York, N.Y.
General Storage Battery Co., 2005 Locust St., St. Louis, Mo.
Prest-O-Lite Co., 30 E. 42d St., New York, N.Y.
U.S. Light & Heat Corporation, Niagara Falls, N.Y.
Willard Storage Battery Co., Cleveland, Ohio.
Marko Company, 1402 Atlantic Ave., Brooklyn, N.Y.
Gould Storage Battery Co., 30 E. 42d St., New York, N.Y.
Amplus Storage Battery Co., 749 E. Van Buren Ave., Chicago, Ill.
Edison Storage Battery Co., Orange, N.J.
Vesta Storage Battery Co., 2100 Indiana Ave., Chicago, Ill.
Aurora Battery Mfg. Co., Aurora, Ill.
Permalife Storage Battery Co., Indianapolis, Ind.
National Carbon Co. (Columbia), Cleveland, Ohio.
Philadelphia "Diamond Grid" Storage Battery Co., Philadelphia, Pa.
E. S. Cowie Electric Co., Kansas City, Mo.
Detroit Storage Battery Co., Detroit, Mich.

Battery Parts

General Storage Battery Co., 2005 Locust St., St. Louis, Mo.
Aurora Battery Mfg. Works, Aurora, Ill.
Campbell Electric Co., 1529 Wyandotte St., Kansas City, Mo.

---

[1] Prices vary in different sections of the country. This is an example of prices charged by a concern in the West.

INSTRUCTION No. 53

REPAIRING STORAGE BATTERIES

To be able to repair storage batteries properly, it is necessary to have on hand the tools and supplies, as well as a lead burning outfit, as previously described.

The usual battery troubles are sulphating and buckling of plates, broken down separators, and sediment accumulation in the bottom of the jar.

When Repairs Are Necessary

1. A battery terminal or connector warmer than the others indicates a loose or poor connection, which must be repaired.

2. Broken, cracked, or leaky jars must be replaced; they cannot be mended.

3. A cell leaking around the cover should be resealed.

4. If the cause of trouble is not apparent, take hydrometer readings and make the high-amperage-discharge test, as described on pages 553, 559. If this indicates internal trouble, take the battery or the indicated cell apart and inspect it.

When to Take a Battery Apart

When one or more cells of a battery do not take a charge after being on charge for 24 hours, make a high-amperage-discharge test, and note the indications, as sugested in the "Digest of Troubles" and on page 553. Then make a cadmium test, as directed on pages 547 to 552.

If the tests prove defects to exist inside, then the battery must be disassembled.

Before disassembling, the defective cell should be located by testing, and inasmuch as other cells may be on the verge of a breakdown, it is advisable to disassemble all cells. If other cells are not defective, they should at least be washed, and have new separators added.

DISASSEMBLING BATTERY[1]

As an example, the Exide "3–XC–13" battery will be used.

Removing Connectors

The connectors are solid lead links (Fig. 1) or flexible lead-coated copper strips, and may be removed by taking a wood bit and boring the connectors ¼″ deep centrally over each post as shown in Fig. 2. For all but types KZ and ZA, use a ⅝″ bit, and for these a ⅜″ bit.

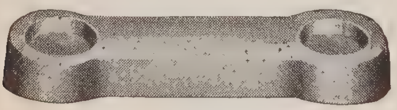

Fig. 1. A lead connector.

Another method is to play a burning flame on the joint, at the same time pulling the connector with a pair of pliers until it comes loose.

Be careful to see that no gas is coming out of the cell when handling a flame about it.

Unsealing Cells

1. Clean any dirt or lead from the top of the battery, taking care that none gets inside the cells.

2. Remove the filling plugs and blow gently into the filling tubes to remove any gas which may be there and which might ignite later when a flame is brought close. Hand bellows are convenient for this purpose.

3. Types JX, LX, LXR, LXRV, PHC, SX and XC have the single-flange type of cover, which has sloping sides flanged outwardly at the base to fit the inside of the jar snugly, while at the top it clears the jar, giving a space of about ¼″ for sealing (Fig. 3).

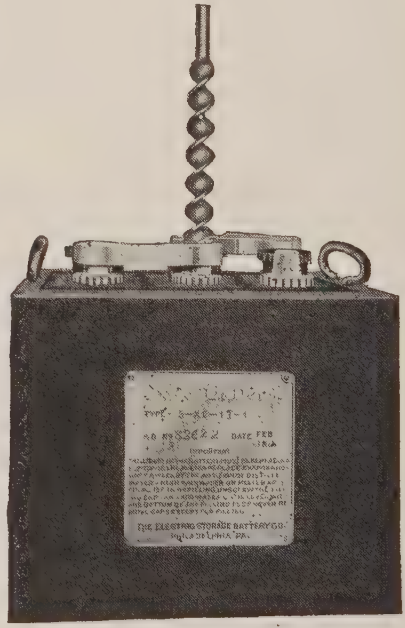

Fig. 2. Boring a lead connector.

To unseal, it is not necessary to remove the cell from the case. Heat a thin-bladed knife, such as a putty knife, and run it through the sealing compound close to the jar wall all the way around. This will loosen the compound and the element with cover attached can be pulled from the jar.

4. Types KXD, KZ, LXRE, MHA, PHA, XE and ZA have the double-flange type of cover, which is made with the two flanges projecting downward, one fitting inside and the other outside of the jar

---

[1] From Instruction Book of The Electric Storage Battery Co. (Exide); copyrighted, 1921.

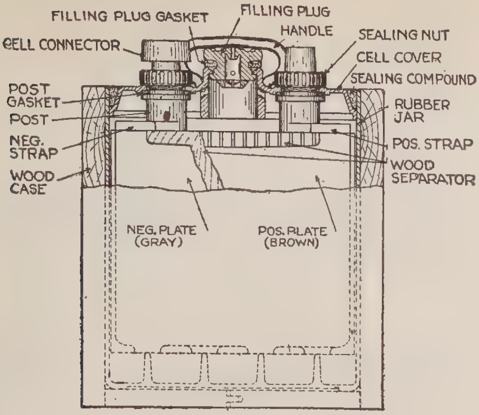

Fig. 3

walls. The two flanges form a channel or slot, holding the jar walls and sealing compound between the flanges (Fig. 3). To unseal, warm the cover all around the edges, and the compound will soften so that the element with cover attached can be pulled from the jar. The warming may be accomplished by passing a moderate flame around the cover, taking care not to hold it on one spot long enough to burn the rubber.

5. **A very effective way of softening the compound** for unsealing any type is to place the cell or battery in a steam box. This consists simply of a box or oven into which live steam is injected at low pressure. By this means, the rubber parts are made somewhat pliable and are much less likely to be cracked in handling, especially in cold weather. Another method is to stand the cell in very hot water, taking care that the water does not get inside of the cell.

Removing Elements from Cell

1. Remove the connections.

2. Unseal the cell. It is unnecessary to remove the cover from the element, but this may be done.

3. Take hold of the two posts with gas pliers and pull the element from the jar. If it should stick, pull the jar along with it and place the cell in very hot water to within an inch or so of the top of the jar. This will soften the rubber and permit the element to be pulled out.

4. Before pulling all the way out, let the element rest a few minutes on the top of the jar at an angle so that the battery solution may drain back.

5. If the element is to be used again, place it in water or in a battery solution until ready to use. This prevents the negative plates from drying out, and will save considerable time during the charge following reassembly.

Removing Jars from Case

1. Remove the connections.

2. Note at which corners of the case the battery terminals are placed, so that they will not be put at the wrong place upon reassembling.

3. Unseal the cells.

4. Remove the elements.

5. Types KXD, LXRE, MHA, PHA, XA and XE have the jars separated in the case by painted wood spacers divided horizontally, and between the two sections runs a tie bolt (Fig. 3). These bolts should be unscrewed one or two turns with a screwdriver, thus releasing the jars.

6. Heat a thin-bladed knife, such as a putty knife, and work it down all around the outside of a jar.

7. Lift out the jars. If they stick, empty the solution and fill the cells with very hot water, allowing them to stand a few minutes. Then pull them out with pliers.

Removing Covers from Cell

1. Remove the connections.

2. Remove the sealing nuts by unscrewing them with the special wrench designed for the purpose. Do not use gas pliers or anything except the proper wrench in removing the sealing nuts, because both the nut and the thread on the post are lead and may be injured.

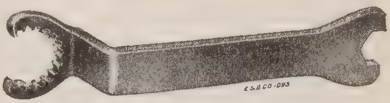

Fig. 4. Sealing nut wrench.

3. Unseal the cells as outlined above, and pull off the covers.

4. If the cell is out of the case and has a double-flange cover, the cover may be removed.

Procure two stout boards about ¼″ longer than the height of the jar and rest the side flanges of the covers on these so that the cell is raised. By warming the cover all around the edges, the compound will soften so that, by pressing down on the posts, the jar with the element in it will readily drop free from the cover.

Taking Elements Apart

1. The cover must be removed.

2. Lay the element down with the plates on edge.

3. Slightly spread the plates and withdraw the separators one at a time, first separating them from the negative plates by running a thin-bladed knife between.

4. The positive and negative groups can then be separated from one another.

5. If the negative plates are to be used again, do not let them dry, but place the group in water or in a battery solution. This will save time in the length of charge after reassembling.

To Tell When New Positive Plates Are Necessary

The positive plates should be examined particularly for washing out of material and buckling (warping).

If the plates are buckled so much that the element will not go back into the jar, the positives should be discarded.

If the plates are only slightly buckled, they can be replaced as they are, since this generally does no harm.

To Tell When New Negative Plates Are Necessary

The negative plates are nearly always in good condition mechanically, as they are not affected by abuse as readily as the positives.

If the positives are buckled, the negatives will be also; but if they are in a charged condition, they can readily be straightened as folllows:

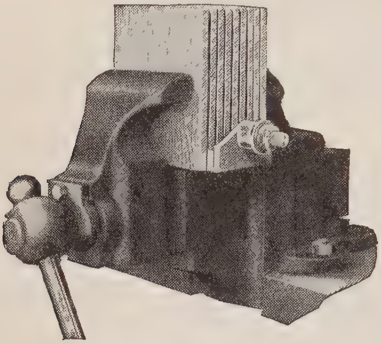

Fig. 5. Straightening plates.

Place boards of suitable thickness between the plates and outside of the group, and slowly apply a gradual pressure. This may be done in a vise, leaving the pile in the vise for some minutes during the operation to give the plates a chance to straighten without undue strain (Fig. 5).

If the battery has been badly abused, "starved," or neglected, the negatives may have shed material. In this case, it is best to use a new group. If the negative material is very hard and not spongy, it is "sulphated," and particular care should be used that the subsequent charge is made complete.

To Tell When New Separators Are Necessary

Unless a battery is new, it will be found advisable to install new separators whenever a cell is dismantled for repairs, since it is of vital importance in a battery to have the separators in good condition.

No wood separators should be used except the specially treated separators furnished by the manufacturer. These should be kept in stock wet, preferably in battery solution.

New separators may be dark, light, hard or soft, according to the kind of wood used. However, none of these qualities affect the value of a separator, which depends on its having been selected and treated properly, so as to have correct porosity and ability to withstand the chemical action of plates and electrolyte.

Before being used, separators should be soaked in battery solution, at least overnight, so that they will be thoroughly saturated before being put into the cell.

Perforated rubber sheets, when used, are nearly always in condition to put back unless broken in handling. It is advisable to carry a small stock of these for emergencies.

Sediment

The sediment in the bottom of the jars will rarely be found to have reached the plates, but whenever a cell is taken apart for any purpose, it is advisable to wash the sediment out of the jar.

In types KXD, LXRE and XE there are four soft-rubber buffers, each resting on one of the ridges in the bottom of the jar. These must be replaced.

Using Battery Solution Over Again

Sometimes impurities get into the solution through carelessness or ignorance, but their detection is not practicable except by an expert chemist. As a precautionary measure, the use of new electrolyte of known purity is recommended when repairing a battery.

When the positive plates are badly disintegrated, it is often a sign of foreign matter in the electrolyte, and in such a case it is safer to discard the negatives and separators as well, since they may hold some of the impurity and be the means of ruining the new positives in a short time.

To Tell When a New Case Is Necessary

Unless the jars have been broken or the battery has been abused in some manner, the battery case will usually be found to be in good condition. If the case has become acid-soaked and rotted, a new one should be used. When the old case is to be used again, it should be soaked in a solution of baking soda and water. This will neutralize any acid and prolong the life of the wood. Rinse with water and allow it to dry thoroughly Repaint the case inside and out with asphaltum or other acid-resisting paint.

REASSEMBLING BATTERY[1]

Replacing Elements

1. Slip the positive and negative groups together without the separators.
2. Replace the covers.
3. Insert the separators.

Replacing Covers

1. Place the covers in hot water for a while. This makes them somewhat pliable.
2. Wipe the posts with a piece of waste moistened with ammonia, rinse with water, and dry thoroughly with clean waste.
3. Place the cover in position, being sure not to omit the soft rubber washers under the cover.
4. Lubricate the sealing nuts with a little graphite mixed to a paste with water; but never use grease or vaseline.
5. Put on the sealing nuts and tighten them, using the special wrench (Fig. 4).

Inserting Separators

1. Place the groups on edge (Fig. 6) and insert the separators from the bottom, one at a time. One separator goes between each positive and negative plate with the flat side of the separator against the negative plate. Separators should be so placed that the grooves will be vertical and not crosswise when the element is in the jar.
2. Types KXD, KZ, LXR, LXRE, LXRV, MHA, PHA and PHC have, in addition, rubber sheets, one of which should be placed against the grooved side of each wood separator before inserting.
3. When all the separators are in place, count them to be sure that none are missing.
4. Stand the element up and tap the edges of the wood separators with a wood block until they project equally on each side of the plates.

---

[1] From Instruction Book of the Electric Storage Battery Co. (Exide); copyrighted, 1921.

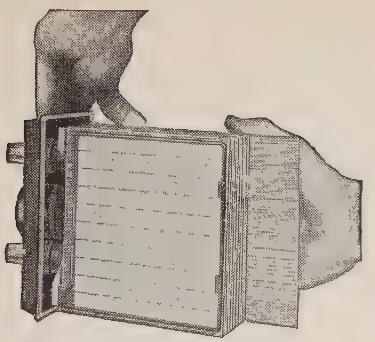

Fig. 6. Inserting separators.

5. Tighten up the sealing nuts, using the special wrench (Fig. 4).

6. Lock the sealing nuts.

Replacing Elements in Jars

1. Place the jars in hot water for a while. This makes them somewhat pliable and less likely to crack under stress.

2. In Types KXD, LXRE and XE be sure to replace first the four soft-rubber buffers in the bottom of the jar, one over each ridge.

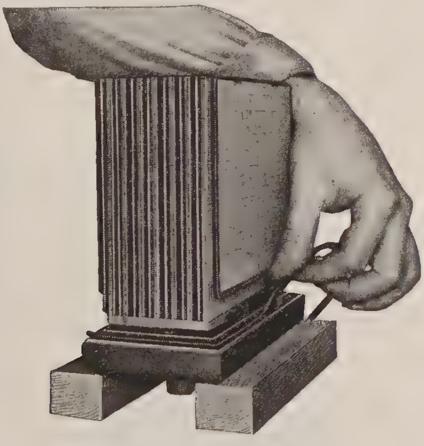

Fig. 7. Applying sealing compound to double-flange cover.

3. For Types KXD, KZ, LXRE, MHA, PHA, XE and ZA, which have the double-flange type of cover, have ready a string or worm of sealing compound about 3/16″ in diameter, made by rolling between boards some of the special compound furnished for the purpose. Stand the element upside down with the cover resting upon two strips (Fig. 7). Lay the string of compound all around the cover channel and then turn right side up.

4. Grip the element near the bottom, in order to keep the plates from flaring out. Take care not to let the outside plates start down over the outside of the jar.

5. The element should fit snugly in the jar. If it does not, place one or more wood separators between the end plates and the jar, taking care that such separators are cut ½″ narrower than the plate, so as not to throw extra strain on the corners of the jar. The ribs of the separators should go against the jar. Do not, however, crowd the jar so that it bulges.

6. Tighten the sealing nuts again and then lock them.

Sealing the Cells

1. Before sealing, always wipe the surfaces to be sealed with ammonia, and then allow them to dry thoroughly, otherwise the compound may not stick, and a leak may result.

2. For Types JX, LX, LXR, LXRV, PHC, SX and XC, which have the single flange type of cover, slowly heat the sealing compound until it runs, but do not get it so thin that it will run down into the cell between the cover and jar. Then pour it into the channel between the cover and the jar walls. Allow it to cool, and finish it off flush with a hot knife. When pouring, be sure the compound is liquid and not lumpy, as in such a case a poor seal will result. A glossy, finished appearance may be given to the compound by passing a flame over it after the job is finished.

3. For Types KXD, KZ, LXRE, MHA, PHA, XE and ZA the sealing compound should already be in the cover channels. Apply heat carefully to the edges of the cover and force the cover down gently. If too much compound has been used, so that it squeezes out around the cover, scrape off the excess with a hot knife while forcing the cover down.

When Cells Should Be Filled with Electrolyte

As soon as the cells are sealed, electrolyte of the proper strength should be added to keep the separators and plates from drying out.

Proper Strength of Electrolyte to Use

1. **After a complete renewal of plates and separators,** fill with electrolyte of the proper strength, as given on page 535.

2. **After a positive plate or separator renewal,** or both, fill with "pure" water instead of electrolyte, since batteries received for repair have the plates in a more or less sulphated condition. This filling with water, together with the proper charge after repairing (see "Charge required after repairing"), is known as the **"water treatment" for sulphated cells.**

How to Fill Cells with Electrolyte

1. Use vessels of glass, china, earthenware, rubber, or lead; never use metallic vessels unless of lead.

2. Carefully pour the liquid through the filling tubes until the level rises in the tubes. If the cover is not on the cell, fill to ½″ above the tops of the plates.

Replacing Cells in Case

1. Be sure to put the cells into the case properly, so that two positives or two negatives will not be connected together, and also so that the battery terminals will not come at the wrong corners of the case.

2. In Types KXD, LXRE, MHA, PHA, PHC and XE, which have wood spacers between the cells, take care that the spacers are in position and then, after the cells are in place, tighten the tie bolts with a screwdriver to clamp the jars.

3. In Types JX, LX, LXR, LXRV, SX and XC, the cells should fit tight in the case; pack them in with thin boards if necessary.

How to Make Connections

1. The cells must all be sealed and in the case.

2. Connectors must be lead-burned. First see that the posts and eyes of the lead connectors are clean and bright. In all lead-burning, absolutely clean surfaces are essential to good workmanship. Lead is soft and very readily cleaned with a knife, file, scraper, or wire brush.

Place the connectors over the posts, lightly tapping them to a firm seat.

Before lead-burning, blow into the filling tubes to remove any gas which may be there.

Lead-burn the joint by first melting the parts to be joined and fusing them together, and then immediately melt in burning strip until the joint is flush. Do not melt in burning strip until the parts have fused together nor after the joint has cooled, and do not use any soldering acid or other flux. A little practice may be necessary before a good joint can be made.

Recharging Battery after Repairing

Note. This method is also used for charging badly sulphated cells, and is known as the **"water treatment"** for sulphated cells.

1. Not sooner than ten to fifteen hours after filling a battery with electrolyte or water, as the case requires, add more to restore the level if it has fallen.

2. With filling plugs out, give the valves a quarter turn, bringing them into a position so that hydrometer readings can be taken. This is to allow of taking hydrometer readings while charging and at the same time prevent flooding, which might occur if the filling plugs were left out and the valves were not turned.

3. If a **complete renewal** has been made, start charging and continue at the amperes shown in the table under "Initial Charge and Repair Charge," page 577, until the battery has received at least the number of ampere-hours also shown. If this rate is maintained, the time required is ninety-six hours.

4. If a **renewal of positive plates or separators** or both has been made, charge at amperes shown in the same table, just mentioned, until all cells are gassing or bubbling freely and evenly, and until the hydrometer reading of every cell goes as high as it will. Then charge for ten hours longer.

5. If the hydrometer reading of any cell continues to rise above 1.310 (1.240)[1], dump the solution, refill with "pure" water, and continue to charge at the same rate until the hydrometer reading of every cell goes as high as it will. Then charge for ten hours longer.

6. Keep the temperature of the solution below 110° (125°)[1] F., interrupting the charge if necessary.

7. After the charge is complete, adjust the strength of the solution to between 1.270 and 1.300 (1.200[1] and 1.230[1]), as explained under "Exide Instructions for Adjusting Electrolyte," page 536.

8. Wipe off the top and sides of the battery case with a rag dampened with ammonia to remove any electrolyte that may have been spilled.

9. Just before putting the battery into service, make high-amperage-discharge test (see page 553).

THE EDISON STORAGE BATTERY

The elements of the Edison storage battery are as follows:

The positive plate, i.e., plates attached to the positive pole, are cylindrical tubes of nickelplated, perforated, spirally seamed thin steel ribbon, filled with alternate layers of a specially prepared nickel hydrate and flakes of pure metallic nickel; the former being the initial state of the positive active material, while the latter is the conductive medium. These tubes are hydraulically crimped at their flattened ends into nickelplated steel grids, a right-hand spiral alternating with a left-hand spiral for equalization of stresses.

The negative plate, i.e., plates attached to the negative pole, are rectangular pockets of nickelplated, perforated steel ribbon, filled with a solid mass of a specially prepared electrochemically active iron oxide and a small proportion of mercury oxide evenly distributed; the former being the initial state of the negative active material, while the latter is the conductive medium. These pockets are hydraulically crimped at their grooved edges into nickelplated steel grids.

The electrolyte is an alkaline solution consisting of specially prepared potassium and lithium hydroxide in distilled water.

Cell and battery voltage: At the 5-hour rate, or the normal rate of discharge, the average voltage per cell is 1.2 volts, while at the 8-hour rate of discharge the average voltage is 1.24 volts. Therefore, when it is desired to discharge at the 5-hour rate, 5 cells would be required for a 6-volt battery.

The advantages of the Edison cells are endurance, reliability, low maintenance, ruggedness, and light weight. The Edison storage battery is the only storage battery made of steel. Its long life is a leading feature in which it is without equal. Its reliability, low maintenance, and ruggedness are proverbial owing to the fact that there is very little sedimentation and, therefore, a very low maintenance, and owing to the fact that it is entirely built of steel, the battery is extremely rugged. There are no jars to break, and the abuses which are common to all types of batteries, which have been the causes of various diseases in the lead-acid type, are almost entirely foreign to the Edison battery, there being no such thing as sulphation, buckling, and growth of plates.

The light weight of the Edison battery is well known, it being for equivalent capacity from 20 to 25 per cent lighter than any other battery on the market, and in the case of the storage-battery vehicle this saving in weight on the battery may be added to the paying load that the vehicle can carry.

The Edison battery is particularly adapted to installations where ruggedness and reliability, not to mention long life, are the main factors. It is used for electric vehicles of all types, including electric trucks, tractors, industrial trucks, storage-battery locomotives, and the more severe classes of station battery work. It is not suited to gasoline automobile starting work, owing to the fact that its inherent characteristics making for reliability, endurance, low maintenance, ruggedness, and light weight prohibit the drawing of tremendous rates of current for short intervals, as is necessary in gasoline automobile starting work. There have been, however, numerous instances of the applications of Edison storage batteries to starting work on gasoline engines up and above the horsepower generally found on automotive vehicles.

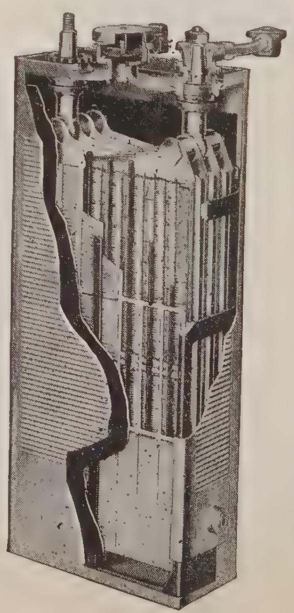

Fig. 8. Part sectional view of the Edison storage battery.

---

[1] The reading in parentheses applies to batteries used in tropical climates.

INSTRUCTION No. 54

TIRES

Tires are used on automobiles to overcome the vibration. If the wheels of an automobile were not properly tired, the machine would soon rack itself to pieces. The great weight and speed of the automobile, and its delicate construction, necessitate provision for protection additional to that of the springs alone.

There are two types of tires, the solid and the pneumatic. The **solid tire** is used to a great extent on electric vehicles and trucks, because they are usually slow-speed vehicles. If solid tires were used on high-speed cars, the vibration would be so great that the car would soon rack itself to pieces.

PNEUMATIC TIRES

The pneumatic tire is the type of tire used on all pleasure cars. With pneumatic tires, the car is suspended on air, which is the most elastic of substances. There are two forms of pneumatic tires: the single and the double tube.

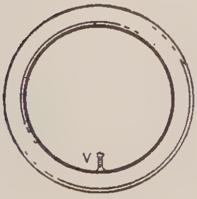

Fig. 1

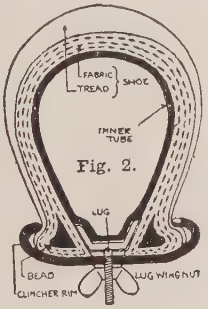

Fig. 2.

Fig. 1. The old-style and original pneumatic tire was a "single-tube tire." The casing itself held the air and did not contain an inner tube.

Fig. 2. The double-tube pneumatic tire. Note that the inner tube sustains the air.

Single-tube pneumatic tire. The first, and now obsolete, method, was a single-tube tire, made air-tight and without an inner tube. This type of tire was merely an outer casing made air-tight, and was fitted with an air valve. It was used extensively during the early days of motoring, but inasmuch as it is now obsolete, we will confine our instruction mainly to the modern type of pneumatic tire.

The double-tube pneumatic tire is the type of tire in general use. It consists of two chief parts: the "inner tube," which holds the air, and the "shoe" or "casing," which retains the inner tube, and protects it from wear (Fig. 2).

A steel rim is placed around the felloe of the wheel, and shaped to fit the tire, its exact shape depending on the design of the tire.

Double-tube tires have projections on the side, called **"beads,"** which fit under grooves or into channels in the side of the rim, the pressure of the air in the inner tube holding them in place.

Inner Tube and Valve Stem

Inner tubes used on automobile pneumatic tires are of the endless type. The only opening into the tube is the **inner valve** (A) (Fig. 3), through which the air is forced. As the tube becomes inflated by air pumped into it, the bead of the tire is forced outward and tightly clinches to the rim channel and can be dislodged only by deflating the tube.

The inner-tube valve-stem is the part shown in Fig. 3. It is the part to which the inner tube is connected as shown in Fig. 4, (T) being the inner tube. The base (G) of the valve-stem is passed through a heavy, tough piece of rubber, called the "valve-stem seat," which is vulcanized to the tube at this point. By stretching the opening in this valve-stem seat, the base (G) is placed inside of the tube and locked by clamp nut (ST) (Fig. 4).

The valve-stem is passed through a hole in the felloe of the wheel when the tire is applied to the wheel and the rim, as in Fig. 27, page 596. The stem is held rigid, after being applied in this manner, by locknut (N) and washer (M) (Fig. 3).

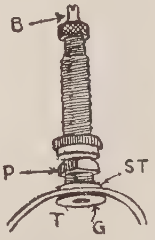

Fig. 4

Note method of clamping the air valve to inner tube.

DUST CAP
PAT. APR. 30 JULY 9 1907 SEPT. 5 1910 REG. U.S. PAT. OFF.
SCHRADER UNIVERSAL DUST CAP No. 2065

Fig. 6. **The dust cap** screws over the valve-cap into the valve-stem, thus protecting the inner parts of the valve-stem from dust, water, etc.

Inner-Valve Principle

The inner valve (A) (Fig. 3), also called the "valve plunger," is an automatic air check valve for retaining the air in the tube. It is screwed into the valve-stem opening, usually by the notched end of the valve-cap (B) as shown in Fig. 5.

(V) is the threaded part which screws into the valve-stem; (W) is metal, with rubber packing (D) around it, which makes an air-tight joint with the walls of the valve-stem; (Y) is a cap holding spring (S) in place, and on its upper part is a rubber washer which is the "valve-seat" which is between the bottom of (W) and the upper part of (Y). This is the seat, or point where the air pressure in the tube is retained because the lower part of (W) is in contact with the rubber washer seat on top of (Y), which is held together by the tension of the spring. This seat is shown open in the illustration.

Pin (U) is firmly attached to (Y), but works freely through enlarged holes in (V) and (W), and these holes also serve as the air passage to or from the valve-seat. The spring holds the valve to its seat, but can be depressed at (U), or air from the air pump will be sufficient to force the valve from its seat.

To inflate the tube, unscrew valve-cap (B) and screw in its place the hose coupling from the air line. Inside of this hose coupling is a projection which presses the pin (U) down against the tension of spring (S), which separates the seat on the upper part of (Y) from the lower part of (W). The air then passes in through the enlarged hole in (V) and (W) and out at the bottom of (W) at the seat, which is now open. When the air-line coupling is removed, pin (U) rises and brings the upper part of (Y) and the bottom part of (W) to a firm seat, and pressure of air in the tube also assists in forcing spring (S) against (Y) and in tightening the seat.

To deflate the tube, valve-cap (B) is removed, turned upside down as in Fig. 5, and pin (U) is pressed down by it, which opens the inner-valve seat. Or the valve-cap (B) can be used to unscrew the inner valve at (V) and can be removed entirely, which is the proper thing to do when removing a punctured tube or when rolling it up as shown in Fig. 13, page 613.

Sometimes the inner valve leaks, owing to the valve cap (B) being screwed down so tight that the rubber disk (C) spreads and forces pin (U) down (see page 613, for inner tube troubles).

Treads of Tires or Outer Casings

The tread of a tire is the part of an outer shoe or casing, which is the part that comes in contact with the road.

The treads[1] **of tires** or outer casings are divided into three types: the **smooth tread,** the **non-skid tread** (Fig. 7), and the **ribbed tread** (Fig. 8). The latter tread is used on "cord tires," as will be explained farther on, as well as on fabric tires.

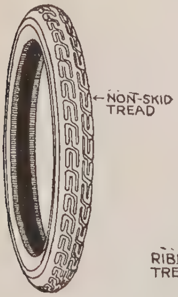

Fig. 7

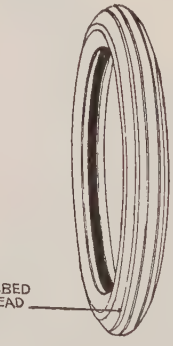

Fig. 8

There are **several different makes of non-skid treads** (as shown in Fig. 9), but the principle or purpose of all is to prevent skidding. The original non-skid tire was the Bailey tread. The Firestone non-skid tread was introduced soon thereafter.

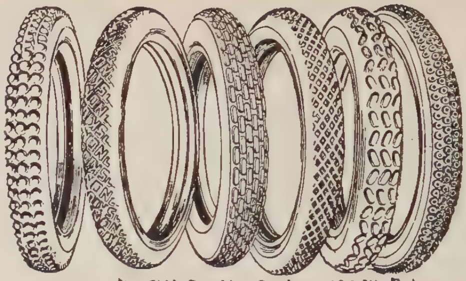

Fig. 9. Some of the different designs of non-skid treads.

The number of accidents which have occurred on account of skidding on slippery pavements has shown the need for some method of prevention.

The original method was by the use of **tire chains** (Figs. 10 to 13) which, so far as the prevention of skidding was concerned, fulfilled their purpose. But the use of chains was found to be detrimental to tires when introduced between the blow-up tire and the hard pavement. And, in addition, chains were found to be hard riding and noisy.

The non-skid tread was introduced to overcome this difficulty, but while they prevent skidding to a certain extent, the chain still remains the only positive preventive of skidding, after all The extra wear and gripping surface, however, obtained with the non-skid tread is well worth the difference in price, and this sort of tire ought at least to be placed on the rear wheels.

The usual tire equipment consists of smooth or ribbed tires for the front wheels and non-skid tread tires for the rear wheels, with rims of the demountable straight side type.

The Non-Skid Tire Chains

For heavy weather and snow time and wet, frozen, or slippery streets, there is nothing equal to a good set of chains: one on each wheel. If only two are used, they should be on the **rear** wheels. If only **one** is used, it should be on the left rear, to avoid being damaged against the curb. Fasten them tightly, but not so tightly that they cannot creep. If they are held rigidly in one place they wear into the tread and ruin it.

The method of applying Weed tire chains over tires is shown in Figs. 10 to 12.

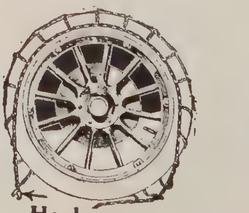

Fig. 10

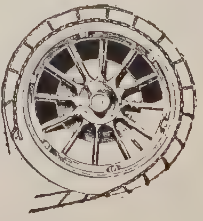

Fig. 11

Fig. 10. Lay the chains over the wheel with the hooks toward the rear, and tuck the slack under the front part of the wheel.

Fig. 11. Start the car forward just enough to run over the slack ends.

---

[1] The smooth tread has been discontinued. Fabric tires are now made with "ribbed" or "non-skid" tread, and cord tires are likewise made with "ribbed" or "non-skid" treads.

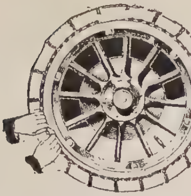

Fig. 12

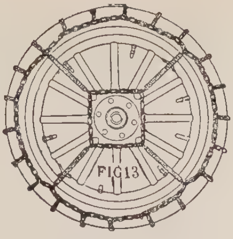

Fig. 13

Fig. 12. Hook the chains as tightly as possible by hand.

Fig. 13. Tire **chain adjusters,** consisting of springs with tempered helical hooks and chain as shown, which automatically takes up any stretch in tire chains, and thus keeps the chain close to the tire. Prevents grinding action and insures silence.

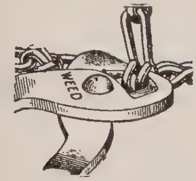

Fig. 14

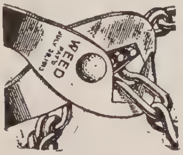

Fig. 15

Fig. 14. Weed **chain pliers** for opening the hooks on Weed cross-chains.

Fig. 15. Weed chain pliers being used to close the hooks. Cutting pliers for repairing chains can also be secured (American Chain Co., Bridgeport, Conn., Mfrs. of Weed Chains).

Tire Protectors

The steel disk type of puncture-proof tire (Fig. 16) consists of three layers of 7/16″ diameter steel disks about 1/64″ thick, imbedded in rubber between the fabric and tread of the tire. The layers of disks are placed in such a manner that it is impossible for a nail to enter the tread of the tire without striking a disk. This tire is called the Lee puncture-proof tire.

The leather-lined puncture-proof tire consists of a specially made tire on the **inside** of which is a puncture-proof strip of chrome leather which is intended to prevent punctures without stiffening the tire. This tire is known as the Woodworth trouble-proof tire.

PURE RUBBER FRICTION BETWEEN

Fig. 16. Lee puncture-proof tire.

Fig. 17

Another example is **the outer leather cover** made of waterproof chrome leather studded on the tread surface with steel rivets. These covers completely enclose the tire, and are attached to the rim, as shown in Fig. 17. The manufacturer claims that they are particularly valuable to use over old tires or to re-tread and strengthen them, and that they are also valuable to people who have to run over roads that are rough, rutty, and rocky, and who travel at less than 25 miles per hour. (Woodworth Mfg. Corpn., Niagara Falls, N.Y.)

Air Pressure in Tires

There are four ways in which one can save on tire bills: first, by keeping the tires at all times well inflated; second, by using your brakes with caution; third, by not overloading the car; fourth, by repairing small cuts in the tread as they appear, and being sure that the wheels are in alignment.

More than three-fourths of all tire trouble is caused by under-inflation. A soft tire, by having its sides bent at a sharp angle, will soon have its fabric loosened from the rubber, with consequent liability of an early rupture. Besides, a hard tire presents less surface to the road, and is therefore less likely to suffer cuts and punctures.

The most important thing to fix in mind on the subject is that **load** as well as **inflation** must be considered to get good results. These two factors are interdependent. You cannot consider one properly without regarding the other.

If you **increase the load imposed on a given tire, you must increase the inflation pressure**—and vice versa—if you are to maintain the proper degree of flattening.

From this it will be seen that there is no fixed pressure which can be set as a standard for any size of tire, regardless of load.

That the inflation pressure should vary in tires of a given size according to the load they are obliged to carry, is obvious when you consider, for instance, a 4-inch tire used on a heavy touring car and another 4-inch tire used on a light roadster. Obviously the weight on the former is a great deal more than that on the latter, so that the former tire will be flattened or distorted a great deal more, providing tire pressure is the same. In order to prevent this flattening from becoming abnormal and in that way affecting the tire detrimentally, it will be necessary to maintain a higher inflation pressure in the touring car than is used in the tires on the light roadster.

If the tire is inflated so that it does not flatten at all under the load, **more service** will probably be received from it. However, this will cause the car to **ride harder.**

If the tire is underinflated, that is, if the amount of air allows too great a degree of flattening, the constant distortion at its point of contact with the ground as the wheel revolves will generate heat in the side walls of the tire. This heat destroys the rubber between the individual plies of fabric and tends to separate them. Separation of this kind **weakens the tire** so that it is not long able to stand up under ordinary road conditions.

Pressure to Be Carried in Tires and Maximum Load per Tire

The pressure to be carried in tires and the wheel-load that the different sizes are intended to carry is shown in the table (Fig. 18) and is in accordance with the recommendation of the S. A. E.

Tire Size	Fabric Tires for Passenger Cars		Cord Tires for Passenger Cars		Cord Tires for Commercial Vehicles	
	Maximum Load per Tire, Lb.	Air Pressure, Lb. per Sq. In.	Maximum Load per Tire, Lb.	Air Pressure, Lb. per Sq. In.	Maximum Load per Tire, Lb.	Air Pressure, Lb. per Sq. In.
3	375	45	400	40	....	....
3½	570	55	600	50	....	....
4	815	65	850	60	850	70
4½	1100	75	1200	70	1200	75
5	1500	85	1700	80	1700	80
6	....	....	....	....	2200	90
7	....	....	....	....	3000	100
8	....	....	....	....	4000	110
9	....	....	....	....	5000	120
10	....	....	....	....	6000	130

Fig. 18. **Carrying capacities and inflation pressures of pneumatic tires recommended by the S. A. E.** (Society of Automotive Engineers). The difference in construction of the "fabric" and "cord" tire is explained farther on.

To find the wheel load for any particular car: First, it is necessary to know the weight of the car, with all the passengers and accessories, water and gasoline tanks filled and on board. After weighing the whole car, weigh back of car. To do this, the middle of the step of the car should be over the edge of the platform scale—if a regular wagon scale is not available.

Weigh the front of the car in the same way, the middle of the step being over the other end of the platform. If this has been carefully done, the last two weights added together should give within twenty pounds of the total weight of the car when weighed complete. Of course the wheel loads are one-half of the respective axle loads as found in this way. In this way you can see if your car is tired properly by referring to the scale showing the size of tires to use.

Inflation Pressure during Hot Weather

The question of whether or not inflation pressure in tires should be reduced in hot weather is a very interesting one, because it is generally supposed that the pressure should be reduced in the summer time.

A test was made with a 33 x 4 tire on one of the hottest days in June, and it was found, that even if the car was driven at excessive rates of speed, the increase in inflation pressure amounted to only 4 pounds, which of course, is negligible, because many times 4 pounds would not cause the tire to blow out. **It may be assumed, therefore, that the same pressure can be used the year around.**

To Get Better Cushioning: Change to Oversize

If it is desired to increase the durability or mileage obtained from the tires, the inflation pressure should be increased. In extreme cases, where better cushioning effect is desired, this can be done by decreasing the inflation pressure. However, that is bound to cut down the mileage received from the tire. The best way to get better cushioning is to change to oversize tires, because in that case a lower inflation pressure can be used.

For instance: Suppose that a 4-inch tire carrying a weight of 815 pounds per wheel should, according to the table, be inflated to 65 pounds. If the motorist found he wished easier riding, the best thing he could do would be to change over to 4½ inch tires, which, with a load of 1,100 pounds, would need to be inflated only to about 75 pounds.

Oversize Tires

All tire makers agree that a larger size tire, giving a larger air cushion, is better than a smaller tire with a smaller air cushion. If you think your tires are too small, place a larger size tire on the rim, in accordance with the table below.

Standard Oversize Tires

Standard Tire Sizes	Oversizes Made to Fit Same Rims
30 x 3½ C	31 x 4 C
32 x 3½ SS	33 x 4 SS
32 x 4 SS	33 x 4½ SS
33 x 4 SS	34 x 4½ SS
34 x 4 SS	35 x 4½ SS
32 x 4½ SS	33 x 5 SS
34 x 4½ SS	35 x 5 SS
36 x 4½ SS	37 x 5 SS

C means clincher.
SS means straight side.

The oversize tires listed above are made in **fabric** construction. The **cord** tire construction is also to be had in all of the sizes mentioned except 31 x 4C.

You can figure the oversize tire your rim will take by adding one-half inch to the cross-section and one inch to the diameter. For instance, suppose your present tire is a 32 x 3½; by adding one inch to the diameter we have 33 and adding one-half inch to the cross-section we have 4, therefore a 32 x 3½ rim will take an oversize tire 33 x 4.

Transposing Tires

Ruts, curbings, and similar tire destroyers may wear the outer wall of a casing nearly to the fabric, but if the tire is reversed, and that side which has been exposed and most worn is placed nearest the car, it will still be serviceable.

As the rear tires sustain more than half the burden in every movement of the car, they will wear more rapidly than the front tires; they also have to bear the traction strain, that of carrying the car forward, and for these reasons they are subject to more wear than the front tires. Furthermore, whenever the car is stalled in a mud hole, the rear wheels revolve a great many times without the front wheels moving.

Many motorists follow the practice of using repaired tires on the front wheels and new ones on the rear wheels. Increased service can also be had by transposing tires. In ordinary wear it is usually true that tires on the right side become worn more quickly than those on the left. This is due to their being run into ruts and stones, when the car is turned out of the traveled roadway, and because the tires of the right side suffer most from curbings and the like as the driver uses the right side of the street. They also carry more than half of the weight when the car leans, which it does mostly, on the right side.

The right rear tire wears faster because of the curve of the streets and roads. The actual cause is probably that the weight is more on the incline.

Standard Sizes of Pneumatic Tires

The standard sizes of fabric and cord pneumatic tires, as adopted by the leading tire manufacturers, are as given in the list following:

Standard Sizes: Fabric Construction for Passenger Cars

30 x 3 Clincher
30 x 3½ Clincher
32 x 3½ straight side
31 x 4 Clincher
32 x 4 straight side
33 x 4 straight side
*34 x 4 straight side
32 x 4½ straight side
33 x 4½ straight side
34 x 4½ straight side
*35 x 4½ straight side
*36 x 4½ straight side
33 x 5 straight side
35 x 5 straight side
*37 x 5 straight side

* Not technically considered standard, yet are still being made.

Standard Sizes: Cord Construction for Passenger Cars and Trucks

All sizes listed under fabric construction are made in the cord type of pneumatic tires for passenger car work, except 30 x 3 and 31 x 4 clincher.

The Buick "light four" car uses a Jaxon rim 31 x 4 straight side, which is made in cord construction. This size and type of rim is also used on certain models of the Briscoe and Maxwell.

Standard sizes of Pneumatic Commercial or Truck Tires. Made only in Cord Construction and Non-Skid Tread—Giant Tires

34 x 5 straight side
36 x 6 straight side
38 x 7 straight side
40 x 8 straight side
42 x 9 straight side
44 x 10 straight side

Note that all of these tires are for straight-side rims of the one-piece, side-ring type.

The straight side-bead tire is now the popular type of bead. In fact, the clincher tire is now made only in sizes of 30 x 3, 30 x 3½ and 31 x 4, the latter size being an oversize for 30 x 3½, i. e., it can be fitted to 30 x 3½ rims.

Ford Tires

The Ford uses 30 x 3 in front and 30 x 3½ in the rear, plain clincher on one-piece clincher rims permanently fitted to the wheel on the touring car and roadster. On the Ford sedan and coupelet, and also on the 1920–21 Maxwell, Chevrolet "490," and the Overland "4," the 30 x 3½ tire on "one-piece clincher rims" but with the "demountable" feature is employed.

Ford trucks use 32 x 4½ straight-side rear, and 30 x 3½ front-demountable clincher rims; and therefore clincher bead tires are used. 32 x 3½ solid tires can also be supplied for the rear.

METRIC TIRES AND EQUIVALENTS

Metric Sizes	Approximate Size in Inches	Metric Sizes	Approximate Size in Inches
650x 65	26x2½	870x 90	34x3½
700x 65	28x2½	910x 90	36x3½
750x 65	30x2½	960x 90	38x3½
800x 65	32x2½	1010x 90	40x3½
830x 65	33x2½	815x105	32x4
860x 65	34x2½	875x105	34x4
700x 85	28x3¼	915x105	36x4
750x 85	30x3¼	820x120	32x4½—5
800x 85	32x3¼	850x120	33x4½—5
860x 85	34x3¼	880x120	34x4½—5
760x 90	30x3½	920x120	36x4½—5
810x 90	32x3½	1020x120	40x4½—5
840x 90	33x3½	1080x120	42x4½—5

* Figures in first column represent millimeters. See Index for explanation of millimeters.

Beads of Tires and Rims

There are three types of tire beads: (1) plain clincher (Fig. 19), which is **flexible,** and is intended for one-piece clincher rims; (2) quick-detachable clincher, with a clincher bead which is **hard,** and is for use on the quick-detachable side-ring type of rim; (3) straight-side bead (Fig. 20) for use on rims with straight sides.

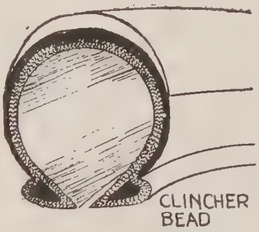

Fig. 19

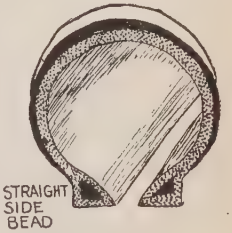

Fig. 20

Note. The **hard-bead clincher tire** formerly used on quick-detachable clincher rims is no longer manufactured.

The **flexible bead clincher** is now made only in 30 x 3, 30 x 3½, and 31 x 4 sizes. The tire in general use is the straight-side bead tire.

THE CLINCHER BEAD TIRE AND RIM

There are three kinds of clincher rims: (1) a **one-piece** clincher rim which is firmly fastened to the wheel felloe, as shown in Fig. 21; (2) a **quick-detachable** clincher rim where one side of the ring is removable, and the tire is removed, as in Fig. 22; (3) a **demountable** one-piece clincher rim, as used on the Ford sedan and coupelet, and other light cars, where the tire can be removed with the rim, and another tire and rim, fully inflated, can be put on the felloe rim of the wheel in its place (see also page 597).

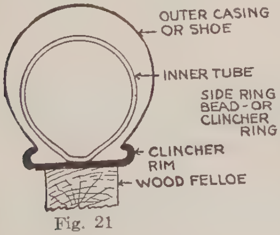

Fig. 21

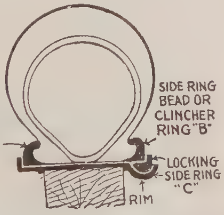

Fig. 22

Fig. 21. Clincher bead tire on **one-piece clincher rim.**

Fig. 22. Clincher bead tire on a **quick-detachable rim.**

To attach or detach a tire on a one-piece clincher rim it is necessary to raise the beads of the tire over the rims as shown in Fig. 21, and that is why the bead is made flexible.

To attach or detach a clincher bead tire on a quick-detachable clincher rim, it is only necessary to remove the "locking ring" and "clincher side ring," as in Fig. 22, and the tire can be slipped on or off without much stretching. For this reason it is not necessary to have a flexible bead.

Therefore a flexible-bead clincher tire can be fitted to either a "one-piece clincher rim" or to a "quick-detachable clincher rim," but it would be a difficult matter to stretch a **hard-bead** clincher tire over a "one-piece clincher rim."

Tire lugs or staybolts This device was formerly used to a great extent when the use of clincher tires predominated, but it is now seldom used. It consisted of a bolt which passed through a hole provided in the felloe of the wheel, as shown in Fig. 2, page 591. The wedge-shaped head was canvas, or rubber-covered, and when drawn tight would spread the beads of the tires firmly into the clincher part of the rim.

The tire lug is still used on some clincher tires, but is usually placed close to the valve-stem, to provide against creeping of the tire on the rim.

When a tire creeps on the rim, or slips, it causes the valve-stem to pull away from the tube, resulting in a bad tear in the tube.

Spreader: The purpose of a spreader (L) (Fig. 3, page 591) is to keep the inner tube from being pinched at the stem hole in the rim, and also to act as a protection in case the dust cap is screwed down too tight. This is very often the case, and as a result, the inner tube is partly pulled or pinched in the rim hole.

Spreaders are not absolutely necessary, but, as stated above, they greatly lessen the chances of tubes "going bad" around the valve-stem, before the rest of the tube has given all the service that has been built into it.

The difference in size of spreaders is necessary, owing to the difference in space between the beads as they set on the rim.

Flaps: These are canvas strips which are placed inside of the tire to insure against pinching of the inner tube by the toe of the bead, and to prevent injury to the inner tube by rim rust. Flaps may be used in all casings, except the flexible clincher type.

To Remove Inner Tube from a Tire on a One-Piece Regular Clincher Rim

Jack up the wheel. Remove the valve cap (**B**) and the inside valve (**A**) by reversing the cap head and unscrewing it, as shown in Fig. 23. Remove the locknut on the valve-stem (see **P**, Fig. 3, page 591).

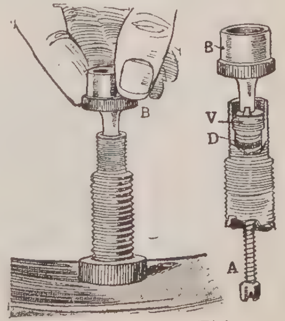

Fig. 23. Shows how the valve cap (**B**) is reversed to unscrew the inner valve (**A**) when the tube is to be deflated.

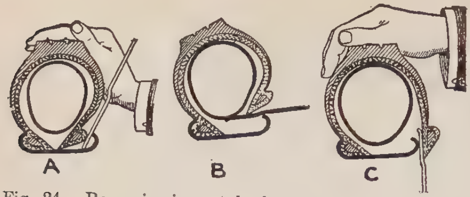

Fig. 24. Removing inner tube from a tire, using a one-piece clincher rim.

Push the edge of the casing from under the lip of the rim with a tire tool as shown at (**A**) (Fig. 24). Pry off as shown at (**B**) and (**C**). This operation must be repeated all around the tire until the outer bead is loosened. The inner tube can then be removed, and the outer casing slipped off, as shown in Fig. 25.

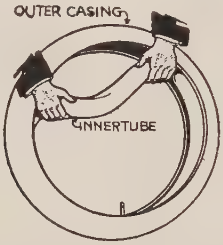

Fig. 25

When taking an inner tube out of a tire, turn the wheel until the valve-stem is at the bottom, as in Fig. 25, then remove the tube, beginning at the top.

Always make it a point to run your hand around the inner tube in the casing until you detect the cause of the puncture, because very often the offending object is hidden in the tire and cannot be seen or felt from outside.

Replacing Inner Tubes

Place powdered soapstone or mica in the case before inserting a tube (Fig. 26). (Too much of this however is likely to work up into little balls and cause inner-tube trouble.)

Then run your hand around the inner tube, smoothing out the creases and placing the tube evenly around in the rim.

Put in a new tube, or patch the old one in accordance with the instruction farther on.

The insertion of the tube may be done with the casing remaining on the rim or with it removed. In either case, it is desirable to turn the wheel until the valve-stem hole is on top (Fig. 27). Before the tire is replaced, the inner tube should be slightly inflated.

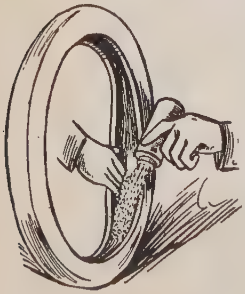

Fig. 26

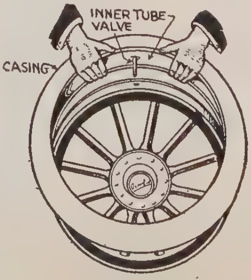

Fig. 27

Do not inflate the tube too much when placing it in a tire, for if you do, you will have difficulty in replacing the locking rim over the bead of the casing.

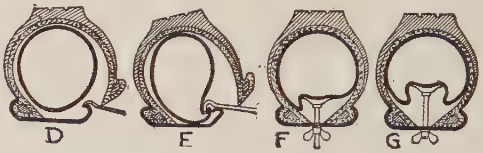

Fig. 28. Replacing an inner tube in a tire, using a one-piece clincher rim and showing precautions to observe to prevent pinching of the tube.

Replacing tire casing on rim: With the inner tube carefully placed in the outer casing, one side of the casing is easily applied. The other side is more troublesome. The hooked end of the lever is used to work the edge of the cover back into the rim, as shown in (**D**) (Fig. 28).

In using this lever, the inner tube may be pinched, as in (**E**); therefore care must be exercised to avoid this.

After the bead of the tire is worked into place, it sometimes happens that the tire lugs or staybolts are not properly placed, as shown in (**F**). Note that the inner tube has become nipped between one of the lug bolts and the cover, and, unless released, this will result in a burst tube. This risk is avoided by taking care to inflate the tube moderately before replacing it in the cover.

The tire lug should be pushed upwards, or towards the inside of the tire as in (**G**), before screwing it down, thus permitting the cover and tube to fit into the correct position. Some tire lugs have a canvas-covered head which sometimes causes inner tube defects, such as nipping and chafing. If bolts with moulded rubber heads be used, these defects are not likely to occur.

The inner tube and tire are properly fitted as shown in (**H**); the tire lugs are in place, and the inner tube snugly in its place, with no nipping at any part.

The inner tube should now be carefully inflated and, when pumped up, should be even all the way round the rim, and run truly when the wheel is rotated.

The air pressure should be in accordance with the table on page 593 (Fig. 18). During the process of inflating, the air pressure can be **tested.** A very handy device for this purpose is a Twitchell air gauge, shown in Fig. 30.

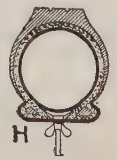

Fig. 29

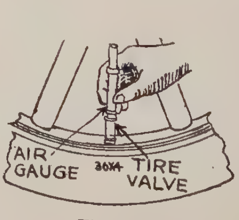

Fig. 30

Note. The instructions for the removal and replacement of inner tubes, as explained above, will apply to all types of inner tubes, except the method of removing and applying the tire to the rim, which varies on different kinds of rims.

THE QUICK-DETACHABLE RIM—SIDE-RING TYPE

The words, "quick-detachable," as applied to a **tire rim,** were originated several years ago, when the one-piece clincher rim, shown in Fig. 21, page 595, was extensively used.

It was a great source of trouble to remove a clincher bead over the clincher part of the rim. Consequently a quicker method was introduced, termed, the "quick-detachable" method, as shown in Fig. 22, page 595. Note that the tire could be removed by removing a "locking ring," (**C**) and a "clincher side ring" (**B**) (see Fig. 22, page 595, and Fig. 31, this page). The tire could then easily be removed. This type of quick-detachable rim was termed a "side-ring" type. This type is now almost obsolete for clincher-tire use, but is used for straight-side tires, as on wire wheels, where the entire wheel is removable.

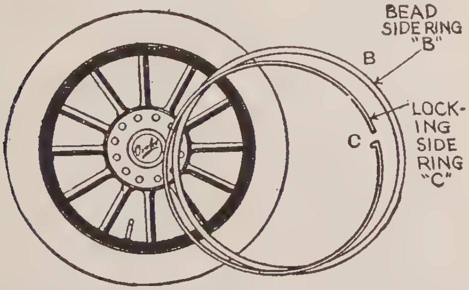

Fig. 31

Quick-Detachable, Demountable Rim—Side-Ring Type

The next improvement to follow was a quick-detachable type of rim, using "side rings," similar to those shown in Fig. 22, page 595, but with **demountable** features, as shown in Fig. 33.

Demountable rims are those rims which are not permanently fastened to the wheel and can be removed with the tire, usually by loosening the clampbolts on the side. This feature, of being able quickly to detach the rim and tire, and thus demounting the tire and rim combined, was a great advancement, as it relieved one of the drudgery of having to remove a tire and repair it on the road. Instead, a spare tire fully inflated on a rim, was carried on a rack, on the rear or side of the car, and was replaced on the wheel instead of the defective tire, and defective tire and rim were placed on the rack to be repaired later.

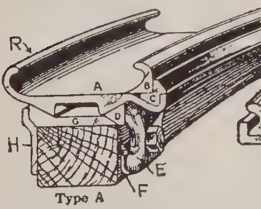

Fig. 32

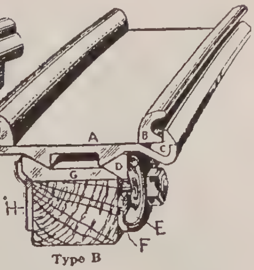

Fig. 33

Fig. 32. A **clincher demountable rim** (not now made for clincher tires) (Firestone, type A).

Fig. 33. A **universal rim;** for clincher or straight side-bead tire (Firestone, type B).

Parts: (**A**) rim base; (**B**) side ring; (**C**) locking ring; (**D**) clamping ring; (**E**) flat clamp; (**F**) clamp bracket; (**G**) felloe band; (**H**) bolt washer.

A quick-detachable, demountable clincher rim of the Firestone make is shown in Fig. 32. Note the difference between this rim and the quick-detachable rim without the demountable feature (Fig. 22, page 595). The difference is, that clamping bolts (**E**) (Fig. 32) and a clamping side ring are provided to hold the clincher rim (**A**) (Fig. 32) in place, and this, when removed, permitted the rim (**A**) to be **demounted** with the tire. At this time, the clincher-bead tire was the type in general use, and the **hard** clincher bead was used for this type of rim.

The universal rim (Fig. 33) was the next type of rim to be used. It was necessary, because the straight-side tire came into existence and proved to be superior to the clincher bead, in that rim cutting, which was a great source of trouble with clincher-bead tires, was eliminated. Therefore, the universal rim would take either a clincher-bead tire, or the straight side-bead tire. Note that the rim (**B**) (Fig. 33) is reversible. By having the rings (**B**) as shown in Fig. 33, the rim would take a "straight side-bead" tire; by reversing (**B**), the rim would take a "clincher-bead" tire.

Side-bead tires on clincher rims: A great deal of complication existed, because the majority of tires in use were clincher-bead tires, and those who had wheels fitted with the clincher rim (Fig. 32) who desired to use straight side-bead tires found it necessary either to have the wheels fitted with straight side rims, or to use **filler beads,** which consisted of strips of fabric like the bead of a tire. These filler beads could be placed in the clincher part of the rim at (**R**), and thus fill up the clinch, and by this means straight-side tires could be used. This type of rims is now obsolete.

The Ford sedan and coupelet, and some other light cars use 30 x 3½ clincher tires on a one-piece clincher rim, which is not quick-detachable, that is, without side rings, but it is **demountable.**

Straight-Side Bead Tires and Rims; Demountable, Side-Ring Type Rim, Q. D.

The clincher bead tire gradually became obsolete, the straight-side bead having taken its place.

An example of a **straight-side, quick-detachable, demountable rim** (Firestone type C) is shown in Fig. 34.

Note that this rim (Fig. 34) is similar in principle to that shown in Fig. 32, but is different, in that it takes a straight-side bead tire only. It is quick-detachable, as in Fig. 32, because there are **side rings,** which can be removed. Thus the tire can be removed from the rim while on the wheel, or the tire and rim can be demounted from the wheel.

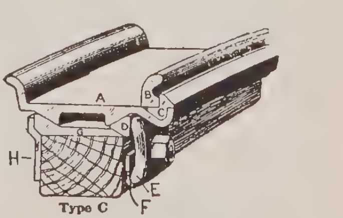

Fig. 34. A **straight-side, quick-detachable, demountable side-ring type of rim** for use with straight-side bead tires only. Note that the tire can be removed from the rim while on the wheel, or the rim and tire can be demounted from the wheel (Firestone type "C" rim).

This type of rim (Fig. 34) is the type, or principle (there are many different makes), used on commercial cars, or trucks.

Example of Demounting Rim and Tire from Wheel and Removing Tire on a Quick-Detachable Side-Ring Type of Rim—Demountable

This example refers to the type of rim shown in Figs. 32, 33, and 34. This rim is not split, but is of the side-ring type.

This type of rim is used quite extensively for commercial cars or trucks, with straight-side bead tires.

It will be found on a great number of older cars with clincher rims, as well as with straight side rims. Note that the rim and tire are demounted from the wheel, and that by removing a side ring, the tire can be removed from the rim; or the tire can be removed from the rim without demounting the rim. An example of this process is as follows:

To Demount Rim and Tire from Wheel

Jack up the wheel and loosen clamp (**E**) (Fig. 35), using the socket wrench (**W**) which accompanies each set of rims. Slide each clamp down as far as it will go; then tighten the nut sufficiently to hold the clamp in that position.

When all clamps have been freed, turn the wheel so that the valve-stem (**A**) is at the top; then swing out the lower side of the rim (Fig. 36), and lift rim, tire, and all off the wheel.

The valve hole in the felloe is tapered, so that this can be done without straining the valve stem. Note: It is not necessary to remove the dust cap when demounting the rim. The dust cap should always be kept screwed tightly against the valve sleeve, except when detaching the tire from its rim.

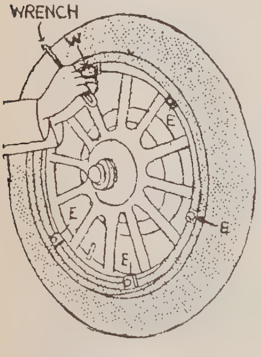

Fig. 35

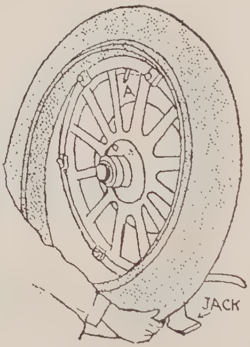

Fig 36

Fig. 35. Loosening clamping bolts.

Fig. 36. Demounting rim and tire from wheel.

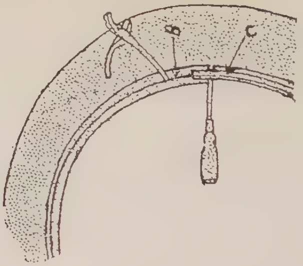

Fig. 37. To remove tire from rim: pry off locking ring (**C**) and remove side-ring bead (**B**).

To Mount the Spare Rim with Inflated Tire

Having taken the clamping ring (**D**) (Fig. 34, page 597) from the rim just removed, place it in the same position (with point toward inside) in the spare rim carrying an inflated tire.

Turn the wheel so that the valve hole in the felloe is at the top; insert the valve-stem (with dust cap and valve sleeve already in place) through the hole and swing the lower part of the rim snugly into place. The ends of the clamping ring (**D**) (Fig. 34, page 597) should come under one of the clamps.

Restore each clamp (**E**) in turn to its original position, overlapping the clamping ring, giving the respective nuts one or two turns with the wrench to hold the clamp fairly tight. Then continue around the wheel again, tightening down all nuts and clamps firmly.

To Apply Tire to Rim

Place the slightly inflated inner tube in the casing, using plenty of soapstone or talc, and set the casing back on the rim.

Put on the side ring (**B**). Apply the locking ring (**C**), by engaging the pin in the notch in the edge of the rim, and then force the locking ring into its groove around the wheel. Inflate the tire to proper pressure. Screw the dust cap on tight against the valve sleeve.

The spreader is held in position in the base of the tire by the pressure of the screw dust cap against the valve sleeve. No locking nut or other device is necessary.

To Remove Tire from Rim

Remove the dust cap and allow the air to escape. Push the valve-stem up into the tire as far as it will go, thereby releasing the pressure of the spreader inside.

Insert the point of [illegible]crewdriver between the side ring (**B**) and the locking ring [illegible] (Fig. 37). Pry downwards, causing an opening between the two rings. Drop a coin or other convenient piece of metal into this opening and hold the opening thus gained. Pry downwards with a screwdriver, which will remove locking ring (**C**). The bead ring and tire may now be removed from the rim. Note that the valve-sleeve will remain in the valve-hole of the rim or felloe.

THE ONE-PIECE STRAIGHT-SIDE DEMOUNTABLE SPLIT RIM

This type of rim (Fig. 38) is a popular type. The illustration shows the type E Firestone rim. There are many other makes. As will be noted farther on, the rim is demountable by loosening the clamp bolt (**E**), which relieves the pressure on (**D**), and thus the rim (**A**) and the tire are demounted from the wheel.

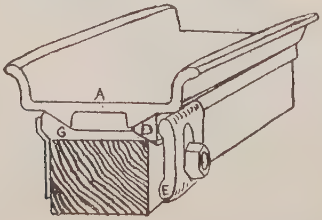

Fig. 38. **A straight-side, demountable, one-piece rim for a straight-side bead tire only.** This rim is a "split" rim. The tire is not removable from the rim while on the wheel. The rim and tire must be removed (Firestone, type E).

Note also that the side rings (**B** and **C**) (as in Fig. 34), which was the so-called "quick-detachable" feature, has been eliminated, and that therefore the tire could not be removed from the wheel while on the rim. When the rim and tire are removed from the wheel, a much simpler method is used to remove the tire from the rim, which is by separating the rim, which is **split** (see Fig. 45, page 600).

As stated, the straight-side, demountable one-piece **split rim** is the popular type of rim. The purpose of having a rim demountable is to permit removing the tire and rim, so that a spare tire, inflated, and on another rim, can be placed on the wheel in place of the defective tire.

If one did not have a spare tire and rim along, then the tire and rim would have to be demounted, and the tire removed. It is easier to remove the **split-rim type,** than is the case with the **side-ring quick-detachable type.**

There are many different types of **one-piece, straight-side demountable split rims.** On some makes, instead of having a **side-clamping ring** (D) (Fig. 38), which is held tight in place by a clamp bolt (E), a **wedged clamp** is used, as shown in Fig. 42.

Principle of the Demountable Split Rim

This type of rim is the rim in general use on passenger cars.

There are **many different makes.** Fig. 38, page 598, shows the Firestone, type E. The one illustrated below is the Stanweld No. 21 or 76. There are many others. The difference is chiefly in the method of seating the rim on the felloe band of the wheel, fastening it to the wheel, and the method of holding the split part of the rim together. Split rims are made demountable only.

An example of how the Stanweld, No. 21 or 76, split rim is held together and separated, so that the tire can be removed from the rim, is shown in Fig. 39.

A split rim is shown with a locking lever (C). The rim is called a "split rim" because it is not endless, but is cut through on one side.

When the rim is removed from the tire, the locking lever (C) is thrown to one side as at (D). The rim is then pried out or lapped as at (E), and the tire is pulled off.

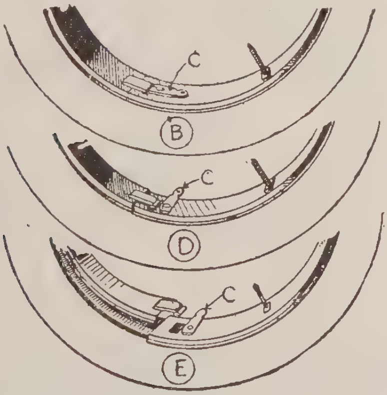

Fig. 39

When the rim is put back in place, the lever (C) is put in place as at (B). The type E rim (page 598) is of the split type, but has a different locking device.

Another type of split rim is shown below in Figs. 40 to 41, and is similar, except for a different locking principle. We will use this type to explain how the rim and tire are demounted, and how the tire is removed from the rim and how replaced. The procedure is very similar on all types of split rims.

How the Demountable Split Rim Is Held to Wheel

The rim is held securely to the wheel by **wedge-shaped clamps** and bolts, as shown in Figs. 40 and 41.

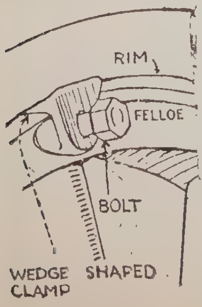

Fig. 40

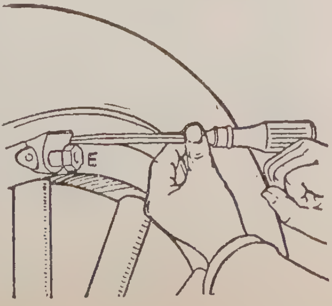

Fig. 41

The difference in construction of different makes of rims of this type is chiefly in the shape, or in the method of applying this clamp, and also in fastening the split part of the rim as explained in connection with Fig. 39.

On the **Firestone, type E,** split rim (Fig. 38, page 598), the clamp (E) is flat, instead of being wedge-shaped. The clamp (E) presses against a triangular-shaped **clamping ring** (D). With the type of split rim shown in Figs. 40 and 42 (the Baker) and many other split rims, the "clamping ring" as mentioned above is not used, the **"wedge clamp"** serving instead.

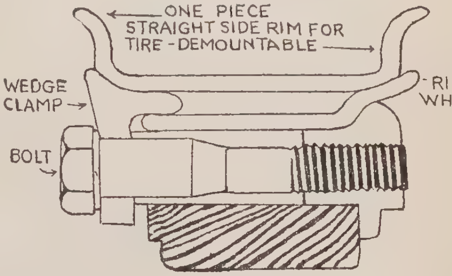

Fig. 42

The **purpose of the wedge clamp** (see Figs. 40 and 42) is to wedge in between the rim and steel rim on the felloe of the wheel. The tighter the bolt is drawn, the tighter it wedges. The wedge clamps are placed equidistant all around the side of the felloe of the wheel, and it is important that they be drawn equally tight all around, else the tire will be thrown out of line and will wabble.

Example of Removing a Demountable Split Rim and Tire from Wheel

The wheel used in this example is what is termed an **"artillery type,"** in which the spokes meet at the center and are bolted between the flanges of the metal hubs. A steel felloe is shrunk on the wooden spokes to carry the demountable rim and tire.

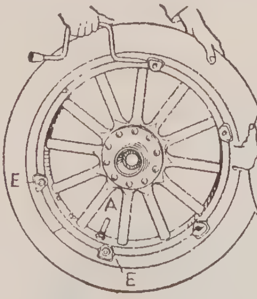

Fig. 43

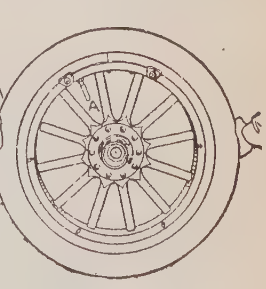

Fig. 44

Procedure: Jack up the wheel. Remove the dust cap and nut from the air-valve stem (A) (Fig. 43). With the rim wrench, remove all of the nuts from the bolts except the ones on either side of the tire valve.

Insert the screwdriver end of the demountable rim wrench between the felloe and wedge clamp, to pry loose and remove (Fig. 43). After the wedges have been removed, turn the wheel until the tire valve is in upper position, and pull the lower portion of the tire toward you until it clears the felloe sufficiently to raise up so as to disengage the valve-stem from the felloe (Fig. 44).

Mounting Spare Rim and Tire

The next procedure is to place on the wheel the spare rim and tire which should be carried on the "tire carrier" at the rear of the car, with the tire fully inflated.

Procedure: Loosen the nut at the lower edge of the "tire carrier" with a rim wrench and turn the lug until it clears the rim. Remove the air-valve stem-cap and nut, and lift the rim off the carrier.

Insert the valve-stem in the proper hole in the felloe, and the driving stud in the driving plate (Fig. 43) and force lower part of rim on the wheel with the foot. Replace the two wedges opposite the valve-stem, drawing them up evenly, but not to their final position; then replace the remainder of the wedges and draw them up evenly until all are tight. Note that the edges of the rim at the split are even and not more than 1/32" apart. If the bolts are not tightened uniformly, the rim will run out of true.

To Remove Tire from the Split Rim

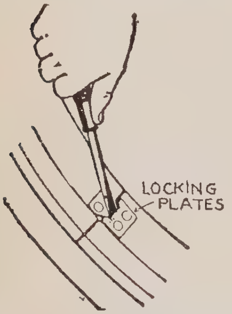
As an example, the Kelsey No. 110 split rim, as installed on the Studebaker cars, will be used. Note that the locking device of the split part of rim on this make is different from the locking device (C) (Fig. 39).

It is not a difficult task to remove a straight-side tire from the rim, as used on Studebaker cars; nevertheless, we outline below the very best procedure in order to reduce this labor to a minimum.

First, be sure the tire is fully **deflated,** then loosen the bead of the tire thoroughly from the rim before proceeding with the following operations:

Operation No. 1: Place a screwdriver between the locking plates of the split part of the rim, as shown in Fig. 45, and force the rim apart, by bearing up on the handle.

Operation No. 2: With the rim slightly forced apart, as shown in Fig. 45, bear down on the handle of the screwdriver, so that one section of the rim will be telescoped into the other, as shown in Fig. 46.



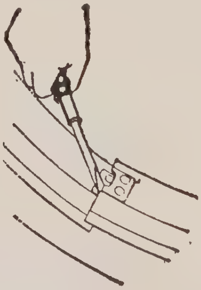


Fig. 45. Forcing split apart

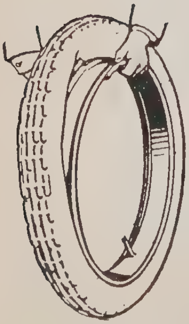
Fig. 46. Lapping split.



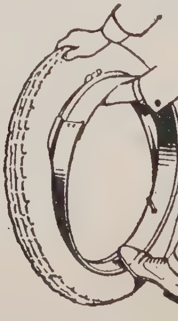


Fig. 47. Starting tire from rim.

Fig. 48. Pulling rim from tire.

Operation No. 3: By means of a screwdriver or a tire tool remove the tire from the rim at the telescoped section (Fig. 47).

Operation No. 4: Supporting the tire between hand and foot, as shown in Fig. 48, pull the rim from the tire with the other hand.

To Mount Tire on Rim

Operation No. 1: In mounting the tire, place the rim on the floor, and, after having installed the tube in the casing very carefully, insert the valve-stem into the rim hole provided (Fig. 49).

Operation No. 2: By following around the tire, pressing with the heel of your shoe, the casing can be forced into position (Fig. 50).

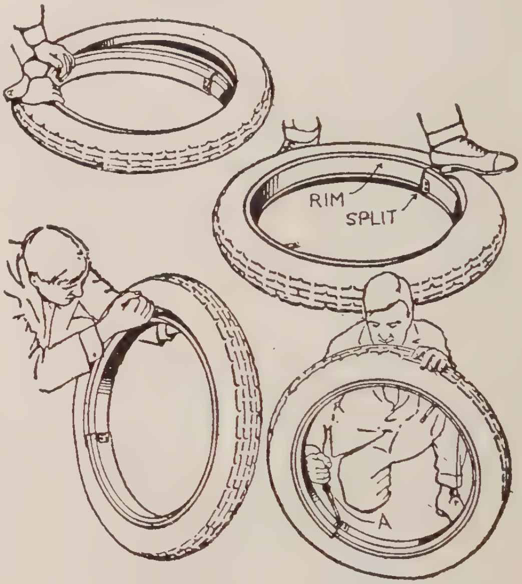

Fig. 49 (upper) Fig. 50 (upper)

Fig. 51 (lower) Fig. 52 (lower)

Operation No. 3: With the rim still telescoped, force a screwdriver, or preferably a tire tool, between the casing and rim (Fig. 51) and slide around the entire rim, noting carefully if the flap is in proper position. If the flap is allowed to become folded over the bead of the tire shoe, a blow-out may result and expanding the rim and removing operation becomes difficult.

Operation No. 4: By using a screwdriver (Fig. 52), and reversing the operation as shown in Fig. 46, the rim can be locked in its proper position.

Additional Pointers on Mounting Tires on the Split Rim

To avoid tire troubles, mount the tire properly on the rim by observing the following:

1. See that the tube is partially inflated when inserting.
2. See that the inner tube valve does not leak.
3. When inserting the tube, use talc to lubricate it.
4. When the rim and tire are mounted on the wheel, draw the wedge bolts evenly, or the wheel will wabble.
5. Before inserting the tube in the casing, see that there is no dirt or other substance in it which might injure the tube. Run your hand all the way around the inside of the casing.
6. If the rim is rusty, scrape off all the rust you can, and then apply a coat of rim paint.

A few pointers as to the method of placing an inner tube in the casing and mounting the casing on the rim are given on the next page.

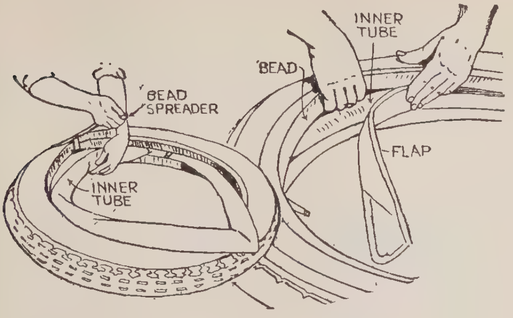

Fig. 53 Fig. 54

Fig. 53. **Inserting tube into casing:** Sprinkle talc inside of casing, being careful not to use too much, or it will form balls. Then inflate the tube just enough so that it will assume sufficient shape to make it easy to handle. The tube is then put into the casing. A very handy tool for spreading the tire when inserting a tube is a "bead spreader" shown in the illustration. Do not permit the tube to touch the ground. Dirt or grit may cut through.

Fig. 54. **Placing flap over tube:** A flap is then placed as shown. Do not stuff it in and permit it to wad, but spread the bead with the hand as shown, and place it evenly and flat over the tube. If it wads, it may cut the tube.

After the inner tube and flap are placed on the casing, then place the casing on the rim. Stand the rim up and insert the valve-stem through the hole in the rim. Next place the rim on its side, as shown in Fig. 55.

Spare Rims and Tires

We often see a spare rim on the rear of a car with an inflated tire on it. This indicates that the rim is of the demountable type, and that the wheels are of wood.

These rims are usually of the one-piece, straight-side, split-type demountable rim. Any other type of demountable rim could be used, as, for instance, the side-ring demountable type.

The Ford uses a demountable clincher rim of plain clincher construction without side rings.

Fig. 55. **Forcing one side of casing over rim:** Use a tire tool. One of the best tire tools obtainable is a piece of spring leaf; the longer, the better. With this tire tool, and by striking the bead of the tire (not the rim) lightly with a hammer, one side of the casing will go over the rim.

When one bead of the tire is over, then start the other bead of the tire into the bead of the rim by means of the tire tool, and a few blows of the hammer. Use the tire tool first and do not use a hammer any more than necessary. When using the tire tool, be careful it does not injure the tube.

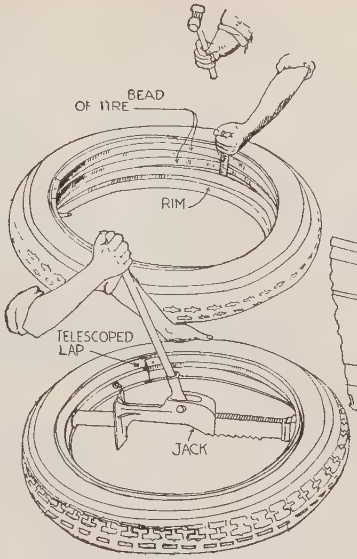

Fig. 55 (upper)
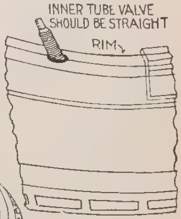
Fig. 56 (lower)



INNER TUBE VALVE SHOULD BE STRAIGHT
RIM

Fig. 57

Fig. 56. **Spreading the rim apart so that it will lock:** There are many methods for joining the lap of the split rim where it telescopes. One method, and a good one is to use a jack as shown in Fig. 56.

Fig. 57. **Inner-tube valve not in correct position:** This is a trouble which often occurs and is one that will not be noticed until the beads of the tire are on the rim. The valve should be perfectly straight. If it is left in the position shown, it will result in the inner-tube valve seat being torn from its base, and this might occur when the telescoped part of the rim is separated, as this will only cause it to be drawn farther. If not, it will tear sooner or later.

The Stanweld Interchangeable Rim

The Stanweld interchangeable rim replaces without alteration of band the following makes of rims:

Stanweld 21 and 22	Dodge Bros.	Standardized-Baker
Stanweld 76	Perlman-Jackson	Baker-Detroit

This rim permits easy and quick tire changing, because the valve-stem does not interfere with the rim when collapsed. A screwdriver is the only tool needed. No new bolts, wedges or nuts are needed.

Some of the popular cars equipped with flat-base rims which interchangeable rim will replace are: Ford (some), Overland, Maxwell, Dodge, Oakland, Oldsmobile, Buick, Paige, Chalmers, Mitchell. For a complete list see pages 603, 604, 605, 606.

WIRE WHEEL RIMS

The wire wheel uses a rim which is not demountable. Instead, the wheel itself is demountable. A spare wheel and inflated tire is usually carried on the tire rack at the rear of the car, and when tire trouble occurs, the wire wheel and tire are demounted from the axle and the spare wheel and tire are placed on the axle in their place.

The type of rim generally used on wire wheels is the plain straight side rim which is permanently fastened to the wheel. The tire is removed from the rim by first removing the side ring (Fig. 58). The removal of this side ring is an operation similar to that shown in Fig. 22, page 595, except that a straight side rim is generally used instead of a clincher rim. If the wire wheel is of 30 x 3½ size, it may have a clincher type of rim.

If a spare wheel and tire are not at hand when tire trouble occurs, then the tire can be removed from the rim by jacking up the wheel and removing the side ring.

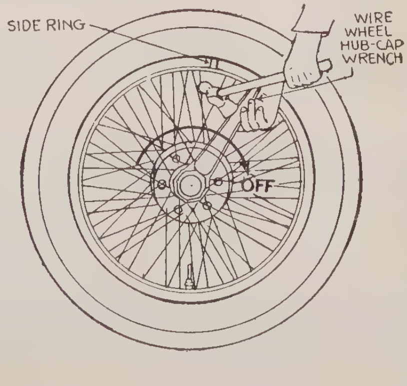


Fig. 58. Illustrating **how a hub cap wrench is always moved** downward toward the **front** of the car when the hub cap is to be taken **off**, and toward the **rear** of the car, when put **on.** Note that the side ring is removed in order to detach a tire. The rim is not demountable.

Wire wheel hub nuts have right-hand threads on the left side and left-hand threads on the right side. A large hub-cap wrench is usually provided for removing wire wheel hub nuts.

To Remove Wire Wheels—Front or Rear

Jack up the wheel until clear of the ground and place the special wrench over the hexagon of the hub cap. Putting on the wrench releases the hub-cap lock-finger, so that the cap can be removed by turning toward the **front** of the car.

The two hubs on the left-hand side of the car have right-hand threads, while those on the right-hand side have left-hand threads. The hub caps are marked with arrows pointing the direction they turn on. To **remove,** turn in the direction opposite to the arrow.

Should the caps be so tight that trouble is experienced in loosening them, let the wheel down until it rests on the ground, to keep it from turning and then tap the end of the wrench forward with a hammer. When the cap is once started, jack up the wheel and unscrew the rest of the way by hand. After the hub cap is removed, the wheel can be pulled straight off the hub.

When replacing the wheel, be sure to push the wheel on the hub all the way, and see that the wheel draws up tightly on the inner hub. To screw the hub cap on, turn towards the **rear** of the car—in the direction of the arrow.

Do not attempt to tighten the hub cap when the wheel is on the ground, as the weight of the car prevents free action of the wrench on the cap, and while the wheel may appear tight, it is only binding and will loosen with driving. When a clicking noise is heard in the wheels, it is generally the result of the hub caps not being drawn tight.

Care of Wire Wheels

It is never necessary for an owner to tighten or touch the spokes unless in case of accident. All spokes have the proper tension when they leave the factory. If new spokes are inserted, do not draw up too tightly with a spoke wrench. The new spokes should be only as tight as the ones already in, of the same length, and ring true with them.

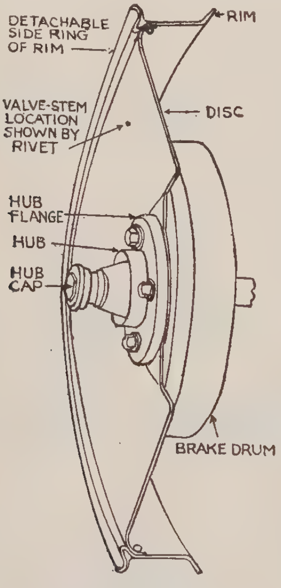
To keep wheels in good working order, they should receive the following **lubrication:**

The taper of the inner hubs, both tapers in the wheel hub shells, and the threaded portion of the hub caps should be wiped clean and covered with light grease every thirty days. Also, occasionally look over the locks in the hub caps; place a few drops of oil in between the spaces provided for clearance. This will assist the locks to work freely and help to counteract the accumulation of dirt, dust, etc.

DISK WHEELS

Different wheel constructions are explained on page 3.

The disk steel type of wheel is now very popular, and in order to explain the advantages of this type of wheel we will use the Disteel wheel as an example.



DETACHABLE SIDE RING OF RIM
RIM
VALVE-STEM LOCATION SHOWN BY RIVET
DISC
HUB FLANGE
HUB
HUB CAP
BRAKE DRUM

Fig. 59. The Disteel wheel using the Goodyear type of rim permanently riveted to the disk.

The advantages of this type of wheel are as follows:

Strength: Being disks of steel they have no spokes to break.

Permanent rims: Rims are not demountable, but are riveted to the disk.

Curved and tapered disk: Shocks cannot be transmitted in a direct line to the axle, but are carried at an angle, thus deflecting the full force of the blow. The tapered construction of the disk diffuses the shock on the same principle as in the case of tapered roller bearings and springs.

Proper distribution of weight: The weight of the Disteel wheel is concentrated at the hub, so that the fly-wheel effect is lost and easy starting and stopping results. The contrary effect—throwing the principal weight to the rim—makes stopping and starting less easy.

Convenience: Disk wheels are easy to clean and easy to change.

The Disteel **wheel itself can be removed** by loosening the nuts holding the hub-locking flange.

The method of changing a tire is to remove the side ring, or to carry an extra wheel with the tire mounted ready to replace the other wheel. Manufacturers are Disteel Wheel Corp'n., Detroit, Mich.

The Tuarc Steel Disk Wheel

Another make of steel wheel is the Tuarc shown in Fig. 60. The wheel is made of steel. A patented clamping ring gives a full-circle grip on the demountable rim to be removed. Thus it is only necessary to carry an inflated tire and rim on the rear tire rack instead of a complete wheel and tire. Manufacturers are Motor Wheel Corp'n., Lansing, Mich.

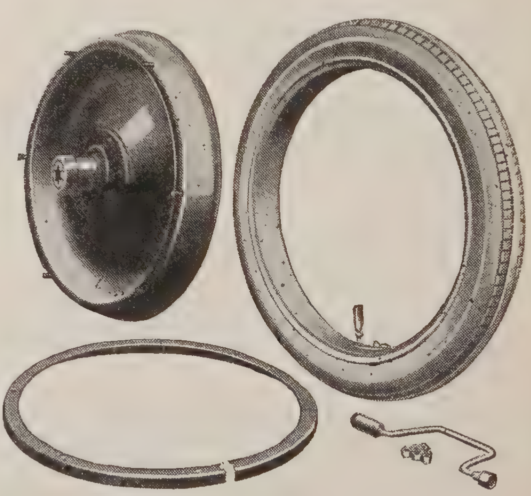


Fig. 60. The Tuarc steel wheel with a demountable rim.

Rim Equipment of Leading Automobiles from 1916 to 1921

The following table gives the name of the car, the year and model, the size of tire, the type of rim, the make of rim, and the catalog number of wedge-clamp, bolts, and nuts. It is a valuable list of data, as it will tell the size and type of tire to order for all makes of cars.

Abbreviations: Fir. for Firestone; Stan. for Stanweld; Stzd. for Standardized; K. for Kelsey; K.U. for Kelsey Universal; K.P.S.S. for Kelsey Permanent Straight Side; Det. for Detroit; Gdyr. for Goodyear; Gdrh. for Goodrich; Perl. for Perlman; Pk. for Parker; J. for Jaxon; B. for Baker; D.B. for Dodge Bros.

Obtained through the courtesy of the Borbein Auto Co., 2109 North 9th St., St. Louis, Mo. This concern carries a complete line of rims and parts, and issues an instructive catalogue on the subject.

Dimensions of Standard Demountable Rims

To illustrate the use of this table, let us assume that a wheel has a 36 x 4 rim (36 x 4 size is not now made) of some old style on it, such as a clincher or old-style quick detachable type, and it is desired that a change be made to take a standard size of tire as listed on page 594. By referring to this page we find that a 33 x 4 or 34 x 4 is the nearest size. The 34 x 4 is not considered a standard size although it is still made; therefore, it would be best to use the 33 x 4.

In order to be able to tell if a 33 x 4 would go on the felloe of the wheel, and to find out if it is necessary to cut the wheel felloe down, or to build it up, refer to the right-hand table. Note that a 36 x 4 measures 26 37/32" outside diameter of the wood felloe, and that, to take a 33 x 4 rim, it must be cut down to 23 27/32" so as to take the 33 x 4 felloe band.

Felloe bands are steel bands placed around the felloe of the wheel, and on which is placed the rim. Felloe bands accompany all complete sets of rims and should be ordered with rims.

This list is for straight-side rims only, except the 30 x 3½ size, which is the clincher demountable.

Size of Tire	A Inside Diam. of Felloe B'nd	B Inside Circum. of Felloe B'nd	C Width Felloe Band	D Outside Circum. of Felloe B'nd	E Distance Between Bolt Holes

TOOLS FOR TIRE CHANGING

For tire changing in a repair shop the following tools are necessary:

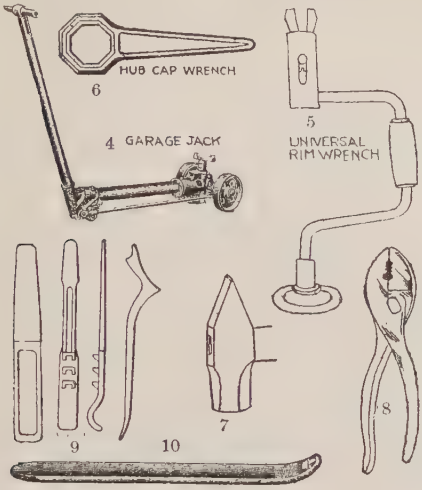

Fig. 61

A garage jack (Fig. 61-4); a universal rim wrench (Fig. 61-5) which is adjustable to 13/16″, suitable for all nuts on all demountable rims; wire-wheel hub-cap wrenches (Fig. 61-6) for Houck and Hays wire wheels; a blacksmith's hammer, about 2 lb. (Fig. 61-7); a large screwdriver; pliers for removing valve and dust caps (Fig. 61-8); tire tools (Fig. 61-9) for clincher one-piece rims, as used on Fords; a tire tool (Fig. 61-10), for removing and replacing casings, made of spring steel, 1″ x 12″; an air compressor. If the shop is not equipped with a power air compressor, see the Jensen pump, page 622, Fig. 60.

For a tire tool for work on all types of rims and tires, there is nothing better than a piece of spring leaf, the longer the better.

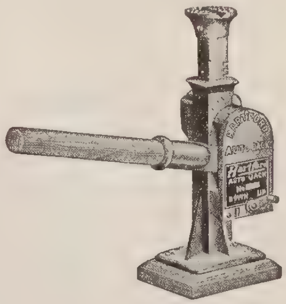

Fig. 62

A good jack is a necessity. With a good jack the heaviest car can be raised with the slightest pressure. This saves time, and will save the car from dropping at a critical time.

A flat block should be placed under a jack when used around a car, to prevent it turning over and sinking in the ground.

Addresses of Some of the Tire Manufacturers

Write for catalogues. You will gain much information from: Amazon Rubber Co., Akron, Ohio; Diamond Rubber Co., Akron, Ohio; Federal Rubber Mfg. Co., Milwaukee, Wis.; Firestone Tire and Rubber Co., Akron, Ohio; Fisk Rubber Co., Chicopee Falls, Mass.; B. F. Goodrich Co., Akron, Ohio; Goodyear Tire and Rubber Co., Akron, Ohio; Hood Tire Co., Watertown, Mass.; Kelly-Springfield Tire Co., 229 W. 57th St., New York, N.Y.; Koochook Rubber Co., Kokomo, Ind.; Lee Tire & Rubber Co., Conshohocken, Pa.; Michelin Tire Co., Milltown, N.J.; Pennsylvania Rubber Co., Jeannette, Pa.; Republic Rubber Co., Youngstown, Ohio; Rutherford Rubber Co. Rutherford, N.J.

INSTRUCTION No. 55

TIRE CONSTRUCTION; CARE AND REPAIR OF TIRES: Vulcanizers; Tools

CONSTRUCTION OF PNEUMATIC TIRES

There are two kinds of pneumatic tire constructions: the "fabric," and the "cord" construction.

In the **fabric construction** the carcass is made of closely woven and **interwoven** cotton fabric.

In the **cord construction,** the carcass is made of loosely woven cords and **not interwoven.**

The fabric carcass type of tire can be constructed by two methods: the "full-molded" method, and the "wrapped" method.

The full-molded method of construction is explained on page 609. It is built up on an iron core or mandrel, and is then placed in a mold (Fig. 2), which in turn is placed in a hydraulic press vulcanizer, the object of the press being to close the halves, (L) and (U) of the molds tightly. With a full-molded type of tire, the entire construction is cured or vulcanized complete at one operation.

With the wrapped-tread method, the fabric carcass, side walls, cushion and breaker-strip are formed or built up in the same manner as a molded tire, but they are semi-cured (half-cured) only in this mold. After this semi-curing operation, the tire is removed from the molds (Fig. 2), and the part where the tread goes is buffed off and cemented with several coats of high-grade vulcanizing cement. A semi-cured tread is then treated with several coats of vulcanizing cement and allowed to dry, after which the tread is applied to the carcass and is rolled down under pressure to remove all air.

An air bag is then placed inside of the tire and the entire tire is **wrapped tightly with canvas cloth strips** about 2″ wide. Then, instead of putting it back in the mold (Fig. 2), where it was semi-cured, it is placed in a horizontal vulcanizer (large kettle), and the final cure (vulcanize) with live steam is given, after which the tire is left standing until cooled. The canvas strips are then removed and tire is laid away for a few weeks to "after-cure."

A wrapped-tread tire can always be distinguished by the slightly roughened surface, which is the impression left from the cloth wrapping.

The advantage of the wrapped-tread construction is the possibility of detecting if there are defects in the tire, as pinches or buckles, which can be determined before the tread is applied, which enables the manufacturer to turn out a perfect tire. This type of tire is more expensive to manufacture.

The rubber used in making the tread and cushion stock of a tire consists of a gummy substance obtained from the milky juice of certain tropical trees, mixed with sulphur to tend to harden it and give it strength. When heated, it changes from a sticky mass resembling chewing gum, to the elastic form in which we see it in a completed tire.

The best rubber is called Para, which comes from the city of Para, near the mouth of the Amazon River. Other good rubber comes from Africa, India, Ceylon, and South America.

The white dust often seen on rubber goods is called "bloom" and comes from the sulphur not chemically combined with the rubber. Old tires in stock a long time accumulate considerable bloom, and get hard.

The strength of the tire lies in this fabric or cord carcass; the cushion and protection for the carcass of the tire is in the rubber. Sea Island cotton, which is very strong, is used for the carcass of the fabric tire, and cords are used for the carcass of the cord tire.

Construction of a Fabric Tire

The carcass, which is the strength of the tire, is built up by placing several layers (4 to 7) of closely woven cotton fabric on a mandrel or core-shaped like the inside of the tire. The carcass is dependent upon the tread, cushion, and breaker for protection (see Fig. 1).

Cotton fabric is used because it is flexible, easily permeated with rubber, and is best adapted to resist heat. If too many layers of fabric were used, it would thicken the carcass, causing it to be stiff, and less flexible, and inside plies would break easily, and heat would be difficult to expel. Heat has a tendency to loosen the "frictioning" between the fabric plies.

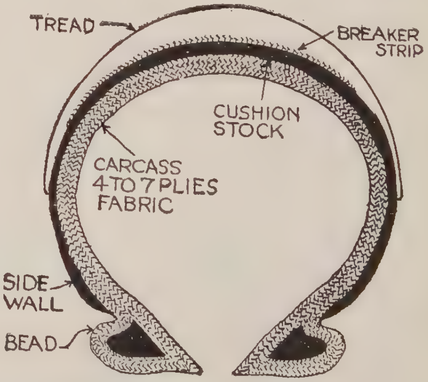

Fig. 1. Construction of a fabric tire.

The tire assembly construction is as follows:

1. **One layer** or ply of fabric is placed over a core on which the tire is to be formed.
2. **A bead** is formed by placing the lower edge of the fabric around the bead form; hard rubber is used to form a bead of a clincher tire, and small wires for straight-side tires.
3. **Other layers** or plies of fabric are placed, one over the other, but before doing so, rubber is infused by pressure into and between, each layer or ply of fabric, which impregnates the fabric thoroughly; this is called **"frictioning."**
4. **A cushion** of 1/8″ soft gum rubber is placed over the fabric carcass.

5. **A breaker-strip** is then placed over the cushion. It is made of coarse loose-woven fabric, and it serves to ward off attacks of sharp objects that may penetrate the tread. When a tire wears through the tread, the "breaker" is exposed.
6. **A chaffing strip,** consisting of a strip of fabric about 2″ wide, is applied to the edge of and above the bead.
7. **Then the side walls,** made of thin tough rubber (made thin to expel heat) are applied.
8. **The tread,** made of thick tough rubber, is applied last.

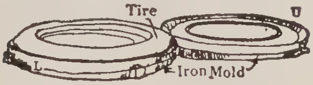

Fig. 2. Iron molds.

9. **The tire on the forming core is then placed in an iron mold** divided into halves (see Fig. 2). The part (**U**) of this mold is placed over the part (**L**), covering the tire, and is fastened down.
10. **The mold with the tire** is then placed in a cylindrical tank, or kettle, or hydraulic press vulcanizer, and "open cured."[1]
11. **Live steam** is turned into this tank at a pressure of 50 to 60 lbs., which corresponds to about 300° F. This tank holds from 25 to 30 tires.
12. **After curing,** the tire is placed in storage to "after cure."

Construction of a Cord Tire

The cord tire differs from the fabric tire previously described in that instead of Sea Island cotton or other closely woven and interwoven fabric being used for the carcass of the tire, cords are used which are loosely woven and not interwoven.

There are two kinds of cord tires, the "cable cord," and the "multiple cord."

The cable-cord tire is known as the Silvertown cord tire, and is a product of the Palmer Tire Co., of England, made in a suburb of London called Silvertown. This tire is made in this country by the B. F. Goodrich Co., and the Carlise and Fiske companies.

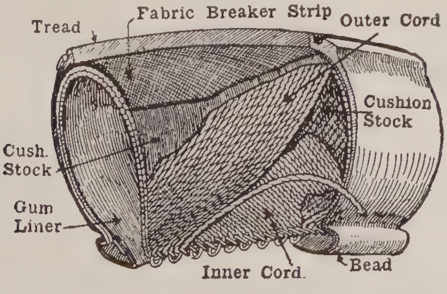

Fig. 3. Construction of the cord tire.

The multiple-cord tire is made by the Firestone, Goodyear, and some of the other tire manufacturers.

The difference between the cable-cord and the multiple-cord tire is in the size of the cords and the number of plies of cords. In the cable-cord tire there are two to four plies of heavy cable cords.

In the **multiple-cord tire** there are six to eight layers or plies of smaller cords or threads.

The cord tire is far stronger than the fabric tire, one principal reason being that the cord tire is not so closely woven or **interwoven** as the fabric carcass tire, and is therefore not broken so easily. The fabric tire is continually sawing itself, as if it were being bent back and forth, and eventually breaks. Another advantage is that a cord tire is not subject to stone bruises, as explained on page 610, as the cords all run one way and are not interwoven as fabric. The result is that they will give without breaking when the tire strikes a stone at high speed. In other words, the carcass will have the same action as the tread—it will stretch under a blow without breaking.

For an example of the construction of the cord tire we will use the "cable-cord" tire as shown in Fig. 3.

The inner lining of a tire is made of a rubber sheet; then the first or **inner layer or ply of cable cord** is laid; then two sheets of pure gum are applied to act as a **cushion** between this and the next ply of cord.

The **second or outer layer** of cord is then applied at right angles, or at an angle of 45°, to the first layer; then two layers of gum cushion stock, then a fabric **breaker-strip,** and then the **tread,** are successively applied.

The body or carcass of the tire, as will be noted, is made of two plies or layers of cords, instead of fabric. These cords are made of cotton fiber, about the size of heavy sewing cotton, twisted into cords about the size of ordinary grocery store twine, but stronger. These cords in turn are woven into cables.

Throughout the process, all units are impregnated, under heavy pressure (hundreds of pounds to the square inch), with a solution of pure, fine rubber. This has much the same effect as waxing shoemaker's thread. The solution permeates every fiber, being literally driven into it.

Treads: There are two types of treads used on cord tires, the "ribbed tread" (Fig. 8, page 592) and the "safety" or "non-skid" tread.

The air pressure carried in the cord tire is given on page 593.

Cord tires are made in sizes which are given on page 594.

Beads of tires are made for tires as noted on page 595.

A heavy truck tire of the cord type is made in sizes given on page 594.

Airplane tires of the cord type are made in 26 x 4 and 32 x 4½ sizes.

The cord tire is a higher-priced tire than the fabric tire, but is the popular tire, as it will outwear the fabric tire and is well worth the difference. This is due to its strong construction. Yet it is resilient and easy riding, and the cords do not break as readily as interwoven fabric.

Cord tires can be made by the "molded" or by the "wrapped tread" method.

---

[1] "**Cured**" means vulcanizing; "**open-curing**" is a process where live steam comes in contact with the raw rubber; "dry curing" is where steam is not in direct contact; "uncured" is raw, unvulcanized rubber.

TIRE TROUBLES: CAUSES AND REMEDY

Some of the tire troubles are: stone-bruises, loose treads, sand blisters, worn treads, chafed tires, rim-cuts, punctures, cuts clear through the carcass, blow-outs.

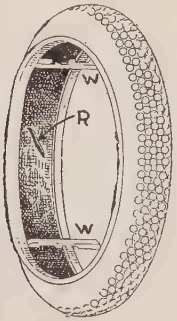

Fig. 4.—**Inside break in fabric** at (R). Note the tire spreaders (W) used to hold the tire apart when examining or repairing it.

Stone bruises are caused by the tire striking a stone at a high rate of speed, resulting in one or all layers of the **fabric breaking,** yet the tread may not even be cut. The inner tube works into this break, and a blow-out (Fig. 6) results.

Tires have been known to blow-out while standing in the garage, as a result of a stone bruise, and it is no doubt often a mystery why it occurred. The reason is simple. The tire struck a stone, or some obstruction when running at a high speed, and the fabric being hard, broke at (R) (Fig. 4) on the inside of the tire, yet the tread showed no effect of the trouble. This is termed a stone-bruise. Examine the tires when off the rim and feel the fabric, inch by inch, for a weak spot. If a break has occurred, you can see it (Fig. 4).

A temporary repair can be made by using "inner" and "outer" shoes (page 611), but it is advisable to repair as shown on page 617, as a blow-out may occur even with this "inner shoe" covering the weak spot.

The cord tire is not as susceptible to stone bruises because the cords are not interwoven, or crosswoven, like a fabric tire, and instead of breaking, they give.

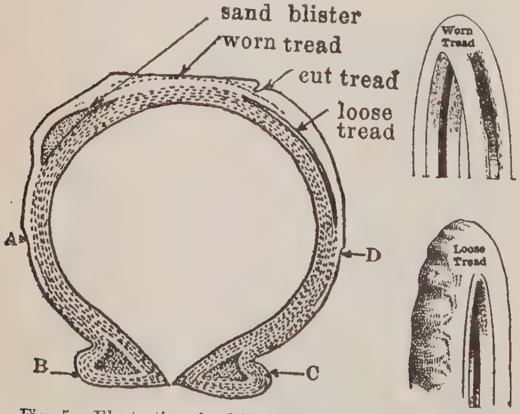

Fig. 5. Illustrating the different troubles that a tire casing is heir to.

Sand blisters are caused by a small hole or cut in the tread through which sand and dirt work under the tire, causing it to pucker up. These will result in a loose tread if not closed up (see Fig. 5). The hole through which the sand worked into and under the tread may be several inches away. Close it up with a plastic substance called "tire dough," or vulcanize it. See page 621: "Sand-blister repair."

Loose treads result from running a tire not properly inflated, or from moisture getting under the tread through a cut in the tread, or from a defect in the tire where the rubber compound is poor and does not adhere, or from setting brakes suddenly.

Loose treads can be repaired, unless the tread is loose about one-third of the way. In this case a new tread must be applied —providing the fabric carcass is not cut (if it is, repair it first)— and providing layers or plies of fabric in the carcass are solid and are not separated.

The molded type of tire is more subject to loose treads than the wrapped-tread construction.

Worn treads in the center, or slightly to the side of the tire, usually are the result of driving in street-car tracks, wheels being out of line (usually on the front) caused by the steering knuckles being bent or the steering apparatus being out of order. See Index under "Alignment of wheels."

Chafed tires, usually worn on the side, result from driving close to curbstones, in street-car tracks, ruts, etc. This permits water to rot the fabric. **Repair** by rebuilding the side walls, and vulcanize.

Rim cuts are the result of running the tire flat after a puncture, or running on the rim which damages the curve in the rim and which in turn cuts the tire at the rim just above the bead. Improper inflation is also a common cause. This permits the edge of the rim to cut the bead when the deflated tire receives a heavy jar. **Rim cuts can be repaired** if cut in only two or three short places, but if cut at sections all around the tire, then it cannot be repaired.

This refers to the old-style clincher rims. Now that most tires are of straight-side construction, rim cutting is not as common a trouble as formerly.

Punctures through tread and carcass, if small, will not cause damage to the carcass, but the tread should be closed by vulcanizing with the small vulcanizer while the tire is inflated on the car, or by some kind of plastic material, such as "tire dough," being stuffed into it to keep water and sand out.

Where tires are cut through the carcass, they can be repaired if the cut does not extend too long and the plies of fabric are not separated. The process of repairing is the same as for a blow-out repair (page 617).

Retreading

Retreading: It is no easy matter to form a correct judgment about any tire with regard to retreading. In some instances a tire case may appear to be sound, and yet may prove to have stone bruises in the carcass on inside examination, or the layers of fabric may be separated from each other. On the other hand, there are undoubtedly covers condemned, because of local damage, which if properly examined, would be worth retreading.

The age of the tire and **condition of the fabric** and cost of the retread **will determine** if it is worth while to retread. The strength of the tire is in the carcass. The rubber tread is merely a protection.

Therefore the condition of the carcass must be determined when deciding as to retreading. There are three questions to determine: (1) is the carcass badly cut in several places—if so, don't retread or repair; (2) are all the layers of fabric of the carcass together and not separated; sometimes these fabric layers separate and pucker up, owing to improper adhesion in manufacture, or to water getting under the tread and into the carcass: (3) is the tire rim cut badly?

Blow-Outs

The greatest tire trouble is blow-outs. A blow-out is simply a hole blown through the carcass or fabric. **There are two classes of blow-outs:** those occurring near the rim, and those in the tread or on the side.

Fig. 6

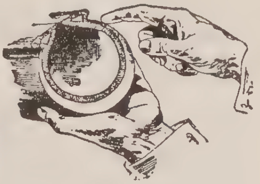

Fig. 7

Fig. 6. When a blow-out occurs it always leaves a weak spot.

Fig. 7. The tire is made thin here for a purpose.

We will designate the first-mentioned as a **"rim blow-out,"** and the latter as a **"tread blow-out."** Wherever a blow-out occurs, that spot always remains weak, because the fabric can never be joined again, but can be repaired (see page 617).

Cause of rim blow-outs: A tire is made thin at the point shown in the illustration (Fig. 7), near the rim, for a purpose. Very nearly all the "bend" and "give" is at this point. If it was made thick and heavy, it would break; therefore, it must be thin and flexible.

If you were to take a wire and bend it quick and often, it would get hot and break. The same is true with this bending point of the tire near the bead—especially if the tire is not properly inflated.

Inside breaks in the fabric are due to stone bruises and to running the tire improperly inflated.

If you were to take a deck of cards and bend them back and forth, it would be noticed that the bottom cards would receive most of the sawing strain. Just so with the several plies of fabric, when the tire is not properly inflated.

Keep the tire inflated, therefore, and many of the tire troubles will be avoided.

A tire may **look** sufficiently inflated and yet have only 40 pounds of air in it, when it should have 70. No amount of kicking, feeling, or looking will tell; the only sure way is to have a reliable air gauge.

Tread blow-outs are the result of cuts on the tread and of stone bruises. Cuts and jabs on the tread of tires permit dampness, oil, or dust to get between the rubber and the fabric, which soon rots and weakens it.

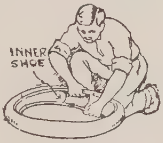
Inasmuch as the fabric must sustain the air pressure, **a weak place in the fabric is enlarged by the pressure,** and a blow-out is the result. Once a blow-out occurs, it can never be repaired so that it will be as strong as it was at first.

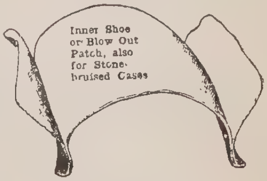
Therefore **repair cuts in the tread and examine tires for internal fabric cuts** caused by stone bruises, when the tire is off the wheel.

External cuts in the tread can be vulcanized while the tire is inflated and on the wheel, and the work can be done with the small vulcanizer shown on pages 615, 617.

A temporary repair of a blow-out or of an internal fabric cut, or of weak places in the carcass, can be effected by inserting an **inner shoe** between the inner tube and the carcass and an **outer shoe** over the tread (Figs. 10, 11, and 12). The defect should be repaired as soon as possible, however, as a cut in the fabric will soon work larger and cause a blow-out from rim to rim.

How to get additional mileage or service out of old tires: Very nearly every motorist has one or more old tires which is of no use. These old tires can be made serviceable again by placing inner shoes inside of the tire, covering the weak spots or holes, and then placing reliners inside of the tire over those reinforced places (see Figs. 8 and 9). Reliners are hard on inner tubes and are not advisable to use in new tires. They should be used only for temporary repair of old tires.





Inner Shoe or Blow Out Patch, also for Stone-bruised Cases

CARE OF TIRES AND TUBES[1]

Proper inflation: Keep tires inflated to the pressure recommended by the maker (see page 593). Nothing ruins a tire so quickly as running it so soft that the canvas continually bends. It is almost impossible to over-inflate a tire with a hand pump.

Running a flat tire, even a short distance, is sure **to be costly.** Better run on the rim, very slowly and carefully, if imperatively necessary, and the distance is short.

Keep grease and oil away from your tires and tubes always. They destroy rubber.

---

[1] A useful and valuable booklet, *Care and Repair of Tires*, issued by the Firestone Tire Co., Akron, Ohio, will be sent free on request, by writing this firm. A good deal of beneficial information is contained therein. Also write B. F. Goodrich Co., Akron, Ohio.

A book well worth the price of $1.50 on *Tire Repairing and Vulcanizing* can be had of A. L. Dyke, Pub., Granite Bldg., St. Louis, Mo.

Speedy deflation demands instant attention. Carry an extra casing and inner tube.

Equalizing traction: It is important that tires of the same diameter be used on the rear wheels. Furthermore, special treads and chains should be used in pairs. If there is a variation in the diameter of the rear tires or in the traction of the wheels, the differential is caused to work whenever the car is in motion. In this way, considerable power is lost, and the differential parts are unnecessarily worn.

Alignment of wheels: It is very important that the wheels should be in alignment. If they get out of line, the tire treads will wear in a very short while. As usual in this case, the tire manufacturer will not guarantee or rebate on a tire tread ruined by wheels being out of line. See Index for "Alignment of the wheels."

Wheels running over a fraction of an inch out of alignment cause a grinding wear on the rubber. Front wheels suffer most.

Side skidding and rounding corners rapidly will cause rim cutting. Avoid running in car tracks.

Setting brakes suddenly, causing the tire to drag, causes loose treads, and worn treads, and damages the tire. Always set brakes gradually. See Index under "Brakes."

Do not drive in the ruts or bump the side of the tires against the curbing or pavements, and don't start your machine with a jump.

If one of your tires sustains a cut to the extent of exposing the fabric, an emergency band or patch should be applied at once.

Keep an odometer record of the mileage of each tire. You will find that you are getting better mileage than you would otherwise imagine.

Keep rims in good order, straight and true. Rust is destructive. Paint preserves.

The rims, if rusted, should be thoroughly cleaned and sandpapered, and then painted with liquid graphite (common stove polish will answer). Also apply to bead of tire.

Inner tubes: Carry them in the coolest part of the car, away from oil cans and tools. The best protection is a soft bag, well dusted with soapstone, in which the carefully folded tubes are put. See page 613, "How to fold an inner tube."

Unless some pressure is retained however, the tube will have a tendency to crack when again inflated, if left folded for a long time.

Occasionally examine your tires and remove small pieces of glass, etc., that may have become lodged in the rubber. They are likely to work their way through, and cause a puncture.

Spare tires should be kept in a place where they are not subjected to light, heat, or rapid changes in temperature.

Nothing will wear a tire faster than sudden locking of the rear wheels with the brakes, and turning corners at considerable speed. Use your brakes with judgment, and turn corners slowly.

Never allow a tire to wear until the canvas fabric becomes injured, because the wall of the tire is prone to become too thin to prevent the pressure of the inner tube from bursting through the weak portion. Remember that the strength of the tire is in the fabric. The rubber is merely a binder which unites the various layers of fabric and forms a covering over the whole.

To make old tires resilient: Apply an ammonia solution with a rag to the tire or tube. Through application of this solution, the tire or tube will regain all the properties of a new one.

Tire paint[1] for painting the inside and outside of tires is mixed as follows to make 1 gallon: Mix 1 quart of gasoline and 5 lbs. of whitening, stirring until thoroughly mixed. Add 1 quart of No. 1043 Firestone cold-patch cement (or any other cold-patch cement) gradually, and stir until mixed.

The solution is applied with a brush and leaves a white surface which will not crack because of the elasticity of the cement.

Another similar tire paint, for finishing the inside of a tire after repairing, may be made by mixing thoroughly one gallon gasoline, one half-pint C-35 cement, 1½ lbs. soapstone, and ½ lb. whiting. Many successful repairmen are using this formula with the best of results.

Inner Tube Pointers

The cross-sections of inner tubes are made a little smaller than the normal air space inside of the cases. It is not, therefore, advisable to use a 4½″ tube in a 4″ case. This usually wrinkles and creases the rubber with bad results. Do not use a 4″ tube in a 4½″ case for any length of time. When this is done the rubber is required to stretch too much, and the heat and the action resulting from displacement of air in the tire quickly use up the nerve and life of the tube.

Lubrication is most important to the conservation of the tube, but it is a matter that is given least attention. Practically all tire manufacturers treat the inside of cases with a white solution to prevent tubes from sticking to the casing, and to reduce the frictional wear. A good lubricant, however, should also be used.

A gray inner tube is not colored. The best gray tubes use pure Para gum with sulphur, to give it strength. This sulphur causes a "bloom," or white gray dust which gives it the color.

A red inner tube has been dyed to give it color, and instead of sulphur, antimony is used, which will stand a greater amount of heat. Heat causes rubber to harden and crack. Gray tubes stick to cases; red tubes will not stick as freely. Therefore, the advantage of a good red tube lies in these two points.

Some owners neglect dusting soapstone inside of the case when changing a tube; others use the soapstone so sparingly that it does but little, if any, good, or they may use so much that it does more harm than good. If a quantity of it be dumped into the case it will collect at one point, and during the hot weather will heat up to such an extent as to burn the rubber of the tube, making it very thin, brittle, and lifeless; this can be recognized by the honeycombed appearance. **Soapstone** is the lubricant most used for tires, and it is quite satisfactory, but not lasting; therefore a fresh supply should be put into the tires at least two or three times during the season. **Powdered mica** has proved a more durable lubricant than soapstone and quite as effective as graphite, as well as more pleasant to handle. The lubricant should be applied with a soft rag and rubbed into the pores of the tube, and also on the fabric all around the case.

The life of an inner tube—if of good rubber—should be two years. As the tube grows older, the rubber becomes hard and porous, and finally reaches the "past repair" stage, which is noticeable through constant slow leaks. New tubes are then advisable.

How to preserve extra inner tubes: Deflate tube and fold, as shown in Fig. 13; powder the tube with a generous amount of talcum powder, then wrap in a piece of canton flannel or cheesecloth and pack in a small wood box with a sliding top. This will protect the tube indefinitely.

---

[1] A liquid tire paint called "Nitrex" protects spare tires, gives a handsome finish to the tire, and protects it from deteriorating. See also page 647.

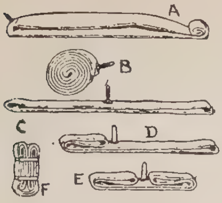

Fig. 13

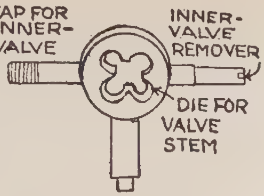

Fig. 14

Fig. 13. **To fold an inner tube:** Remove "inner-valve," then roll slowly as at **(A)** and **(B)** to exclude air. Then lay flat and fold as at **(C)**, **(D)**, **(E)**, and **(F)**. A flannel bag is suitable for carrying extra tubes in.

Fig. 14. **Four-in-one valve tool:** die for recutting threads for valve cap; tap for inner-valve threads; inner valve remover.

Inner Tube Troubles

Slow air leaks from a tube are sometimes traced to the "inner-valve" leaking.

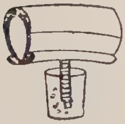

Fig. 15

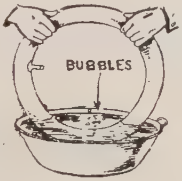

Fig. 16

Fig. 15. **To test an inner valve for a leak:** inflate the tube; place the end of the valve, with valve-cap removed, in a glass of water: if bubbles appear, the inner valve leaks. Put in a new one.

Fig. 16. **To test an inner tube for a leak:** partially inflate the tube and place it in a pan of water; air bubbles will appear at the leak. Mark leaks with indelible pencil.

To test the base of a valve for leak, submerge the valve part of the tube in water, with the tube partially inflated.

To test for an inner-valve leak, inflate the tube and test, as shown in Fig. 15. If leaky, try cleaning the inner valve, and screwing down tight. If this does not remedy the leak, then put in a new inner valve.

A slow leak may also be due to the valve-stem base being loose, or to the inner tube rubber being porous, through age. Old tubes in time harden, become porous, and leak slowly.

To test for valve-stem or slow leak or puncture see Fig. 16.

The average life of a tube is from twelve to eighteen months, perhaps two years; but once it begins to harden, it is advisable to replace it with new tubes.

Punctures may result from a puncture through the tire from outside, or it may result from rough places inside of the case, such as soapstone balls, etc., or from the tube being pinched.

Tube pinching: This is one of the most common causes of damage to inner tubes. Many tubes are pinched beneath the bead of the tire or beneath the staybolts (see page 596, E and F); see also "stone-bruises," page 610.

The valve may leak: It sometimes happens that a tire becomes deflated because of a leaking valve, and the condition may easily be supposed to be due to a puncture. If no visible sign that the tire has been penetrated is discovered, a test of the valve-stem can be made without removing the inner tube, by putting a few drops of water in the valve-stem. Bubbles will indicate a leak, or the valve can be tested as shown in Fig. 15.

If such is found to be the case, the valve parts should be tightened with the notched cap **(B)** of the valve-stem inserted in the valve and used as a wrench, as shown in Fig. 5, page 591.

If this does not remedy the trouble, entire new inner-valve parts **(A)** (page 591) should be put in place. Every repair kit is supplied with them, and they as well as caps **(B)** should be kept in the kit constantly.

METHOD OF REPAIRING INNER TUBE

In a case where the inner tube is punctured, but the casing practically uninjured, as in the case of puncture by a nail or tack: First of all, satisfy yourself that the tack or nail is not sticking in the casing, for if it is, your repaired tube will be punctured again before you have gone 1,000 feet. Having done this, the inner tube may be removed (wholly, or in part, as may be necessary) and either repaired or replaced.

There are two methods of repairing an inner tube: (1) by **cementing a patch** over the puncture, and (2) by **vulcanizing.** The cement patch does not hold, and will leak in time; but the vulcanizing of the tube, as shown on pages 614, 615, will make a permanent repair. The best plan would be to insert a new tube and vulcanize the damaged one later. An inner tube properly vulcanized is as good as new, but it is much easier to make the repair at home.

Do not carry inner tubes in the tool box where they are liable to be bruised or otherwise injured.

The modern method is to have a spare rim with a tire inflated, ready to put in place of the damaged tire, as previously explained. Without this equipment, it will be necessary to repair the tube, or to put in a new one.

Cementing a Patch

If a cement patch is necessary, owing to the absence of a vulcanizer, then proceed as follows:

Select a patch of the right size, that is, large enough to extend three-fourths of an inch or an inch beyond the puncture in each direction. Wipe off every trace of moisture or bloom, and roughen with emery cloth the surfaces to be joined. Apply two coats of cement to the tube surface and to the patch, removing with the fingers all superfluous cement; the less of it there is, the quicker the repair.

Allow the cement to dry until it adheres strongly to the fingers (five minutes at least will be needed), then, and not until then, apply the patch; compress strongly and look carefully to see that the edges of the patch do not loosen.

Before putting back the tire, assure yourself that the cause of the puncture is removed, such as a nail or tack or rough spot inside of the casing, or else the tube will puncture again.

Note. **Never try to join two surfaces while they are still damp,** for rubber cement joints are of no value unless everything is dry. Never apply friction fabric to an inner tube, but always a patch of pure caoutchouc. Friction fabric is not air-tight.

Even though a sound tube has been inserted on the road, the punctured tube should be mended promptly to be ready for another emergency. There is scarcely a limit to the number of repairs a tube will bear, but patches applied with cement cannot safely be considered permanent repairs. It is a paying investment to **make vulcanized repairs** as opportunities present themselves.

When a patch becomes loose: It will sometimes happen that a tire will become partially or even entirely deflated without apparent cause—that is, without any nail or other puncturing instrument being visible. If you have had experience with occurrences of the kind, you will immediately suspect a loosened patch, and proceed to verify your suspicions. Partly inflate the tire, and your ear will tell you whereabouts the leak is. Remove only as much of the casing as will enable you to attack the job conveniently. You will very likely find that, although the air has burrowed a small channel between the patch and the tube in one place, other portions of the patch are holding on tenaciously. Why an inner tube patch does not stick uniformly all over, is something that no one ever could understand.

A drop of gasoline applied with care does wonders in persuading the patch to peel off, and afterward, in cleaning the surface of the tube; but do not apply the solution until you have well roughened the place with sandpaper. Put the old patch away for future use, and apply a fresh patch and two coats of solution; spread on thinly and rub in well, especially the first (you cannot rub the second coat hard, or the lot peels off); squeeze the patch and tube together as hard as possible with finger and thumb, beginning in the center of the patch and working out to the edges. You may hold a block of wood under the tube and beat the patch with a hammer if preferred, but go gently. One motorist belabors his patches unmercifully, and says they never come off. Judicious beating does no harm, and screwing up in the vise between two pieces of wood and leaving all night also works wonders.

Vulcanizing Inner Tubes

Cement patches are only temporary or emergency repairs. The tube should be vulcanized.

A small vulcanizer, as shown in Fig. 19, below, can be used for vulcanizing inner tubes, which is a very simple operation. The tube is cleaned around the puncture and coated with vulcanizing cement. Then a piece of raw rubber, the same as that from which tires are made, is placed over the puncture. The vulcanizer is applied as shown in the illustrations (Figs. 19, 29, page 616), and heat is applied for about fifteen minutes, the actual length of time depending on the kind of vulcanizer that is used, and the thickness of the rubber being vulcanized.

For small cuts, sand blisters, etc., on tires, this vulcanizer will also answer, but for blow-outs and large cuts in tires a larger vulcanizer is necessary.

By giving cuts on casings a little attention now and then, tire mileage can easily be doubled or trebled. Small cuts, neglected, admit dirt and water to rot in the fabric until a blow-out occurs that ruins both tube and casing. The only sure remedy is vulcanization, which, in many instances, can be done while the tire is on the wheel inflated.

What Is Vulcanization?

Vulcanization is the process of cooking or curing raw Para gum. Exactly as in baking a loaf of bread, the best results can be obtained only when the proper amount of heat is used.

The temperature ranges from 250° to 300° F., about 265° being considered best.

It requires 15 to 20 minutes to vulcanize a layer of Para 1/16″ thick at 265° F. temperature, and 5 additional minutes for each additional 1/16″.

It is immaterial whether the vulcanizer be heated by electricity, gas, gasoline or steam. The idea is to keep the vulcanizing surface at a steady and proper degree of heat.

Small Vulcanizing Outfits

There are several standard types of small vulcanizers available. They are designed with a view to supplying machines that are adapted to the most convenient sources of heat. On the road, gasoline is always available; therefore for tube work and small casing repairs a gasoline-heated vulcanizer is handiest. Where there are electric lights, they naturally suggest the cleanest and handiest heat. Motorists who have city lighting current in their garages prefer the electric vulcanizer, on account of its convenience and large capacity. Most of the work is done at home, and an electric vulcanizer, which has its heat controlled automatically and maintained as long as desired (an essential feature), has this advantage that, by leaving it on a tire as long as is necessary, the thickest tread repair can be cured clear through, aside from being able to make a superficial repair. Successive repairs can be made without loss of time, as the vulcanizer can be moved from one tube to another.

The following will clearly explain **the method of tire repairing.** It is the writer's intention to deal with the vulcanizing subject only in an elementary way. To those interested in the tire repair business we suggest writing to C. A. Shaler Co., 22 Jefferson St., Waupun, Wis., for a copy of their very complete books *How to Open a Tire Repair Shop* and *Care and Repair of Tires.* We recommend also writing to Williams Fdry. & Machine Co., Akron, O.; Akron Rubber Mold and Mchy. Co., Akron, Ohio; Lowell Mfg. Co., Lowell, Mass., for additional information.

To Vulcanize an Inner Tube with a Small Gasoline or Alcohol Vulcanizer

Preparation of tube and patch to repair a punctured tube: Clean the spot around the puncture about two inches in diameter with emery paper; then wash off clean with gasoline. Cut sufficient repair rubber to cover the puncture, and dampen with gasoline the surface of the rubber to be applied to the tube, allowing it to dry thoroughly. Then apply the repair rubber to the tube directly over the puncture, as illustrated in Fig. 17.

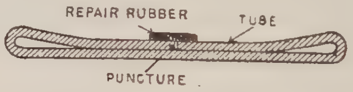

Fig. 17

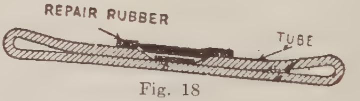

Fig. 18

To repair a rent, pinched, or torn tube: Shear off the damaged part to a beveled edge, and follow the cleaning and washing instructions given above. A piece of repair rubber the exact size and shape of the hole must be placed in position, and another piece of repair rubber larger over all than the hole must be placed on the damaged part, as illustrated in Fig. 18.

Care must be taken that the tube is thoroughly cleaned with emery paper and gasoline, and that the surface of the rubber applied to the tube is washed with gasoline and allowed to dry.

To apply the vulcanizer: Clamp the vulcanizer directly over the prepared tube and fasten securely and uniformly with the thumbscrews, being careful to have the patch centralized beneath the vulcanizer, as illustrated in Fig. 19.

Operation of vulcanizer: After preparing the tube as instructed, attach the vulcanizer as shown. Stand the vulcanizer on the bench, running-board, or floor. Pour the gasoline between the heating flanges, using the measure furnished, and light it. After the flame goes out, which will be in about ten minutes, let the vulcanizer cool a few minutes and the repair is done.

When vulcanizing a casing, clamp the vulcanizer in place with the chain furnished with it (Fig. 22). Heat the vulcanizer with the cylindrical lamp which is furnished. There is no exposed blaze and no chance to spill burning fuel, so that it is perfectly safe to vulcanize a tire while inflated on the wheel.

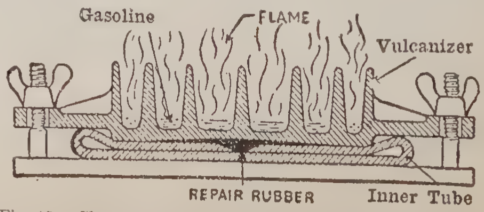

Fig. 19. Showing inner tube being vulcanized, and how the gasoline or alcohol heats the vulcanizer on the Adamson type of gasoline vulcanizer.

To Vulcanize Slight Cuts in a Tire

The small vulcanizer (Fig. 22) can also be used for vulcanizing small cuts, etc., on treads of tires, as explained below.

To prepare casing and patch: Thoroughly cleanse the cut or tear by using sandpaper or a pocket knife, and wash perfectly clean with a rag, using gasoline. Cleanse a layer of repair gum with gasoline, insert it in the cut, and trim it flush with the casing. If the injury is void of material, then build up even with the casing by cleaning each layer of repair gum with gasoline and firmly pressing into place.

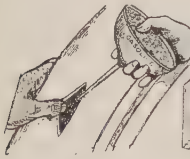

Fig. 20

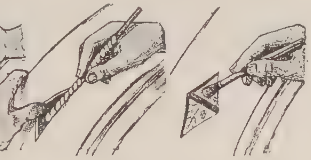

Fig. 21

Fig. 20. Clean with gasoline.

Fig. 21. Get dirt out; then cut the old rubber away, and give another cleaning.

To apply vulcanizer: Firmly clamp the center of the vulcanizer directly over the prepared patch, using care to have the patch centrally located against the face of the vulcanizer as illustrated in Fig. 22. Before applying the vulcanizer, its face may be dusted with soapstone or talcum powder, or a cake of ordinary soap can be rubbed against it to prevent the repair gum from sticking.

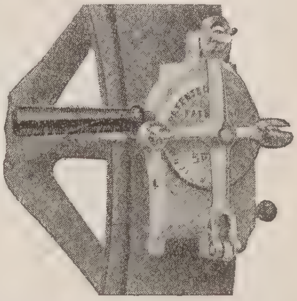

Fig. 22. The Shaler tourist's gasoline or alcohol vulcanizer, vulcanizing a cut on the outer casing.

EXAMPLE OF AN INNER TUBE REPAIR WITH A SHALER PORTABLE ELECTRIC VULCANIZER

Vulcanizing Inner Tube Punctures

Clean the tube thoroughly with gasoline and coarse sandpaper (see page 614). Cement the edges of the hole and apply a thin layer of cement. Let the cement dry.

If the puncture is a small hole, fill even with the surface of the tube with layers of Para rubber cut the size of the hole. Cut a patch of Para ⅛″ larger than the hole or puncture, and apply over it. Then cut another patch ½″ larger than the hole and apply over the first. Cover with waxed paper and apply the vulcanizer.

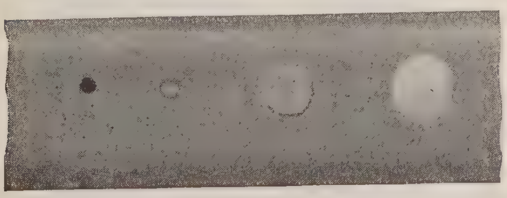

Fig. 23. Repairing a tube puncture.

Edges of punctures or small holes should be beveled with scissors to make a larger uniting surface and to provide room for the new material. Repairs of this sort are to be **vulcanized for fifteen or twenty minutes** at 265°F.

Inner Tube Cuts and Tears

Clean as directed, both inside and outside of tube; coat edges of the cut and inside and outside of the tube with cement, and let dry.

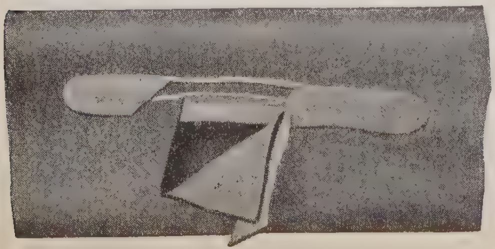

Fig. 24. Repairing a slit in the tube.

Cut a strip of Para rubber as wide as the tube is thick, and stick on the edge of the cut; cut a strip one half-inch wide, place **inside of the tube** under the tear, bring the edges of the tear together, and stick them down to this strip. (The use of semi-cured stock for the inside patch is preferable, as it obviates the use of paper inside the tube.) Apply another strip of Para rubber, one half-inch wide on the **outside of the tear. Vulcanize for twenty-five minutes.** Cover the repair with waxed paper before vulcanizing.

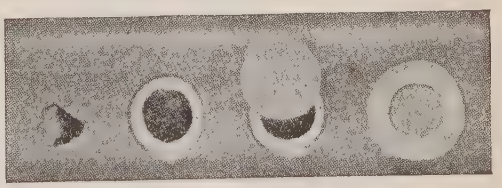

Fig. 25. Repairing a tube blow-out.

Blow-Outs in Tubes

When mending large, irregular bursts or blow-outs in which a piece of rubber has been blown out of the tube, the best method is to trim down to a clean, solid surface, making the hole somewhat regular in shape. The hole may be filled with layers of Para rubber cut to fit.

Inner Tube Splices

It often happens that, when a tube is badly torn, it is easier to cut out a section and replace it with a new piece of tube. In making repairs of this kind, be very careful not to alter the original length of the tube.

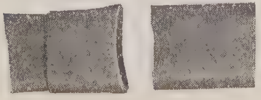

Fig. 26

Fig. 27

Fig. 26. **Splicing** an inner tube; showing tube ready to lap.

Fig. 27. Tube after **lapping.**

Clean the outside of one end of the tube for about four inches. Fold back the other end, turning the tube inside out, and clean for the same distance. Apply at least three coats of cement to each end. (Fig. 26.) A repair of this sort requires a considerable amount of cement if no Para rubber is used, because the adhesiveness of the joint depends upon the cement alone. A narrow strip of Para between the two tubes will add to the strength of the joint. Butt the open end against the folded end, and telescope the latter over it. **Vulcanize in three operations,** the first for twenty minutes, the last two, fifteen minutes each. A block should be used underneath the tube, to prevent pinching the edges of the tube. The vulcanizer is placed on top.

Valve-Stem Seat Repair

Select a good place on the tube, then clean a space about 4″x2½″, and cut a hole about ¼″ in diameter.

Remove the parts from the valve-stem and stretch the hole in the tube over the base of the valve-stem. Push the stem clear through into the tube. It is to be kept inside and away from the repair until after vulcanization.

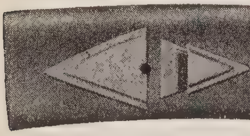

Fig. 28

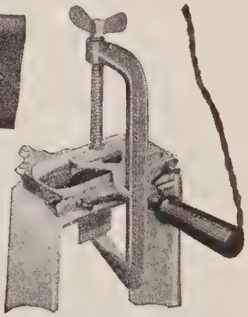

Fig. 29

Fig. 28. Valve-stem seat repair.

Fig. 29. The electric vulcanizer is connected to a lamp socket.

Cement the entire clean surface around the hole in the usual manner.

Cut an oval or diamond-shaped piece of Para about 2″ x 3″, having a hole in the center to correspond with the hole in the tube. Roll it down on the tube so that both holes register. Cover with a layer of blow-out canvas of the same size and shape. Cover all with another layer of Para rubber ¼″ larger all around than the first. **Vulcanize forty minutes.** Shake the valve-stem on the inside of the tube to the vicinity of the hole, and force it through the opening until the base rests against the inside of the tube; then slip the clamp disk **(S-T)** and spreader **(L)** (Fig. 3, page 591) over the valve-stem, and fasten them securely with locknut **(P).**

Pointers When Vulcanizing Inner Tube with Steam Vulcanizer

The time required for vulcanization is determined by the depth of the new material inserted, and not by the size or area of the repair. The following is based upon the maintenance of a uniform steam pressure of 45 pounds.

If the tube is in a very much worn condition, place a piece of rubber tubing larger than the pad under the pad, and vulcanize at a lower steam pressure and more slowly. With a steam pressure of 45 lbs.:

For tubes 1/16″ thick, vulcanize for	7 minutes.
For tubes 1/12″ thick, vulcanize for	8 minutes.
For tubes 1/10″ thick, vulcanize for	10 minutes.
For tubes 1/ 8″ thick, vulcanize for	13 minutes.

How to test a repair: Test the part vulcanized by pressing the thumb nail into it. If it is responsive and elastic to the touch and resembles the rest of the tube in this respect, it is perfectly vulcanized. If, however, it clearly **retains the mark of the nail,** it is under-vulcanized and should again be placed in the vulcanizer and given a longer heat. It is best to add time, **not temperature.**

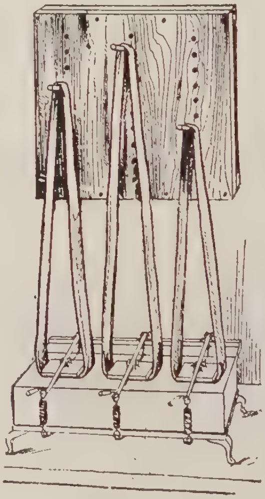

Fig. 30

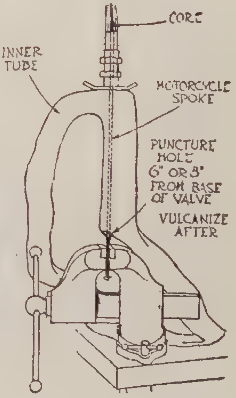

Fig. 31

Fig. 31. Sometimes the inner-valve core becomes immovable from the stem. The diagram explains how to remove. (*Motor Age.*)

TIRE REPAIRING AND VULCANIZING[1]

As previously stated, it is the writer's intention to deal with the vulcanizing subject only in an elementary way. The tire repair business is one in which expert knowledge can be gained only by actual experience. The material following, however, will give one an idea as to the principle, and also of the equipment for small shops and how to make all ordinary repairs.

There are several methods of vulcanizing. It is immaterial whether the vulcanizer be heated by electricity, gas, gasoline, or steam. The idea is to keep the vulcanizing surface at a steady and proper degree of heat. The steam vulcanizer, of course, is used in the larger vulcanizing shops.

Troubles Which Necessitate Tire Repairs

Owing to external causes:

1. **Tread cuts,** which permit dirt to work under the tread and cause "loose treads" and "sand blisters." The moisture also rots the fabric and weakens it.

---

[1] The following books are recommended to those who desire more information on tire repairing: *Tire Repairing and Vulcanizing* ($1.50); *Tires and Repairing* ($2.00); *Tire Business Answered* ($2.50); *Better Tiremen* ($2.00) (sold only with the complete set named above); all by Tuford. Address A. L. Dyke, Electrical Dept., Granite Building, St. Louis, Mo.

2. **Cuts clear through tread and carcass:** When a cut is made through tread and carcass it is a perfect cut, but if blown out, the edges are ragged.
3. **Fabric broken and weakened inside,** through striking a stone on the tread of the tire.
4. **Blow-outs** are the result of surface or tread cuts. The admission of moisture causes the fabric to rot, and the pressure of the tube blows through the weakened place with a loud report.

   The blow-out is also frequently attributed to a "stone bruise," as explained on page 610.
5. **Broken back** is a serious and common injury, and is the result of insufficient inflation. The layers of fabric separate. This might be termed a "fabric separation."

Importance of Repairing Slight Cuts on Tires

A set of tires should be gone over at least once every two weeks, and the cuts in the treads of the casings should be sealed up by vulcanizing them. This can be done with the tire inflated and on the wheel. In this way deterioration of the fabric is prevented, and the tires will give a mileage three times as great as that usually given.

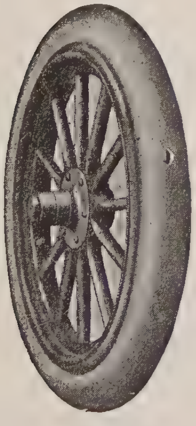

Fig. 32

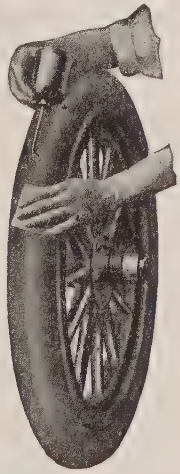

Fig. 33

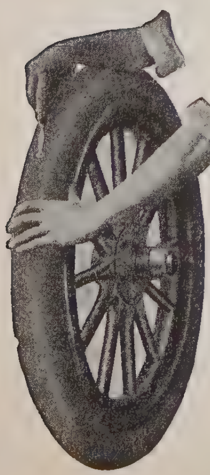

Fig. 34

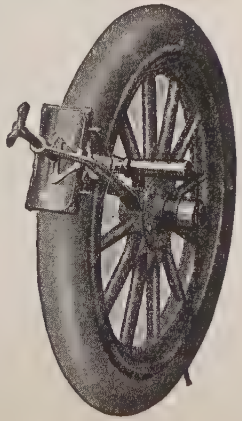

Fig. 35

A tire in which there is **a small cut and a "sand-blister"** or pocket is shown in Fig. 32. If not repaired at once, sand, dirt, and water will be forced into it and rot the fabric until it becomes so weakened that the inner tube will blow out through it and ruin the casing.

The gash being cleaned and filled with new, live Para rubber is shown in Figs. 33, 34.

The Shaler portable electric vulcanizer in place on the tire is shown in Fig. 35. Note that it has not been necessary to remove the tire from the rim. The vulcanizer is left in the position shown for thirty minutes. The portable electric vulcanizer is well adapted for repairs of this kind.

The foregoing instructions cover the **external repairs** of "tread cuts," "sand-blisters," and slight "loose treads."

Internal and External Tire Repairs—Sectional Method

There are two methods for reinforcing and building up tires for internal repairs: (1) the "wrapped-tread" method, and (2) the "sectional" method.

With the **wrapped-tread method,** as explained on page 608, the tire is built up or reinforced from the **inside,** whereas with the **sectional** and **step cutting** method, it is built up from the **inside and outside.**

Step Cutting and Sectional Repair of a Blow-Out

How a blow-out is prepared for reinforcing and building up by the "sectional" method is shown in Figs. 36, 37. Note how each layer of fabric is "stepped off." For example, there may be four layers of friction duck (canvas fabric) in the carcass.

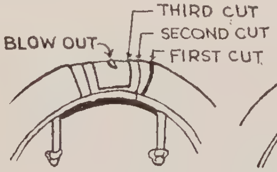

Fig. 36

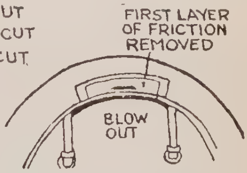

Fig. 37

Fig. 36. Preparing a blow-out for vulcanizing.
Fig. 37. Preparing side-wall blow-out for vulcanizing.

To proceed, the tread stock is cut down with a knife. The first cut made (Fig. 36) goes over each bead, and all fabric within these limits is removed. The second cut does not go over the bead, but falls inside, and borders the first cut by about one inch.

This removes two ply of canvas and the reverse process, or building up, replaces this canvas, "breaking joints" as a mason breaks joints in stone or brick setting, and the final layer of fabric adds one ply to the original strength. The casing is then reinforced with one layer of canvas on the inside, and the total strength, or four ply, has been restored.

A side-wall blow-out in the process of repair is shown in Fig. 37. The same principle of "stepping off" and reinforcing is used. This "stepping off" is one of the most important points to observe in making good tire repairs.

Vulcanizing with Molds

Steam vulcanizers, used in large repair shops, usually employ the **sectional method** of repairing, and use molds for vulcanizing.

Where the blow-outs are on the tread, after repairing, the tire is placed in the sectional or cavity mold (3) (Fig. 47, page 620), to be vulcanized or cured, and is held down by a clamp (C) (Fig. 43). This vulcanizes both inside and outside.

Where the blow-out is on the side-wall, or for a rim-cut repair, it is necessary to insert an "air bag" (Fig. 39). Then the bead mold is placed over the tire, and entire repair is completed at one operation.

Where inside repairs only are cured, or where the tire is to be dried out before vulcanizing, the "inside patch vulcanizer," at (4) (Fig. 47) is suitable.

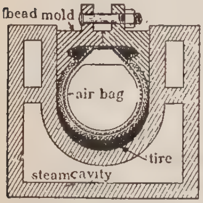

Fig. 39

Fig. 38 (upper)

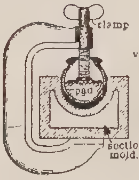

Fig. 40

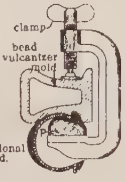

Fig. 41

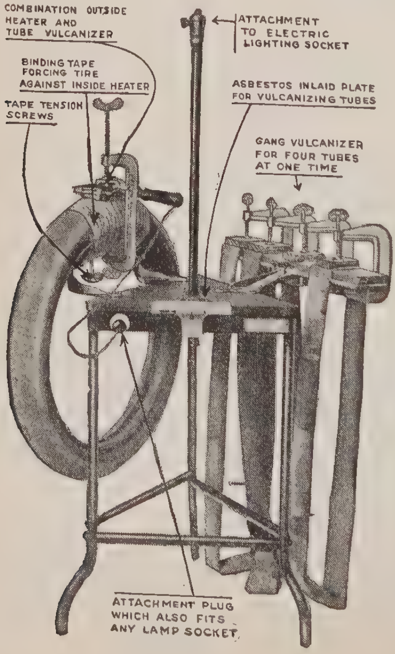
There are two methods of holding the tire in the mold for tread repairs: (1) by a clamp and pad and mold, as in Fig. 40, and by the use of an air bag (Fig. 38) which expands the tire, used in connection with a cavity mold (Fig. 39).

Where side walls or beads are repaired, the clamp and bead mold and pad (P) (Fig. 41) can be used, or the air bag and bead mold (Fig. 39) can be used.

Shaler Electric Vulcanizer

The Shaler electric vulcanizer, type ACE, is illustrated in Fig. 42, as also the Shaler steam vulcanizer (Fig. 45). Each employs the **wrapped-tread method** of vulcanizing; an example is given on page 620.



COMBINATION OUTSIDE HEATER AND TUBE VULCANIZER
BINDING TAPE FORCING TIRE AGAINST INSIDE HEATER
TAPE TENSION SCREWS
ATTACHMENT TO ELECTRIC LIGHTING SOCKET
ASBESTOS INLAID PLATE FOR VULCANIZING TUBES
GANG VULCANIZER FOR FOUR TUBES AT ONE TIME
ATTACHMENT PLUG WHICH ALSO FITS ANY LAMP SOCKET

Fig. 42. Shaler electric vulcanizer, type ACE.

Air bags or cavity molds are not used with either of the Shaler vulcanizers. Inside molds or mandrels are inserted for inside repairs, and outside molds or mandrels, or hot plates are used for outside repairs (see page 619, Fig. 45).

The two vulcanizers shown below are of two different types. Fig. 43 illustrates the Akron-Williams model 6F steam vulcanizer, employing the molded method with cavity molds, and Fig. 45 shows the Shaler type NPR steam vulcanizer. This vulcanizer repairs all sizes of casings by the wrapped-tread method and casing forms or heaters are used instead of molds.

An explanation as to the difference between a tire which is repaired by the "wrapped tread method" and one repaired by the "molded method" is given as follows:

Wrapped tread: Refer to Fig. 42 and observe that after the tire has been properly treated, ready for vulcanizing, a piece of waxed paper is placed over the repair and **tape is wrapped** around it. The thumbscrew of the "outside heater" (Fig. 42) is then drawn tight and the electric current is turned on.

Molded method: Refer to Figs. 39 and 43 and observe that the tire is placed in a **mold,** and steam is turned on in the steam cavity (Fig. 39); thus the repair is not wrapped.

The A. K. Sectional Steam Vulcanizer

This vulcanizer is suitable for small repair shops in towns where there is a fairly good number of 4½" and 5" tires. It vulcanizes by the **molded method** with which air bags are used. Steam is generated in boiler (**B**) by gas or gasoline fuel connected at (**G**).

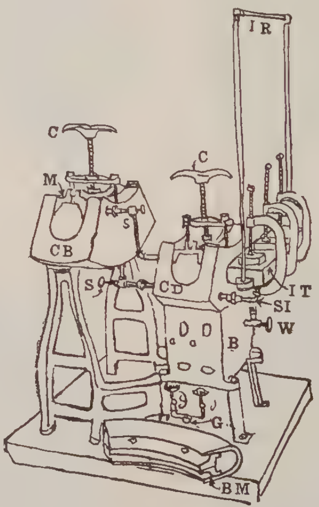


Fig. 43. Akron-Williams type 6F steam vulcanizer.

There are two cavity molds, (**CB**) for 4½" and 5" tires, and (**CD**) for 4" and 3½" tires. Tires of 3" size can be vulcanized by placing the 3" mold (**BM**) in the mold (**CD**). These molds will vulcanize "inside" and "outside" of the tire, as also "side wall" and "bead" repairs. See Fig. 39, and note the bead mold, also (**M**) (Fig. 43).

After the tire is prepared to be vulcanized, an air bag is inserted; it is then placed in mold (CB). The air bag is then inflated to 50 lbs. pressure, clamp (C) applied, and steam turned into the mold at (S).

Where there is considerable repairing, the inside repair mold or patch (4) (Fig. 47), is used. This is also handy for thoroughly drying out tires before vulcanizing.

Inner tubes are vulcanized by placing them over rack (1R) (Fig. 43). The part to be vulcanized is placed on plate (IT) through which steam passes.

Cost of a Small Steam Vulcanizing Plant

The **approximate cost of an outfit,** using the type 6F vulcanizer, together with the material required is given below. Note that the prices are only approximate.

1 model 6F vulcanizer (Fig. 33)	$245.00
5 airbags, 3″ to 5″ x 16″ long	22.70
1 gal. No. 1086 vul. cement	2.40
1 qt. No. 1043 cold patching cement	.67
1 lot inner tube valve patches	1.50
5 lbs. tread stock[1] (cures gray)	5.00
10 lbs. tread stock[1] (cures black)	10.00
5 lbs. inner tube repair stock[1] (red)	7.50
2 lbs. inner tube repair stock[1] (gray)	3.00
2 lbs. inner tube repair stock,[1] cured on one side only, for inside reinforcement	3.00
5 lbs. cushion stock	6.25
5 lbs. breaker-strip fabric	6.25
5 lbs. bead-cover fabric	10.00
10 lbs. carcass fabric	15.00
5 lbs. carcass fabric frictioned, one side only, for last ply next to tube and reinforcements	11.25
1 lot asst'd sizes Schrader valves, inner valves, valve caps, soapstone, waxed paper	7.50
1 lot tire tools as shown in Fig. 46	7.05
Total	$364.07

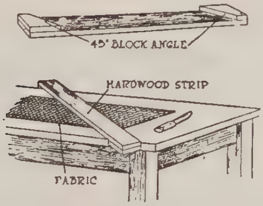

Fig. 44

Fig. 44. **Cutting tire fabric:** A simple but effective device for permitting fabric to be cut on the bias, with a wet knife, instead of shears, is illustrated here. A hardwood strip, forming the straight edge, is placed 45° across the tire repair bench, and each end fitted with hardwood angle blocks in the manner shown. These edges even up against the edge of the bench and secure a perfect 45° cutting angle.

The Shaler Steam Vulcanizer

This steam vulcanizer (Fig. 45) as well as the electric vulcanizer (Fig. 42) are adapted for small-town vulcanizing plants, or for garages where a tire repair department is added. The capacity of each of these vulcanizers is 20 tubes and 1 casing per hour. The vulcanizer (Fig. 45) can be secured with two casing forms or mandrels, which will give double capacity.

All sizes of casings can be repaired with the Shaler vulcanizers by the wrapped-tread method, an example of which is given on page 620.

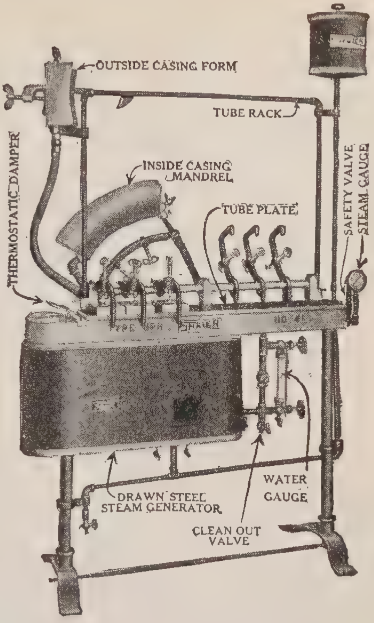

Fig. 45. Shaler steam vulcanizer, type NPR, No. 41.

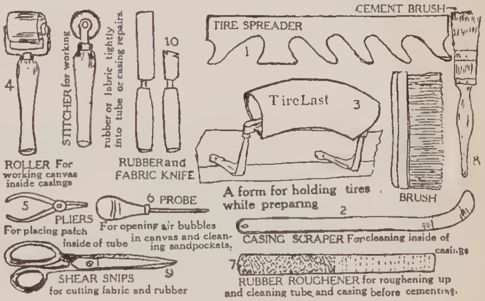
Shaler Vulcanizing Tools

Some of the tools required for tire repair work are illustrated and listed below.



CEMENT BRUSH
TIRE SPREADER
1
4
STITCHER for working rubber or fabric tightly into tube or casing repairs.
10
TireLast
3
8
ROLLER For working canvas inside casings
RUBBER and FABRIC KNIFE
A form for holding tires while preparing
BRUSH
5
PLIERS
For placing patch inside of tube
6 PROBE
For opening air bubbles in canvas and cleaning sandpockets.
2
CASING SCRAPER For cleaning inside of casings
9
SHEAR SNIPS for cutting fabric and rubber
7
RUBBER ROUGHENER for roughening up and cleaning tube and casing before cementing.

Fig. 46. Tire repair tools enumerated as follows:

1. Tire spreaders	$0.50
2. Casing scraper	.45
3. Casing mandrel	2.00
4. Roller for inside canvas work	.50
5. Pliers	.35
6. Probe	.20
7. Rubber roughener	.45
8. Cement brush	.25
9. Shears for cutting fabric	.75
10. Fabric knives, 60c. and 40c.	1.00
11. Stitcher for working rubber and fabric into casing	.60
Total	$7.05

Vulcanizing Rubber, etc.

Para rubber, per sq. ft.	$0.75
Para rubber, 5 lb. roll	6.75
Para Ruber, one side cured, per 5 lb. roll	7.50
Wax paper (sufficient for 1,000 repairs)	.25
Vulcanizing cement, per qt.	.75
Vulcanizing cement, per gal.	2.50
Blow-out canvas, Para-coated, one side, per sq. ft.	.50
Blow-out canvas, Para-coated, both sides, per sq. ft.	.60

Large Steam Vulcanizing Plant

An example of a steam vulcanizing plant of large capacity is given on next page. The vulcanizing plant shown in the illustration (Fig. 47) consists of the following parts:

---

[1] Means vulcanizing rubber. Do not use "self-curing gum," or old rubber; it will not vulcanize.

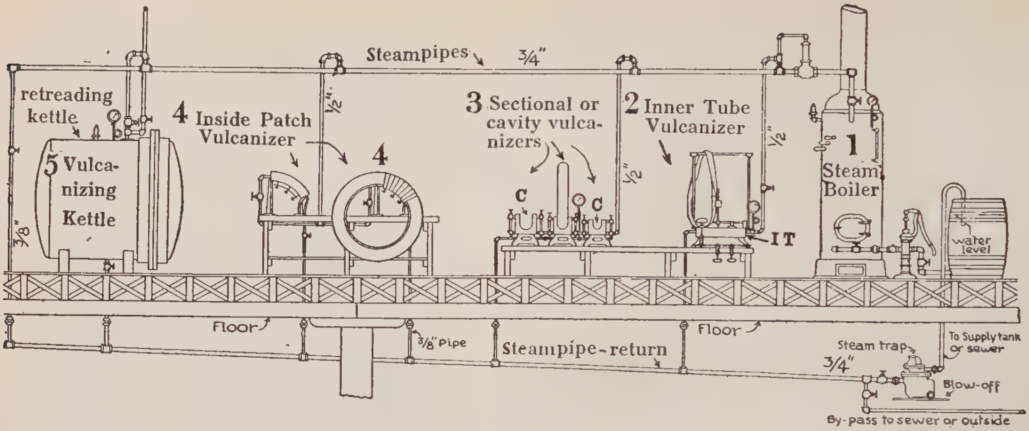


Fig. 47. Example of a large steam vulcanizing plant.

1. **Steam-boiler,** using coal or wood as fuel.
2. **Inner tube vulcanizer.** The steam passes through the iron plate (IT); part of the tube to be vulcanized is placed on this plate and the other part hangs over the rack above it.
3. **Sectional or cavity molds** for repairing tire casings. These are used to vulcanize the inside and outside of the tire in sections. These molds (C) are made to take different sized tires. See Fig. 39, and note that a bead mold is placed over the tire when it is in the cavity mold (C). These bead molds are made for clincher or straight-side beads.

   The air bag, shown in Fig. 38, is placed in the tire and blown up to a pressure of about 50 lbs. to hold it in shape when being vulcanized in the cavity mold (C). Steam passes through the cavity mold, thus giving the necessary heat.
4. **Inside patch vulcanizer,** consisting of an iron core shaped like the inside of a tire, through which the steam passes. The tire is placed over this core when only inside repairs are being made. Also used for drying out tires when repairing. Tires should be free from all moisture when being vulcanized, as moisture turns to steam when heat is applied, and forces the fabric layers apart, making a weak repair.
5. **Vulcanizing kettle,** used in rebuilding or retreading tires. This is used only in very large shops.

REPAIRING A "BLOW-OUT" BY THE "WRAPPED TREAD METHOD" OF VULCANIZING, AND ALSO OTHER REPAIRS

The "sectional" method, where repair is built up or reinforced from the outside, was explained on page 617. With the **wrapped-tread method,** it is built up or reinforced from the inside.

While we speak of **blow-out repairs,** this also covers **repairs for cuts through tread and carcass,** and also **side-wall and rim repairs.**

The following matter is taken from the Instruction Book of the Shailer steam vulcanizer as shown in Fig. 45.

Method of Step Cutting, When Necessary

If the fabric immediately around the hole is rotten and shredded so badly that it is impracticable to work it back into the repair, it will be necessary to remove any loose canvas that may be around the blow-out, "step cutting" it out in two or three steps, similar to the process shown in Fig. 36, page 617, but from the inside. This method, however, will not be required once in twenty repairs.

Cut the steps so that the smallest is at least 2" larger in every direction than the hole through the tire, and make each succeeding step about 1½" larger all around the one below it.

Coat all over with cement, working the cement in between plies of fabric at the ragged edges of the damaged part. After the first coat has dried for an hour or two, put on another coat, and let it stand for several hours—over night if convenient.

Cut layers of blow-out canvas (Para-coated on both sides) to fit the steps from which fabric was removed, and work them thoroughly in place, one at a time. Roll from the center to the edges of the patch, and if air bubbles form under the canvas, prick them with an awl and roll them flat. It is necessary that the canvas be laid smoothly, and that perfect contact be secured between the different layers.

Then put on another patch an inch larger all around than the largest step. Finish with plain friction canvas or canvas Para-coated on one side. This last layer must be long enough to cover the preceding patches entirely and to **reach to the clincher on the outside.** Use from four to six layers of canvas, depending upon the size of the tire and the size of the hole through it.

Reinforcing without Step Cutting

The following method is to be followed where **the fabric is not rotten.** The procedure is as follows:

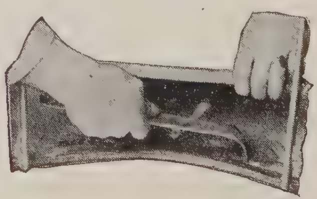

Fig. 48. **Clean the inside of the tire** about 6" on each side of the hole. Use gasoline to soften. Scrape until bare canvas is exposed, but do not cut the fabric.

Note that in these illustrations "tire spreaders" are used to hold the tire apart while being repaired.

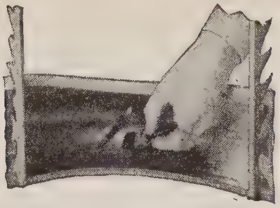

Fig. 49. **Apply two coats of cement over the cleaned surface.** Let the first coat dry one-half hour before applying the second. Cement the hole through the tire thoroughly.

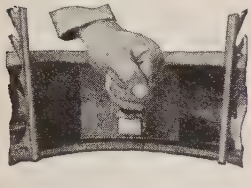

Fig. 50

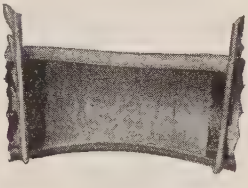

Fig. 51

Fig. 50. **Cut the first layer of the fabric** (Para-coated on both sides), so that it will extend 1″ beyond the hole in every direction. Roll smoothly in place, pricking any air bubbles to let air escape.

Then cut a second layer of fabric (Para-coated on both sides) large enough to cover the first one, and let it extend an inch over it in every direction.

Then cut a third layer (Para-coated on both sides) 1″ larger, and place it over the second layer in the same manner and roll it down.

Then cut a fourth layer (Para-coated on one side) 1″ larger than the third layer, and apply the Para-coated side next to the third layer. In large tires use 5 layers. After the third and fourth layers are applied, the appearance of the patch after all layers have been rolled down will be as shown in Fig. 51.

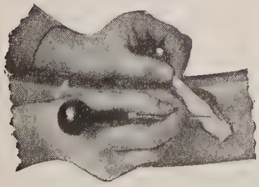

Fig. 52

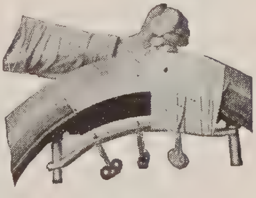

Fig. 53

Fig. 52. **Turn the tire over and fill the gash with tread stock** of narrow strips, and press down carefully. No cement is necessary. Do not fill the hole too full. Sprinkle inside with soapstone.

Fig. 53. **Place the tire over the "inside casing mandrel"** (also termed "form") (see Fig. 45). Lay a piece of waxed paper over the outside repair and place bead strips along the bead as shown; then wrap on tape and tighten the tension of the hand screws, so as to pull the tire down on the mold.

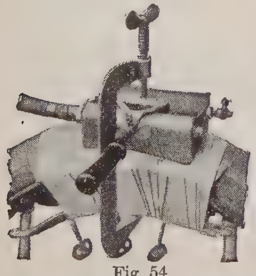

Fig. 54

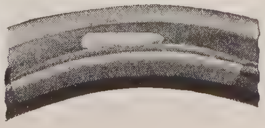

Fig. 55

Fig. 54. **Place the "outside casing form," or mold, over the outside repair,** and apply the steam. Cure for fifteen minutes; then loosen the clamp, and tighten the tape. About 15 minutes in all is required; for larger tires, 1 hour at 40 lbs of steam pressure is desirable.

Fig. 55. **Showing a blow-out repair near the rim.** The same method is used, except that the last layer of fabric is brought clear around the bead and up outside of the tire far enough for the bead strip to get a good grip. Then use the curved side of the "outside casing form," or mold, for rim work. (See also Fig. 45 for location of this on the vulcanizer).

Repairing a Sand Blister

1. Cut half-way around the blister, cutting through the rubber to canvas (**C**), and leave the rubber attached on the side nearest to the tread of the tire. Turn back the flap (**F**) thus formed, and remove all dirt; then clean and cement as directed above for casing cuts.

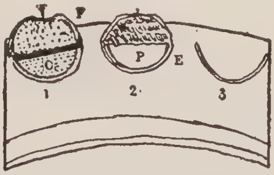

Fig. 57. Repairing a sand blister.

2. Cut a strip of Para rubber as wide as the rubber on the tire is thick, and stick it on the edge of cut (**E**). Then cut a thin sheet of Para the exact size of the canvas, and roll back in place and stick it down tightly (**P**).
3. At (3) is seen the repair after vulcanizing. Be sure to vulcanize the hole where dirt entered and caused the blister. It may be a foot away. Vulcanize according to instructions for small cuts (page 617).

A tire pump is an excellent bellows for blowing dirt out of a cut for a repair to be vulcanized. A sheet of waxed paper should be placed between the vulcanizer and the tire to prevent sticking to the hot iron.

To Repair a Section of a Tire Where Tread Is Loose

Cut through the tread; clean the under side of the tread and canvas thoroughly. Apply two or three coats of cement; when dry replace the tread, wrap with tape, as shown in Fig. 53 (this is the wrapped method of vulcanizing); then cure with inside and outside heaters, as instructed for blow-outs (Figs. 53, 54).

Example of an Anti-Skid Tread Repair

Should a tire have a non-skid pattern on the tread, and a section is to be replaced, the wrapped-tread method as explained in the Shaler instruction book is as follows:

Take a piece of canvas (Para-coated on one side) large enough to cover the repair. Apply to the coated side three layers of ordinary tread stock. Find a good place on the tire, dust it with soapstone, and apply this "pad" (Fig. 58) with the raw rubber side next to the tread. Place the tire on the vulcanizer, wrap tape over the pad and tire, tighten the tape, put on the "outside casing form" heater (Fig. 45, page 619), and cure for half an hour. The pad will then have taken an impression of the tread

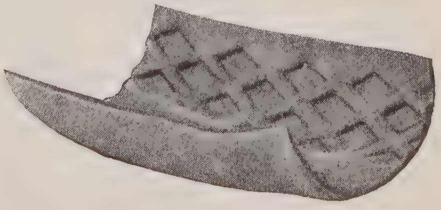

Fig. 58

and will be like Fig. 58. This may be done while you are waiting for the cement to dry on the repair.

When the repair is ready to vulcanize, place the pad over the repair, and wrap binding tape over it. When heated, the original tread pattern will be duplicated. Save the pad for future use, and mark it.

If it is unnecessary to replace a portion of the tread, but it is desired to protect the tread from being flattened by pressure of the tape when curing, simply make a thick paste of soapstone and water, and then fill the depressions in the tread with it before wrapping with the tape. When the repair is cured the dried soapstone is brushed off, and saved for future use.

AN EXAMPLE OF PRICES TO CHARGE FOR TIRE REPAIR WORK

The following are standardized prices adopted by a tire dealers' association in the Northwest, subject, however, to change without notice.

Sectional Repairs on Casing

3 in. sec. 10 in. long	$3.75
3½ in. sec. 10 in. long	4.50
4 in. sec. 10 in. long	5.50
4½ in. sec. 10 in. long	7.00
5 in. sec. 10 in. long	8.50

Retreading Fabric Casings

30 x 3	$10.50	32 x 4½	$22.50
30 x 3½	12.00	33 x 4½	22.50
32 x 3½	14.00	34 x 4½	23.50
31 x 4	16.50	35 x 4½	24.50
32 x 4	17.50	36 x 4½	26.75
33 x 4	18.50	35 x 5	34.25
34 x 4	20.50	37 x 5	36.00

Retreading Palmer Cord Casings

	Min.	Max.
3½ in. sec.	$ 5.50	$ 6.75
4 in. sec.	6.75	7.75
4½ in. sec.	8.50	9.50
5 in. sec.	10.25	12.00
6 in. sec.	25.00 and up.	

Tread Repairs

Tread repairs on 3-in. to 4-in. casings, $1.75 and up.
Tread repairs on 4¼-in. to 5-in. casings, $2.75 and up.

Reinforcing Casings

Inside reinforcement on 3¼-in. and 4-in. casings, $1.75 and up.
Inside reinforcement on 4½-in. and 5-in. casings, $3.00 and up.

Tube Repairs

Valve cores applied	$0.25
Tubes demounted	.50 and up
Tubes mounted	.75 and up
Add'l punctures	.25 each
New valve bases	.50
New valves 3 in.	.75
New valves 3½ in. and up	1.00

Reinforcements, blow-outs, and sectional work extra.

We reserve the right to turn down any tire during any stage of inspection, and we are not liable for so doing.

Where tread bands are used, add 10 per cent to the foregoing prices.

Flaps and Flap Repairs

Old flap repair	$0.50
New flap, 3½ x 4	1.50
New flap, 4½ x 5	2.00

Special repairs, not quoted, are based on cost of material and labor.

AIR COMPRESSORS FOR USE ON THE CAR

Air compressors can be classified under two headings: (1) hand or foot air pumps; (2) power air compressors.

Hand and Foot Air Pumps

This type of air pump is made in the "single" and "**compound**" type.

The single-acting hand air pump (Fig. 59) is made with a single barrel. It is seldom used, because it requires a heavy exertion to pump a tire to the proper pressure, unless the fulcrum is great enough to reduce the effort required to manipulate the pump.

A very satisfactory type of hand air pump for general garage use, employing the fulcrum and lever principle, is shown in Fig. 60. It consists of one welded steel cylinder packed with gum rubber to prevent leakage. The plunger is made of oak leather. Ball valves prevent back pressure. The name of this pump is the Jensen, manufactured by the W. H. Howell Co., Geneva, Ill.

A compound type of hand air pump is shown in Figs. 61 and 62. This type of pump employs two barrels; on some types there are as many as three barrels.

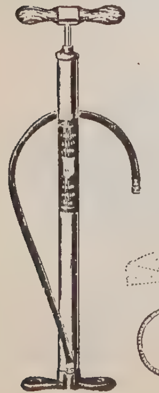

Fig. 59

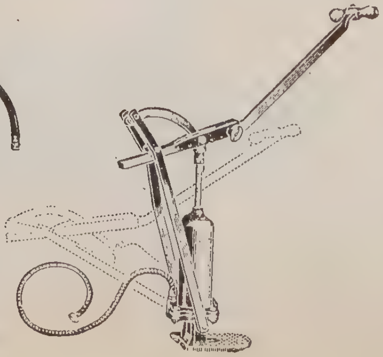

Fig. 60

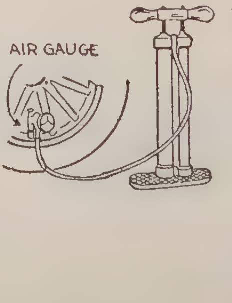

Fig. 61. Showing a compound air pump with an air pressure gauge attached. The gauge shows the amount of air pressure in lbs. per square inch.

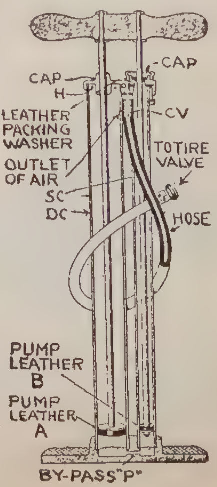

Fig. 62

Principle of operation: The air is drawn in from the atmosphere into the large cylinder and is compressed by the down stroke of the handle; at the same time it is forced into the smaller cylinder through by-pass (P).

The up-stroke of the pump forces the air from the smaller cylinder into the tire through check valve and hose (CV), and the large cylinder sucks in another charge.

While the air admitted into the large cylinder is receiving its first compression, it is forced through passage (P) (connecting the two cylinders) and up past cup leather (B) into the upper portion of the smaller cylinder. The cup leathers (A) and (B) are fitted to their pistons in opposite positions, that is, the leather (A) is put in with its open side downward, and leather (B) has its open side upward. If both leathers are put in the same way, the pump will not work.

A pump of this kind differs from a single-cylinder pump, in that each stroke is a power stroke, while in a single-cylinder pump only the down strokes are power strokes.

Keep the leather packing washer (around the piston rod of the small cylinder) tight, otherwise the air will blow through here instead of going into the tire.

Power Air Compressors for Use on the Car

Under this heading there are two types of pumps: (1) the impulse air pump; (2) the power-driven air compressor.

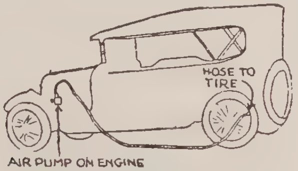

Fig. 63. Illustrating how the connection is made from the air pump (driven from the engine, or transmission shaft) to the tire. The air hose is detachable, and is usually carried under the seat.

The Brown impulse air pump: This pump (Fig. 64) has the appearance of a compound pump, because of the large and small cylinders, but they are built in this form to make it possible to pump the high pressures necessary for large tires, and at the same time not have any too good a compression in the engine cylinder. The lower piston, with its large area, receives its impulse from the compression in the engine cylinder, and transmits it to the upper piston through the medium of the hollow piston rod, to which both pump pistons are attached.

Action: As the engine piston makes its suction stroke, it draws fresh air through valve (1) which opens inwardly, and at the same time, both pump pistons make their downward stroke. You will note that piston rod (6) is hollow. This is the air passage to the upper cylinder through ball check (12). As the engine piston makes its compression stroke, it forces its charge of compressed air into the upper cylinder and against the lower piston of the pump, and causes it to make an upward stroke. This piston being so much larger than the upper piston, the charge is further compressed and sent through outlet valve (21), at the top, thence through the hose to the tires or the tank.

These pumps are very often spoken of as compound pumps, because of the fact that the air pressure is raised in two stages; but don't forget that the first stage is performed in the engine cylinder and not in the pump cylinder. It is a single-stage pump, capable of raising the pressure from 50 or 60 lbs. in the engine cylinder to 100 lbs. or more in the tire or the tank. It is advisable to let the pump make a few strokes before attaching the hose to the tire valve.

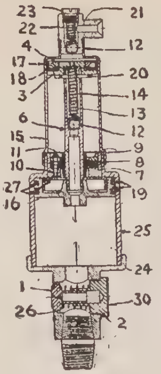

Fig. 64

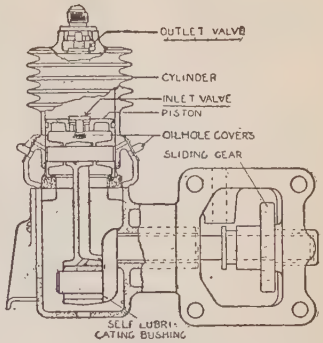

Fig. 65

Fig. 64. The impulse pump, sometimes termed the spark-plug pump, because it is screwed into the spark-plug hole and operates by means of the compression of the engine cylinder. (1) Inlet valve disk; (2) Inlet valve body; (3) Upper piston; (4) Upper piston nut; (6) Piston rod; (7) Stuffing box; (8) Rod packing; (9) Rod packing nut; (12) Ball check valves; (13) Upper piston pin; (14) Check valve spring; (15) Upper cylinder shell; (16) Lower piston; (18) Piston cup leather; (19) Piston rings; (21) Outlet valve; (22) Outlet valve spring; (23) Outlet valve cap; (24) Cylinder base; (25) Lower cylinder shell; (26) Inlet valve seat.

Fig. 65. **A power-driven tire air compressor** explained below.

Power-Driven Tire Air Compressor

The illustration is of the compressor used on a Cadillac car. It is bolted to the left-side transmission case and is driven by a sliding gear which meshes with the reverse idler gear in transmission. The sliding gear is thrown in when needed, and out when not needed, by a lever.

To operate: Stop the engine, wait until the transmission gears are idle, then shift the gear of the compressor in mesh with the reverse idler gear. Then start the engine, being sure that the gear-shift lever is in neutral position.

Run the engine at speed of 900 to 1,100 r.p.m. This is indicated by the ammeter showing 16 or 18 amperes, if the third-brush is properly regulated on the generator. Do not race the engine when inflating tires. Throw the gear out of mesh when through pumping tires. Lubricate the compressor often. By observing the illustration, it will be seen that the inlet of air is taken in through the "inlet valve" in the top of the piston, from the crank case of the pump, when the piston travels down. It is compressed and forced out of the "outlet valve" as the piston travels up.

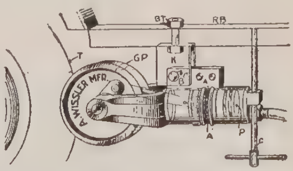

Fig. 66. Wissler friction-drive air pump: (T) tire; (GP) grooved pulley on pump connecting rod; (K) bracket bolting pump to running board; (A) air intake; (P) piston; (C) adjustment of tension of (GP) to (T). The rear wheel is jacked up, with the engine run on low or reverse gear. (Wissler Inst. Co., St. Louis.)

POWER-DRIVEN AIR COMPRESSORS FOR GARAGE USE

There are two types of air compressors for general garage use: (1) the air-cooled compressor; (2) the water-cooled compressor.

Where compressors are used almost continuously, the water-cooled type is recommended, because, for heavy constant duty, the air-cooled compressor would heat. When heating occurs, the air drawn into the hot compressor expands; then when it cools in the tank, it contracts, with the consequence that the pressure drops. The usual pressure is maintained at about 150 lbs., which is sufficient for all ordinary requirements. The pressure in the tank must, of course, be somewhat higher than at the outlets, usually about 15 lbs. higher. This, naturally, is determined by the number of outlets. There is usually a safety valve on the air tank which can be adjusted accordingly.

When purchasing a compressor be sure that it is over-size rather than under-size, as the business may grow; furthermore it is hard on the compressor if it is operated continuously when under-size.

Tank capacity: The following table is taken from the instructions furnished with the air compressors manufactured by the Brunner Mfg. Co., Utica, N.Y.

Size Tank to Use

Tank	Size	200 lbs.	180 lbs.	160 lbs.	140 lbs.
20 gal.	14x30	4 Tires	3 Tires	2 Tires	1½ Tires
32 "	16x36	6 "	5 "	4 "	3 "
40 "	16x48	9 "	8 "	6 "	4 "
50 "	16x60	12 "	10 "	8 "	6 "
65 "	18x60	15 "	13 "	10 "	8 "
80 "	18x72	19 "	17 "	13 "	10 "

Tank sizes, at the pressure given above, will inflate the given number of 35 x 4½ tires to 85 lbs. as shown in the table. For example, a 40-gallon tank at 180 lbs. pressure will inflate eight 35 x 4½ tires to 85 lbs.

After inflating tires of this size, each will have from 89 to 90 lbs. left, with which to inflate several smaller tires.

Drive methods: The air compressor can be driven by a belt from a line shaft, or by an electric motor. When self-contained—all in one unit—it can be driven by a belt, by a silent chain, or by gears.

Pointers on belt-driven compressors: A belt should be used of the width of the compressor pulley. If a smaller belt is employed, it will slip and stretch. Leather belts are best, as it is easier to lace them than fabric belts.

The speed of the compressor should be exactly that which the manufacturers advise. If it is run too fast, the compressor will heat; if run too slow, the capacity will be reduced.

How to Determine Speed and Size of Pulley to Use for Driving Air Compressors

The speed at which air compressors should operate is of importance and is determined by the sizes of pulleys. It should be remembered that the larger the driving pulley, the faster the compressor, having a given size of pulley, will be driven, and vice versa. We give here the method of determining the pulley sizes and speeds under different conditions:

When the compressor is driven direct from an electric motor, a 3″ pulley is generally used in order to keep the pulley on the compressor as small as possible. **To determine the size of the compressor pulley,** multiply the speed of the motor pulley by the diameter of the motor pulley, and divide the result by the number of revolutions of the compressor.

Example: What size of compressor pulley is required to drive an air compressor at 340 r.p.m. direct from an electric motor having a 3″ pulley and running at 1,700 r.p.m.?

1,700 × 3=5,100÷340=15″ pulley on the compressor.

When it is desired to drive a compressor from a motor by means of a countershaft, to ascertain the size of the countershaft pulleys, multiply the speed of the motor by the diameter of its pulley, and divide by the desired speed of the countershaft; this gives the size of the driven pulley on the countershaft. Then multiply the recommended speed of the compressor by the diameter of its pulley, and divide the result by the speed of the countershaft for the size of its driving pulley.

Example: It is desired to drive an air compressor, having a 9″ pulley, at 350 r.p.m. by a motor having a 3″ pulley and a speed of 1,700 r.p.m. The compressor cannot be driven direct from the motor, and a countershaft must be used. What size of pulley must the countershaft have?

1,700 × 3=5,100÷425 (speed of countershaft)=12 in., the size of the driven pulley.

350 × 9=3,150 ÷425 (speed of countershaft)= 7.4 in.

The nearest commercial pulley is 8″. Therefore an 8″ driving pulley is used on the countershaft.

When the countershaft runs at the same speed as the compressor, then the pulley on the compressor and the drive pulley on the countershaft must be of the same diameter, irrespective of what that diameter is (anywhere from 3″ to 3 ft.).

When an air compressor is driven from a line shaft without a countershaft, and the size of the driving pulley is required, multiply the speed of the compressor by the diameter of its pulley, and divide by the speed of the line shaft.

Example: An air compressor having a 9″ pulley is to be driven at 350 r.p.m. from a line of shafting having a speed of 450 r.p.m. What size of pulley must be used on the line shaft?

350 × 9=3,150÷450=7 in., the size of the driving pulley on the line shaft.

See also Index under "Diameter of pulleys; how to find," for further suggestions on the subject of finding the diameter of pulleys.

Installing an Air Compressor

Place the compressor on a firm foundation in a location where the pipes will not have to extend too far. Locate it preferably where short pipes can be used, and where fresh air and not gasoline fumes will be drawn into the compressor. It is best to draw the air from outside the building with a screened air intake.

Locate the tank where it can be easily drained, as vapor in the air condenses and should be drained. It does not matter if the tank is placed in a horizontal or in a vertical position.

Locate the air pipes where they can be used most and will be accessible for the greatest number of purposes, such as for outside free air service, for the vulcanizing department, for the tire-testing tank, for the buffing machine, etc.

Use flexible, woven-fabric-covered hose of very small diameter, as it is better than rubber.

Pipe and pipe joints should be connected by using shellac, asphaltum, or a mixture of litharge and glycerine to insure air-tight joints. The elimination of air leaks is a very important factor. Use the size of pipe recommended by the manufacturer of the compressor. The pipe leading to **the inlet** of compressor should never be smaller than the full diameter of the compressor inlet opening, and also of the outlet pipe. Iron or steel pipe is satisfactory.

Attach the **outlet pipe** from the air tank as high as possible from the tank, to avoid water condensation going to the tires.

A draincock in the pipe should be placed at the lowest point, especially when outside of the building, as the condensation is likely to freeze.

Air-Compressor Outfits

The Brunner air compressors[1] are used here as an example. The illustration (Fig. 67) is the layout for a belt-driven outfit, and in Figs. 68 and 69, electric motor-driven compressors are shown.

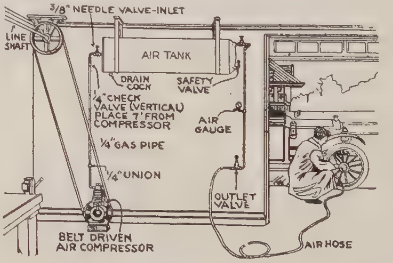

Fig. 67. **Belt-driven garage outfit No. 2,** for garages housing from 15 to 20 cars, and for vulcanizing shops.

1	No. 100 belt-driven compressor, 8″ T. & L. pulleys (1 tight and 1 loose)	$24.00
1	20 gal. 14″ x 30″ galvanized air tank	20.00
1	Model "B" air gauge	3.00
1	No. 75 vertical check valve	1.80
1	No. 72 safety valve for air tank	2.75
1	No. 83—¼″ needle valve	1.80
1	No. 83—⅜″ needle valve	1.80
1	No. 82—⅜″ needle valve with swivel	1.80
1	Tire connection and 25′ hose	6.55
		$63.50

Fig. 68. **A self-contained air compressor outfit** using Brunner No. 102 air compressor suitable for garages up to 60 to 70 car capacity. This air compressor is air cooled and is driven by an electric motor, ½ h.p.

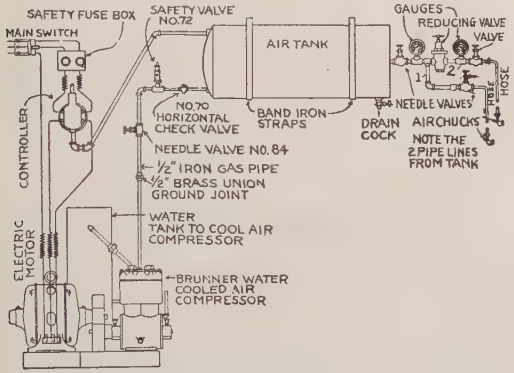

Fig. 69. **A heavy-duty air compressor outfit** using Brunner No. 17 vertical air compressor. This air compressor is water cooled and driven by an electric motor, 2 h.p. Designed for very large garages, for tire air service, and also for operating paint sprayers, small pneumatic tools, general shop work, etc. Note that there are two pipe lines leading from air tanks 1 and 2. No. 1 is at normal pressure of the tank, and No. 2 is at a reduced pressure through the reducing valve.

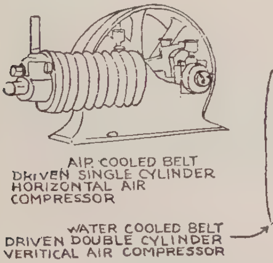

AIR COOLED BELT DRIVEN SINGLE CYLINDER HORIZONTAL AIR COMPRESSOR
WATER COOLED BELT DRIVEN DOUBLE CYLINDER VERITICAL AIR COMPRESSOR

Fig. 70

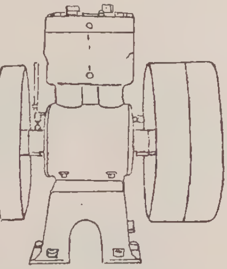

Fig. 71

Fig. 70. Brunner **belt-driven single-cylinder horizontal air compressor,** adapted to small vulcanizing shops: bore 1 13/16″; stroke, 2″; guaranteed pressure up to 175 lbs. at 350 r.p.m., the capacity is 1 cu. ft.; at 400 r.p.m., 1 1/6 cu. ft.; at 450 r.p.m., 1 1/3 cu. ft. free air per minute; uses 1½″ belt for an 8″ loose and tight pulley; power required, ¼ h.p. at 100 lbs. pressure; outlet pipe is ¼″; weighs 23 lbs. and costs $24.00.

A Brunner **belt-driven double-cylinder vertical air compressor** gives about twice the capacity. Price, with 9″ pulley and friction clutch, $53.00. Requires ½ h.p.

Fig. 71. Brunner **belt-driven double-cylinder water-cooled vertical air compressor** for continuous service under high pressure; bore 3″; stroke 3″; capacity at 250 r.p.m., 6 cu. ft.; at 500 r.p.m., 12¼ cu. ft. of air per minute. Pulleys 16×3″: fly wheel. Requires 1½ h.p. at 100 lbs. pressure, 300 r.p.m. Price, $135.00 complete.

Portable Air Compressor

A Brunner portable motor-driven air compressor outfit is shown in Fig. 72. It can be moved to different parts of the garage, and is suitable for inflating tires direct without the aid of a tank and storage system.

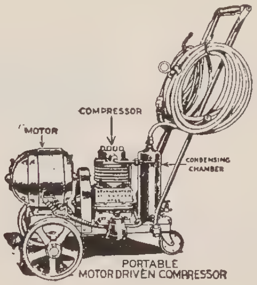

Fig. 72

The attachment plug is screwed into a lamp socket which operates the ¼ h.p. electric motor. This operates the air compressor which stores air in the tank. The advantages are apparent. Manufactured by the Brunner Mfg. Co., Utica, N.Y.

Compressed Air Used for Other Purposes

Compressed air for cleaning the upholstering is used in many up-to-date garages. With special connections and a vacuum tank the work is rendered easy and is done quickly. It is also used for spraying paint, for small pneumatic tools, etc.

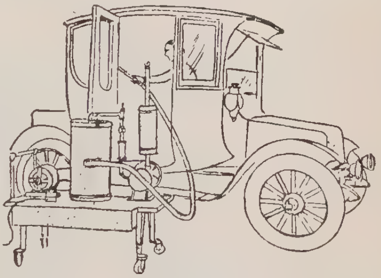

Fig. 73. Cleaning car with a motor-driven vacuum cleaner.

Care of Air Compressors

An air compressor might be compared with a gasoline engine. A piston draws air into the compressor cylinder through an inlet valve on the suction stroke. As the piston returns on its next stroke, the valve closes and the air is compressed and forced through the outlet valve to the air-storage tank.

The valves must seat properly, otherwise the pressure will be reduced. The valves are of the poppet type.

Lubrication of compressors is a subject of importance; that is, it is highly necessary to use the proper grade of oil as recommended by the manufacturer. Too much oil will gum the rings and get into the air tank, and will also necessitate frequent valve grinding. Lack of oil will result in burned-out bearings.

Cylinder-head bolts should be drawn tight, otherwise the compressor will fall below its capacity. Cylinder head gaskets should be used as recommended by the manufacturer. Paper or rubber will not do.

Knocks are often due to loose flywheels, carbon on the piston, or to worn bearings.

Compressed-Air Fittings

Fig. 74

Fig. 75

Fig. 74. **Wire-wrapped air hose for garage work:** inside diameter ¼″ and ⅜″.

Fig. 75. **Copper-wrapped brass-wire-woven flexible hose:** inside diameter ¼″ and ⅜″. For hand or portable pumps. The hose generally used is 3/16″ or ¼″ diameter.

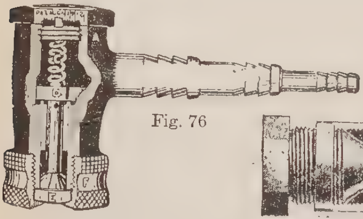

Fig. 76

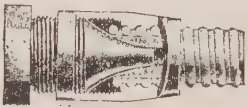

Fig. 77

Fig. 76. Romort style "A" **automatic air valve for use on air hose where it is in constant use.** Bronze; instantaneous in opening and closing; air-tight; step-up stem fits any size tubing from ¼″ to ½″.

Fig. 77. **Air hose couplings:** Takes care of any hose, large or small, metal covered or rubber; the hose is expanded at the end and the threaded nipple is so designed that it always holds firm—the harder the pull the tighter the grip; bushing is furnished to use on hose of small diameter. The type shown is the Romort "Universal," and is shown connected to metal covered hose. It can also be used on plain rubber air hose.

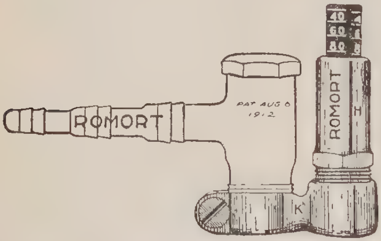

Fig. 78. **Tire tester and air-valve attachment** combined. The Schrader tire air-pressure gauge is shown attached to the Romort automatic air valve.

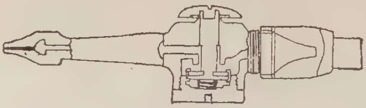

Fig. 79

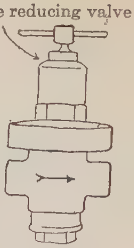

Fig. 83

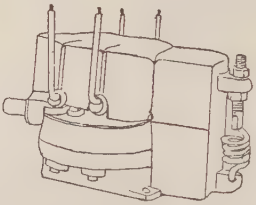

Fig. 80

Fig. 82

Fig. 81

Fig. 79. Romort **blow gun:** bronze metal; can be used wherever there is a lathe or other machine where it is necessary to remove chips, dirt, or other waste matter; entirely automatic; the valve closes when pressure on the trigger is released; connection to the hose is made by the Romort Universal hose connection, which fits all popular sizes of rubber hose and prevents the gun from blowing off the hose; can be used in the garage for cleaning all the dirt from tires to be vulcanized, for cleaning cushions, and for various other purposes.

An automatic blow cock, used in connection with an air-storage system for dusting out cars, cleaning engine and parts, can be had of the Stevens Co., 375 Broadway, New York, N.Y.

Fig. 80. Brunner **automatic electric air-pressure controller** (model M): Especially designed for use in motor-driven air compressors for garages, pneumatic water systems, etc.; automatically maintains air-tank pressure between predetermined limits; compact and substantially built; mechanism carefully made throughout with all moving parts protected from dirt and dust by metal cover; carries sufficient current to operate single, two, or three-phase A. C. motors up to 2 h p. and 440 volts; also suitable to operate D. C. motors up to and including ½ h.p.; regularly adjusted to start motor at 115 lbs. tank pressure, and stop it at 140 lbs.; can be adjusted at factory for other limits, but there must be 25 lbs. difference between maximum and minimum limits.

Fig. 81. Brunner **vertical check valves** for air lines for female connections ¼″ and ⅜″.

Fig. 82. Brunner **safety valves:** Have a ball seat; can be adjusted to blow off at any desired pressure up to 175 lbs.; intended as a tank safeguard by preventing higher tank pressure than that for which the valve is set.

Fig. 83. Brunner **pressure-reducing valve:** Metal construction, designed for work on air tanks carrying up to 150 lbs. initial pressure, and will reduce air-line pressure to a steady flow at any point between 10 and 60 lbs. to the square inch; by turning the adjusting screw in the top, the pressure can be instantly raised or lowered to any point between these limits; for service in reducing pressure on pneumatic tools or any other service where accuracy or great durability is desired.

SOLID TIRES

Solid tires can be divided into two classes: (1) the single, and (2) the dual type. The single solid tire is the type in general use. It has what is termed a hard base pressed on a single solid tire. The rim used is a channel-type non-detachable rim.

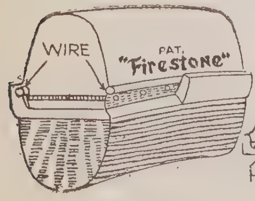

Fig. 84

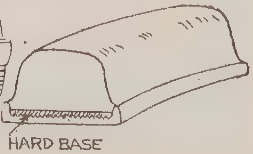

Fig. 85

The original automobile solid tire (Fig. 84)(now obsolete) was held in place by side wires.

The hard-base pressed-on type of solid tire and channel rim is shown in Fig. 85.

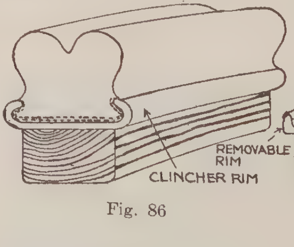

Fig. 86

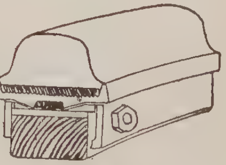

Fig. 87

The cushion tire is used where more resiliency is required. The rubber is softer than that in the regular solid tire. Fig. 86 shows a cushion type of tire on a clincher rim. This rim is now obsolete, and a channel rim, the same as used with other solid tires, is now used. This type of tire is used extensively on fire-department trucks.

The solid tire mounted on a quick detachable, demountable rim is shown in Fig. 87. This rim is now obsolete, the principle involved in the hard-base pressed-on tire being used instead.

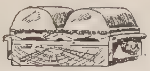

Fig. 88

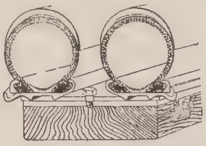

Fig. 89

The dual solid tire (Fig. 88) is now being replaced with single Giant solid tires. The dual construction consisted of sections or blocks, mounted on demountable rims.

The dual pneumatic tires for truck use (Fig. 89), mounted on quick-detachable side-ring type rims is now seldom used; instead, the Giant pneumatic cord tire, or the Giant solid tires are used.

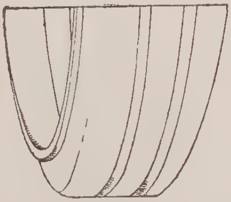

Fig. 90

The Giant single solid tire (Fig. 90) is the type of solid tire in general use for heavy trucks. It has a hard base and is pressed on the rim.

Standard Sizes of Solid Tires and Carrying Capacity

The solid tire in general use is divided into three classes:

1. The "Regular" single solid tire.
2. The "Cushion" solid tire.
3. The "Giant" solid tire.

Carrying Capacities of Firestone "Regular" Solid Tires and also "Cushion" and "Giant" Tires

For tires of 36″ or less:

3 inch, maximum load per wheel, 1,000 lbs.
3½ inch, maximum load per wheel, 1,300 lbs.
4 inch, maximum load per wheel, 1,700 lbs.
5 inch, maximum load per wheel, 2,500 lbs.
6 inch, maximum load per wheel, 3,500 lbs.
7 inch, maximum load per wheel, 4,500 lbs.
8 inch, maximum load per wheel, 5,500 lbs.
10 inch, maximum load per wheel, 7,500 lbs.
12 inch, maximum load per wheel, 9,500 lbs.

Dual solid rubber tire capacities are figured by multiplying the figures given above by 2.

For tires of 38″ and 40″:

5 inch, maximum load per wheel, 3,000 lbs.
6 inch, maximum load per wheel, 4,000 lbs.
7 inch, maximum load per wheel, 5,000 lbs.
8 inch, maximum load per wheel, 6,000 lbs.
10 inch, maximum load per wheel, 8,000 lbs.
12 inch, maximum load per wheel, 10,000 lbs.
14 inch, maximum load per wheel, 12,000 lbs.

Standard Sizes of Firestone Regular Solid Tires

32 x 3
34 x 3
36 x 3
32 x 3½
34 x 3½
36 x 3½
32 x 4
34 x 4
36 x 4
34 x 5
36 x 5
40 x 5
34 x 6
36 x 6
40 x 6

Standard Sizes of Firestone Giant Solid Tires

34 x 7
36 x 7
40 x 7
34 x 8
36 x 8
36 x 10
40 x 10
36 x 12
40 x 12
40 x 14

Cushion solid rubber tires are made in the foregoing sizes, except 32 x 3, 36 x 3, 40 x 5, 34 x 7, 34 x 8, 36 x 12.

Solid Tire Troubles

Solid tire troubles occur mostly as a result of cuts and bruises which soon cause the tire to wear rapidly. These are caused by driving in car tracks, by chains being too tight, wheels being out of alignment, by skidding, by overloading, by speeding on bad roads, etc.

The solid tire cannot be successfully vulcanized. Therefore the only recourse is to run the tire for as long a time as possible.

Chains for Solid Tires

Chains for solid tires are a very important factor, as the solid tire has a tendency to skid—more so than pneumatic tires. They are also essential for gripping the road, snow, ice, etc.

Several methods of applying chains and grips are shown below.

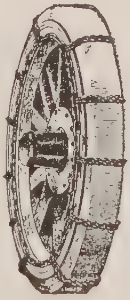

Fig. 91

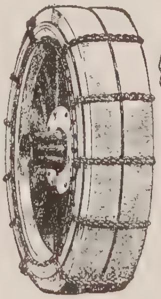

Fig. 92

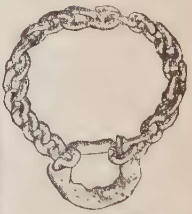

Fig. 93 (upper)

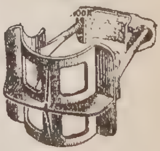

Fig. 94 (lower)

Fig. 91. Weed solid tire chains for single solid tires.

Fig. 92. Weed solid tire chains for dual solid tires.

Fig. 93. Woodworth solid tire chains.

Fig. 94. Mud hooks.

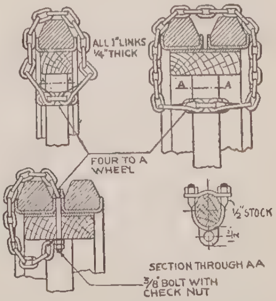

Fig. 95. Either twisted links or straight link chains may be used on solid tires as shown above. Chains should be applied at 4 points on each rear wheel. They should be removed when not required. The illustration at the lower left shows where clearance will not allow a chain on the inside tire of dual construction (Gen'l Vehicle Co.).

Increasing the Tire Repair Business

There are many ways of building up a tire business. Many tire repairmen, instead of depending alone upon obtaining work from the owner, build up a respectable business through the garages and gasoline filling stations. Garage men will not go out of their way for this, and therefore the usual discount allowed is 25 per cent. Tires can be left at the garage man's place and can be called for by the tire repairman.

Another way to increase business is to suggest to owners of trucks to change the solid tire to pneumatics. Of course you would not suggest changing solids to pneumatics on a 5-ton truck hauling sand or coal for short distances, but where a 2, 2½, or 3-ton truck is making daily trips of 75 or 100 miles over fairly good roads, it would pay the owner at least to fit the front wheels of such a truck with penumatics, and this is the business you should look for.

Before soliciting this work, first consider carefully if pneumatics will do the work. Having decided that the change would be an advantage to the owner, the next step is to decide the proper size of tire to use.

This may be done by running the front end of the truck, fully loaded, on a scale. Then when you know the weight which the front tires are carrying, it is a simple matter to refer to the table on page 593, and select a size of cord tire designed to carry that weight.

For a 1-ton capacity truck, a 34 x 5 cord pneumatic tire is the usual size. If only two wheels are to be fitted with pneumatic tires, then fit the **front wheels** with this size.

For 1½-ton capacity trucks, use 36 x 6 cord pneumatics; for 2-ton trucks, 38 x 7 or 40 x 8 Giant cord pneumatics, or 38 x 7 on the front and 40 x 8 on the rear.

The carrying capacities for solid tires and for pneumatic tires are given on pages 627 and 593.

Of course, if a 2-ton capacity truck usually carries light loads of a bulky nature, but not up to capacity, the proper course is to figure the load carried by each wheel and select tires accordingly.

Some of the points to bear in mind relative to fitting a truck with tires are as follows:

Pneumatic tires, of course, will give greater truck protection through the absence of vibration, and will also increase the radius of travel per day. The minimum speed is increased because it is not necessary to slow down for rough spots in the road. In such work as hauling in oil fields it is almost impossible to use solid tires, and only pneumatic tires can be used. In coal mines and on extremely rocky roads and with heavy hauling, the pneumatic tires would be more expensive, and solid tires are better adapted here.

The cushion tire is pressed on to the wheel, just like the regular solid tire. The cushion tire might be classed half-way between the solid tire and the pneumatic tire, in that it is softer than the solid tire and has greater resiliency, but is a solid tire in the true sense of the word. The fire department uses the cushion tire to a great extent, and it is also used on 1, 1½, and 2-ton trucks to a large extent.

For extremely heavy duty, such as 3½, 5, and 7½-ton trucks, where extremely heavy loads are carried and at a very slow speed, **the Giant solid tire is the most economical.**

Very few trucks have the same size tires all around, and we find that sometimes most of the load is carried on the rear. If the same size tires are carried on all four wheels, then the load should be equally distributed.

For example, suppose we had a truck weighing 4,000 lbs. and it carried a load of 2,000 lbs.: this would give us total load carried by the four wheels of 6,000 lbs., providing the load was equally distributed on all four wheels. By dividing the 6,000 lbs. by 4, we have 1,500 lbs. load per wheel. Therefore by referring to our capacity table on page 627, we should use a 4″ tire which carries a wheel load of 1,700 lbs. Always figure over rather than under.

If, however, three-fourths of the load is carried on the rear wheels, or 4,500 lbs., then one-half of this 4,500 lbs. would be carried on each rear wheel, or 2,250 lbs. per wheel. By referring to our capacity table on page 627, we find that we should use a 5″ tire on the rear, and a 3″ tire would be sufficient for the front.

For the best plan for finding the wheel load for any particular size tire: See page 594, which explains how to weigh, and how to find out how much of a load each wheel carries. Then refer to the table giving the carrying capacity of the different sizes of tires.

When fitting truck wheels with pneumatic tires, which are already equipped with solid tires, it will be necessary to have new rims fitted to the wheels. This should be done by a wheelwright who specializes on this work.

The usual cost of such work runs about $15 per wheel plus the cost of the rims, with a discount of 20 per cent to the dealer. The time required for changing two wheels would be about one day.

For example, **the cost of changing two solid-tired wheels to pneumatics** would be estimated, approximately, as follows:

Wheelwright's charge, 2 wheels at $15.00	$ 30.00
2 34 x 5 rims complete with felloe bands, bolts, etc.	40.70
2 34 x 5 cord pneumatic tires at $53.50	107.00
2 34 x 5 high-test red inner tubes at $5.85	11.70
	$189.40

Usually, when the owner of a truck agrees to have the solid tires changed to pneumatic tires, he insists on having his solid tires traded in on the job. This can usually be adjusted with the tire branch, so that an arrangement for taking them on trade can be made.

INSTRUCTION No. 56

OPERATING A CAR: Gear Shifts, Control Levers and Pedals of Some of the Leading Cars; Pointers on Selecting a New Car; Judging and Testing a Second-Hand Car

HOW TO OPERATE A CAR

When learning to operate an automobile, the first step is to become familiar with how to start and stop the engine and how to control the speed. This can be learned best with the engine running.

The simplest way in which this can be done is to jack up the rear wheels so that they are clear of the ground, letting the weight of the car rest on a solid box. The point is to get the driving wheels clear of the ground, and free to revolve without moving car.

The different speeds may then be handled, and the movements of the levers and pedals may be gone through with, without being under the necessity of steering, the steering being the simplest and easiest part to learn. Care should be taken to block the front wheels so that the vibration of the engine cannot shake the car from its support.

Lever Systems

There are three types of side-lever systems: (1) the type which operates the planetary transmission gears; (2) the type which operates the old-style progressive gears, and (3) the type which operates the selective type of gear.

The planetary gear type is used on the Ford car, and is very simple. See the Ford instruction.

The progressive gear type is now seldom used. Its principle and operation is shown on page 25.

The selective type is the type most used, and it is with this type that we shall deal principally. This type is shown on pages 26, 28, 29.

The gear-shift lever used with a selective transmission is constructed in two types: the "gate" type, and the "ball and socket" type (page 27).

The emergency or hand-brake lever is usually placed alongside the gear-shift lever. On early model cars these levers were placed on the side of the car, but are more commonly found in the center (see Fig. 3 page 630). For a further description of the selective lever operation, see pages 26 to 29.

Pedal Systems

The foot brake is a pedal operated by the right foot. **The clutch pedal** is a pedal operated by the left foot.

The accelerator is usually placed to the right of the foot-brake pedal.

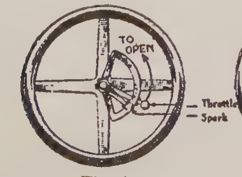

Fig. 1

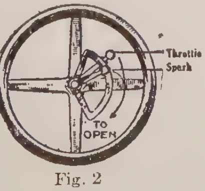

Fig. 2

Fig. 1. On most cars the throttle and spark lever are moved up to open the throttle and advance the spark. Full open throttle and full advanced spark would then be all the way up. Full retard would be all the way down.

Fig. 2. On some few cars the throttle and spark lever are moved down to open and advance.

Note. On some makes of cars the long lever is the spark lever.

The spark and throttle levers are, in most instances, placed on the steering wheel. On a few cars they are placed under the wheel on the steering post. The throttle lever is usually the longest of the two. The movement of the throttle lever, whether up or down, to open the throttle is easily determined by noting the movement of the throttle on the carburetor. The spark lever for advancing can also be determined by noticing the direction in which it moves the timer or interrupter on the magneto. Usually the **throttle and spark lever are pushed up** to open and to advance.

Note that on the Pierce-Arrow "series 32" and the Cadillac "type 61" (pages 638, 635), the spark and throttle levers are now made very short.

Preparing a Car for Service

Before attempting to drive the car, make sure that it is ready for the road. See to the following:

1. That there is gasoline in the tank at the rear.
2. That the radiator is filled to the level of the overflow with clean water, or with an anti-freezing mixture in winter.
3. That the crank case is filled with oil to the level indicated by the oil gauge.
4. That the storage battery is properly connected.
5. That the gasoline shut-off cock between the vacuum tank and the carburetor is fully open.
6. That the car is provided with a driving license.
7. That the fan is working.
8. If the car has been standing idle for several days, it may also be necessary to prime the vacuum tank by removing the pipe plug in the cover and introducing a pint or so of gasoline (see page 115). Be sure to screw the plug in tight when replacing it.
9. See that the tires are properly inflated (see page 593).
10. See that a spare tire is supplied for emergency use.

How to Start the Engine

As an example, the Studebaker "Light Six," model "EJ" will be used.

Gear-shift lever: See that the gear-shift lever stands in **neutral** (upright) position, where it is free to move sideways.

Position of spark lever when starting engine: The automatic advance as well as a hand or manual advance of the spark is used on this car. The spark lever (short lever) is placed in normal driving position, or about two-thirds of the way to the top of quadrant when starting the engine with the starting motor.

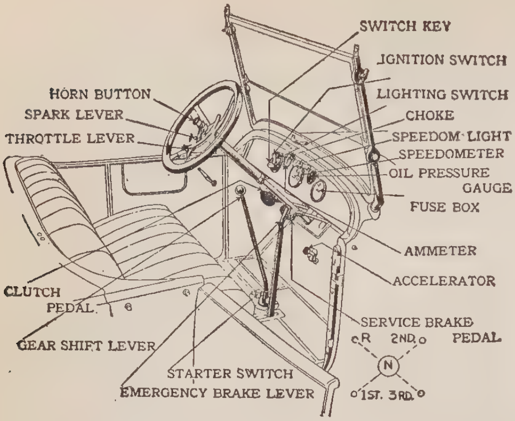

Fig. 3. Studebaker model "EJ" control levers, etc.

If an engine is equipped with a manual or hand control alone, and with no automatic advance of spark, it is best to retard the spark when starting, especially when starting the engine with the hand crank.

Position of throttle lever: Open the butterfly valve in the carburetor slightly by means of the hand-throttle lever on the steering gear sector; turn the ignition switch to the "On" position.

If the engine is cold, it will be necessary to pull out the carburetor "choke" button, located on the instrument board (Fig. 3). It may be found necessary to leave the "choke" button pulled part way out for a short time until the engine is warm. (See carburetor instructions.)

Make sure that the gear-shift lever is in "neutral" position; then press down on the starter switch. The instant the engine starts on its own power, release the starter switch. **This is important.**

After the engine starts, advance the spark lever half-way on the sector. If the engine does not start within a few seconds after you have pressed down on the starter switch, release the switch, as the continued use of the starter will discharge the battery. Investigate and find out where the fault lies, and correct it before attempting to start the engine again. (See "Digest of Troubles," page 454.)

In connection with the releasing of the starting-motor switch pedal, be sure to remove your foot from the starting switch, the moment the engine starts, and be sure that the lever springs back into its original position.

The time required for the operation varies from one half-second under good conditions when the engine is warm, to from five to ten seconds for cold weather starting. If the engine does not start within the period mentioned, release the starting switch, since you will know that something is out of adjustment and that you are throwing an undue strain on the battery. (For a full explanation of this operation and the proper care, see the starting-motor instructions, referring to the type of motor system with which cars are equipped.)

Cranking the engine by hand: If, for any reason, the driver wishes to crank the engine by hand, the adjustment for starting should be the same as for operation of an electric starter except that the spark should be retarded. When cranking by hand, be sure to make the crank engage at the point with the handle nearest the ground. Then it should be pulled up clockwise with a short, snappy pull.

While on this subject, an explanation should be given of the proper method of cranking an engine, as illustrated in Figs. 4, 5, and 6. The reason for the necessity of starting a gasoline engine, either by cranking by an electric motor, or by hand, is explained on page 31.

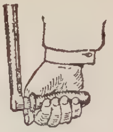

Fig. 4

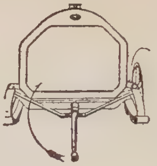

Fig. 5

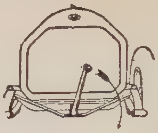

Fig. 6

Fig. 4 shows the proper method of grasping a starting crank.

Fig. 5 shows the direction as indicated by the arrow point, in which to **pull up** on the crank with a quick, snappy pull, in order to spin the engine crank shaft. With the crank grasped as shown in Fig. 4, and the "pull-up" made as in Fig. 5, there is no chance for a back-fire of the engine to cause a kick-back.

In Fig. 6, note that if the starting crank is **pushed down,** and if the engine should back-fire, which often occurs, when the engine is being slowly cranked, if—under these conditions— the spark lever is advanced, the full force of the kick-back is against the arm, and a sprained or broken wrist may result. **Never push down on a starting crank** to start an engine. **Pull up.**

Another point to remember is, do not tire yourself out by continually cranking, if an engine does not start after cranking five or six times. Find the cause of the failure to start.

After the engine is started, close the throttle and place the spark lever about half or two-thirds on sector until the engine runs slowly and evenly. On the Studebaker "EJ," the instructions are to place the spark lever at full manual advance; on the Buick, about half-way, and on the Westcott, at two-thirds advance.

As the engine warms up, the "choke," button should be pushed in; in fact, this should be done as soon as possible.

Never allow the engine to run any length of time with the air regulator turned to "choke," as this gives an excessively rich mixture and uses an abnormal amount of gasoline.

Handling the Spark

Ordinarily, on most engines using an automatic advance of spark, the spark lever should be about half to three-quarters of the way to the top of the quadrant for normal driving conditions. On the Studebaker "EJ," the automatic spark advance for starting and running speeds is full advance; on the Westcott, using an automatic advance, the spark lever is placed about three-quarters of the way to the top of the quadrant or sector; on the Buick about half way. The automatic spark advance, which is incorporated in the ignition system, will control the spark position without further attention on the part of the driver. It is arranged so as automatically to advance or retard the spark to the proper position, depending on the speed of the engine; but as the car slows down, as on ascending a steep hill, or when negotiating a heavy road, it is necessary to retard the spark lever by hand until the engine runs smoothly and without knocking.

With engines not equipped with an automatic advance of spark, it is best to start the engine with the spark lever near full retard, and then, after the engine is started, it should be advanced. The exact location of the lever will depend upon the speed of the engine.

Just how much the spark should be advanced, or, rather, how much spark advance the engine will stand, depends largely on how fast it is running. The faster the engine is running, the more the spark should be advanced. Bear in mind constantly, however, that there is such a thing as overdoing it and advancing the spark lever too far. When this is done, the ignition takes place before the charge has been fully compressed, and consequently the piston is obliged to overcome the pressure of the expanded gases of the exploded charge before it can commence on its power-delivering stroke.

Furthermore, when the spark is advanced too far, a slight pounding noise in the engine is the result. This pounding is sometimes not noticed by the beginner, as it usually is but slight, owing to the substantial construction of the crank shaft, and by the uninitiated it is often accepted as permissible.

Advancing the spark too far is very injurious, because by it the bearings, crank shaft, and connecting rods are required to withstand strains which are greatly in excess of those produced when the ignition occurs at the proper moment.

The engine should never be allowed to run for any length of time with the spark retarded.

With a retarded spark and a late explosion, the combustion or burning of the charge of gas is not complete. This causes a great amount of carbon to be deposited on the walls of the cylinders, combustion chambers, piston heads, spark plugs, etc. It also causes the engine to heat to a much higher temperature, which causes a very severe action on the valves and valve seats. When the charge is ignited at just the right instant, the combustion is practically complete, so that when the valves open a thoroughly burned charge passes out. On the other hand, when the charge is ignited late, the charge is still burning when it passes through the valve opening and tends to heat, burn, and scale, and to cause pits on the valve and valve seats. In time, this creates a condition which prevents the valves from seating properly or fitting tightly, and therefore a loss of compression and a corresponding loss of power is the result.

Starting a Car—Shifting Gears

How to start a car: After the engine has started, be sure that the oil-pressure gauge and ammeter are indicating properly; then release the hand brake. Place the left foot on the clutch (left) pedal (see Fig. 3), and press it forward as far as it will go, thus disengaging the clutch. The engine is now running independently of the transmission, the gear-shift lever is supposed to be in "neutral" position, and the clutch is held "out" by the left foot. The next operation is to place the right hand on the gear-shift lever and to move it to the left, sidewise, and pull it back into "first" gear position.

Next, slowly release the pressure on the clutch pedal, at same time pressing easily on the accelerator pedal with the right foot, to increase the speed of the engine. As the clutch takes hold, the car will commence to move forward.

Shifting from first to second gear: When the car is moving about four to six miles an hour, the gear shift from "first" to "second" gear should be made. This is done by disengaging the clutch, as explained above, and moving the gear-shift lever forward to "neutral" position, then to right and forward again to "second speed" position. Re-engage the clutch and accelerate as before. The gears are now in "second gear" position. (See gear-shift movement of the Studebaker at the lower right-hand corner of Fig. 3, and of the Buick, Fig. 9, page 635.)

Shifting from second to third or high gear: The car should be accelerated to about eight to ten miles an hour, and the gear shift from "second" to "third" gear should be made by pulling the lever straight back, the clutch being disengaged as before. "Third" or "high" gear is used in all ordinary driving, but there are times when it is necessary to shift to second gear: for instance, when climbing hills, or when on rough or heavy roads, or when slowing down for traffic.

To increase the speed of the car under these conditions, the butterfly throttle valve of the carburetor is opened gradually, by means of the accelerator, and the spark lever should also be advanced as the speed increases.

Pointers on Shifting Gears when Starting Car

When shifting from a lower to a higher gear, as **when first starting,** it is important that the speed of the car be accelerated just before making the change, so that the two gears that are to be meshed together will be running at approximately the same speed. The proper handling of the clutch pedal and accelerator so as to make the motor "pick up" its load quickly, and at the same time prevent it from "racing" when the clutch is released, requires considerable practice.

In changing gears, especially when starting the car from a standstill, always let the clutch pedal come back gently, otherwise, a quick release of the foot clutch pedal will let the clutch take hold with a violent jerk.

In shifting gears from one speed to another, the motion should be made firmly and without hesitation. If the gears fail to mesh correctly the first time, release the pressure on the control lever and clutch pedal for a moment and try again. With a little practice, the various changes can be made easily and without noise.

When there is a grinding noise on shifting gears, it is usually the result of the clutch not being "thrown out" sufficiently, and the engine is thus driving the main transmission shaft. By pressing firmly on the foot clutch and quickly shifting the gears, the shift should be made without a particle of noise—providing the clutch pedal is not released until the shift is made.

If there is noise, such as a clashing of gears, with the foot clutch pedal thrown out fully, then the clutch is dragging, or the transmission main shaft bearings are worn.

Most cars use a selective type of transmission, giving three forward speeds and one reverse speed. The Locomobile uses four speeds forward and one reverse speed. The Pierce-Arrow (Fig. 21, page 637) also uses four forward and one reverse. The "series 32" model (Fig. 22, page 638) uses three speeds forward and one reverse.

Stopping Car and Engine

To stop the car, slow down the engine by removing the foot pressure on the accelerator pedal by pressing down on the clutch pedal with the left foot. Then disengage clutch, gradually press down on the foot-brake pedal (right pedal), so as to bring the car to a gradual stop. At the same time move the gear-shift lever to "neutral" position at which time the foot can be removed from the clutch pedal. After the car has stopped, apply the hand brake by pulling the hand-brake lever to the rear. Never leave the car standing with the hand brake released.

If the road surface is wet and slippery, a greater breaking effect may be had by pushing in on the foot-brake pedal intermittently, i.e., hold the brake pedal down for an instant only, then release and apply again. Keep doing this until the car is brought to a stop. If the brake is constantly applied, the rear wheels will be locked and traction will be lost.

To stop the engine, turn the ignition switch off. Before doing so, however, it is good practice to open the throttle with the hand-throttle lever, thus permitting the engine to take in a full charge of gas before coming to rest and leaving it ready for a quick start next time; also move the spark lever to the starting position and set the hand brake before leaving the car.

Lock the ignition switch when leaving the car standing alone. Never leave the car with the engine running, as this is a useless waste of gasoline, and there is always a chance that someone may throw the gears into mesh.

Reversing

To reverse the motion of the car, it is first necessary to stop the car. Never attempt to shift into "reverse" gear when the car is in motion. With clutch disengaged, move the shifting lever to left and forward, and then gradually engage the clutch and accelerate the engine as before. One rule that the driver must always remember is that the clutch must be disengaged whenever gears are shifted.

Starting Car on a Grade

To start a car when on a grade, start the engine as before; then release the hand brake and hold the car with the foot brake while shifting gears. Now accelerate the engine with the hand throttle while gradually releasing pressure on both pedals together. It takes practice in operating the clutch and brake pedals to make the one take hold while releasing the other without "stalling" the engine.

Shifting from a High to a Lower Gear after Car Is Under Way

Shifting down is the term used when a car is running on high gear and it is desirable or necessary to shift to a lower gear.

Shifting from third or high to second: To shift from "third" or "high," to "second" gear, disengage the clutch; accelerate the engine to approximately twice the revolutions at which the engine was turning over previous to shifting gears; then push the lever to "second" gear position and re-engage the clutch.

"Low" or "first" gear is ordinarily used only in starting, but in exceptional cases of very heavy pulls, it will be better to shift back to "first" gear, which is done in a similar manner as the shift from "third" to "second." In coming to a bad piece of road, full of ruts, bumps, or holes, it is best to shift immediately into "second," or "first" if necessary. Thus, you have much better control of the car and can pick up more readily. When using lower speeds you can control the car almost entirely with the accelerator, letting yourself down easily into holes and over bumps without having to slip the clutch.

When passing through traffic, it is sometimes desirable to change to a lower gear on level ground without slowing down the car. To attempt this by de-clutching and putting the lever directly into the lower speed notch—in the same way that this is done while ascending a hill—would be to invite a very noisy clash of the gears.

Instead of this, **the change is made in three progressive steps,** as shown in Fig. 7, and the speed of the car is not reduced to any appreciable degree.

The first movement shown at (A) in the illustration (Fig. 7) is to disengage the clutch and shift the gear-shift lever forward **from high to neutral** (center position as shown in the dotted lines). This leaves the car coasting with the engine running.

The clutch is now let in, and the levers are in the position shown at (B). Now this is the point at which skill is required, and where practice is necessary.

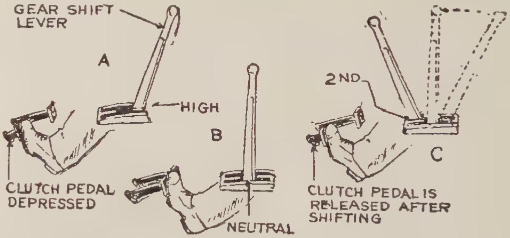

Fig. 7. Example of **shifting from high to second gear while the car is in motion:** (A) clutch out and gear-shift lever brought to neutral; (B), gear-shift lever in neutral position; (C), clutch out and gear-shift lever pushed forward to second; clutch is then released.

The engine is speeded up until it is turning over at the same rate of speed as it would be were the low speed engaged. It will take a little practice to accustom the ear to judge by the sound of the engine whether it is turning over at the correct speed or not.

After the engine is speeded up to the proper degree, the clutch pedal is depressed, and the change gear lever brought into second speed gear as at (C). The same method will apply in going from second to first.

Changing from higher to lower speed on a grade: When the car is facing **upwards,** it is a little more difficult to be able to judge when the speed is sufficiently great to justify a change from first to second speed. The hill may be of such slope that it is an easy matter for the car to take it on high in ordinary running, but may still be so steep that the pause in the gear-shifting act is sufficient to cause the speed to drop considerably. In a case of this kind the driver should be able to judge at just what speed he should throw out his clutch and make the change. The steeper the hill, the greater will be the speed required before the change can safely be made.

Trouble in dropping to lower speed on a hill can be averted if the critical moment at which to make the change is learned. If the driver waits too long, he may "kill the engine," and sometimes place himself in a very serious position.

If he tries to make the change too soon, he will clash gears.

By changing at the critical moment, however, an easy, quick change can be made.

"Running in" a New Car

When setting up and starting any new piece of complicated machinery, you would ordinarily expect to watch it pretty closely, and go a little easy with it until its various bearings, parts, etc., had become thoroughly "worked in." An automobile is no exception to the rule. While every bolt and nut in the automobile is drawn tight, and secured with either cotter pins or lock washers when the car leaves the factory, nevertheless it is advisable to go over a few of the more important points and make sure that everything is in perfect shape.

The following points should receive your special attention during the time that the car is being driven the first few hundred miles:

Between the upper crank case and the oil pan, or between the cylinder heads and the cylinder block, there are usually gaskets. During the first few days of service a gasket may become slightly compressed, thus loosening the crank case to oil-pan bolts. Consequently it will pay to **go over the nuts on the bottom of the oil pan** with a wrench and tighten them up. Drive a few days, and try them again. Continue to do this until the gasket has become fully compressed and the parts have settled into permanent working position. If you will take this precaution, the joint will be absolutely tight and you will never have any trouble, such as loss of oil or water, and dirt being washed into the oil pan and then circulating with the oil through the bearings, causing excessive wear and cutting.

At first, it will be well occasionally to **go over all of the bolts that hold the engine to the frame,** and see that they are kept tight. If you find them perfectly tight after inspecting them two or three times, you need never fear that they will loosen up.

It is advisable to **put a wrench to all nuts on different parts of the car** and make sure that they are perfectly tight after it has been driven a hundred miles or so. When they have once been screwed up as tightly as possible and the car has been thoroughly "run in," there will not be so much danger of loosening up and causing damage.

Spring clips will loosen if the nuts on the clips are not tightened occasionally. **It is very important to tighten these nuts often.**

Fender bolts also demand attention.

The universal joints should be kept well supplied with grease.

Lubrication of a new car. It is needless to remark that lubrication is one of the most important things to look after on a new car. All parts should be thoroughly lubricated and greased as directions provide. Follow the lines there suggested. In the absence of directions from the maker, study the lubrication subject carefully.

Remember one thing: cheap oil will cost ten times more, maybe a hundred times more in the long run, in the way of repairs. The best oil is none too good.

Also remember that oil should be changed in the engine **often,** for reasons stated on page 167. Just how often to change will be determined by the amount of gasoline in the oil, which one should take particular note of, when changing.

"Running in" a New Engine

"Running in" a new engine is a very important factor in the life of a car. More harm can be done during the first few days than one can imagine—if care is not exercised. For an explanation of this, read pages 171, 167, relative to the importance of lubrication and slow running for the first 500 or 1,000 miles, in order to work the pistons properly to a smooth fit to the cylinders, and so as to avoid cutting or scoring the cylinders. See also Index under "Reaming cylinder."

Don't race an engine: Never open the throttle suddenly, or leave it open very far, when the car is standing and the engine is running idle. This is known as racing the engine, and there is nothing more injurious, especially when the engine is cold. More engines have been ruined by racing while idle than have been worn out in actual driving under load.

When the engine stands over night, don't immediately race the engine to warm it up, because the oil has drained from the bearings, the cylinder walls, etc. Consequently it is going to take a few minutes to lubricate these parts properly. Therefore first let it run slowly for a minute or so.

Hill Climbing

Until you have become thoroughly familiar with the operation of the car, and have mastered the things necessary to make a good driver, do not attempt to climb "on high" every hill you see, just because your neighbor possibly has said that his car would do it. **There can be nothing more detrimental to the engine and driving parts than to try climbing everything on "high."**

The first and second-speed gears are placed in the car for a purpose, and if the hill that you are approaching is at all steep, shift into **"second"** a little before you are really on the hill. Do not try to go into "second," however, at any time unless the speed of your car has been reduced to the pace at which the second speed would carry you if it had already been changed. Many accidents, and serious ones, have resulted from a driver attempting to rush a hill "on high," getting half-way up, and having the speed of the engine so reduced that when he came to shift into low it was too late; the engine would not then accelerate sufficiently to carry the car up on low, and possibly the brakes were not working just as they should, the result being that the car would back down the hill faster and faster, until it finally landed in the ditch. Backing down hill with brakes is a task for a skillful and experienced driver, and even he cannot guarantee a good job. It is a most confusing situation and requires the instant exercise of good judgment.

The secret of successful hill climbing is to keep your engine running a little faster at all times than its work requires it to run, i.e., to keep it **"ahead" of its work,** so that it is ready for extra duty without stalling at the critical moment. The foregoing does not mean that many hills cannot be climbed "on high," but it is best not to try until you are sure of yourself and of your ability to get into **second,** or even **first** if necessary, half-way up the hill, and also to determine from the sound of the engine whether it is "working hard." If you must go into a lower gear on a hill, shift with a quick, firm movement, and take care not to let the momentum of your car be reduced any more than is absolutely necessary. Every second that you have the clutch disengaged on a hill for gear shifting, counts, as the car slows down at a very surprising rate.

If, on climbing a hill on "third," the engine has been stalled before reaching the top, it may require considerable skill to start from your standing position on the incline. Immediately upon finding yourself in such a predicament, apply the hand brake with all your strength, and **be sure that the brake ratchet catches;** then throw the gear-shifting lever into neutral. After starting the engine again, push out the clutch (leave the hand brake still on), push the gear lever into first speed, and slightly race the engine (the only condition under which it is permissible, excepting when in a mud hole or the like); then take hold of the hand brake and keep the engine speeded until the brake has been entirely released, the clutch entirely engaged, and a safe start has once more been made up the hill. Experience is the best possible teacher where there is a considerable amount of hill work to do.

Importance of the Clutch

The clutch of an automobile is a device by means of which the power of the engine and the driving mechanism may be connected or disconnected at the will of the driver. This particular part is probably used more than any other part of the car, and a careful study of its purpose and principle is advised. Though the device is simple and its use plain at first glance, the clutch, nevertheless, lends itself to a number of skillful uses in the hands of the experienced driver. **Remember always to "throw out" the clutch before changing gears.**

When the clutch is "let in," or engaged, this should at all times be done smoothly and so gradually that the motion of the engine shaft is transmitted to the drive shaft without jarring.

A suddenly let-in clutch will do one of two things: it will either rack the mechanism of the entire car, or stall the engine. With a little practice the left foot may be schooled to **let the clutch in quickly, yet gently and smoothly.**

When you meet a stretch of road covered with sharp, broken stones, it is an excellent plan to speed your car a little before you reach the stones and then disengage your clutch, permitting your car to coast over the bad spot. By shutting off the driving power you protect your tires against a very destructive action, termed the "traction," which otherwise would be set up between the sharp stones and the tires.

When reversing, remember to bring the rear wheels to a dead stop before letting the clutch in. Complete familiarity with the motions of going from one speed to another and back again should also be acquired before attempting to run on the open road.

Learn to drive by throttling the engine, instead of constantly throwing the clutch out. The average driver uses the clutch about twice as much as he should.

Instructions on Steering a Car

Steering is largely a matter of practice.

The positions to assume in steering or driving a car are shown in Fig. 8 (2), (3), (4), and (10). A very slight movement of the steering wheel or lever is sufficient to turn the car, and too sudden a turn may cause an upset.

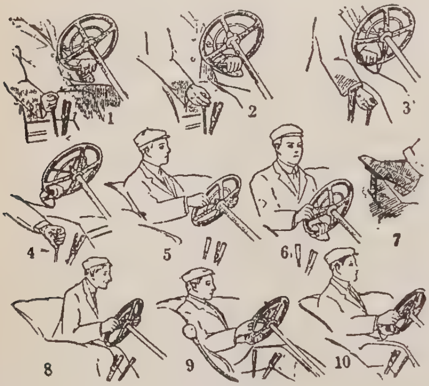

Fig. 8. **Correct and incorrect positions in driving:** (1) fierce grip, a bad method; (2) correct hold for forward movement; (3) finish of forward movement; (4) alternative grip suitable for many gears; (5) awkward hold of wheel; (6) proper and comfortable hold; (7) wrong foot position; (8) nervous, uncomfortable position; (9) careless, lounging position; (10) correct "seat." (*Popular Mechanics.*)

When learning to drive a car, it is a good plan to select a straight road, as wide as possible, and with the engine running slowly, throw in the low speed. The car will move forward slowly, and it will then be necessary to steer. The first inclination will be to grip the wheel as tightly as possible, but after a little running a light grip will be found sufficient. At this stage it is necessary to learn **self-control** first, and not to get "rattled."

If the car begins to run off the road, or into an obstruction, throw out the clutch and apply the foot brake, so that it comes to a standstill. When the excitement has died down, try again, and it will not be long before steering comes easily.

There is no time lost between the turning of the steering wheel and the turning of the car; **when taking a corner do not move the wheel until the car is at the point where turning is necessary.**

How to Use the Brakes

When the brakes are suddenly applied with full force to the wheels of a car speeding along at the rate of, say, thirty miles an hour, the braking action will be so powerful as immediately to stop the rotation of the driving wheels—but the car will not come to an immediate standstill; its momentum will send it forward, and the locked rear wheels will slide over the ground with **most destructive effect on the tires.**

When you consider that in railroad practice the so-called "flat wheel" is produced by too sudden braking, you will be able to appreciate the effect which a similar practice must have on the soft rubber tires of an automobile.

Bear in mind, therefore, that the best method of using the brakes is that which applies pressure on them so gradually that the forward movement of the car and the rotation of the wheels **come to a stop together.**

Nothing is more severe on a car than the spectacular stopping often indulged in by ignorant drivers, in an effort to "show off."

The careful driver shuts his power off before he reaches the stopping point and permits the car to carry him along on its momentum, bringing it, with a gradual application of the brakes, to a halt at the exact spot.

In order to slow down gradually, as when approaching a crossing, close the throttle and apply the foot brake without disengaging the clutch. It is more economical to wear out the brakes than to wear out the clutch. It is of course necessary to disengage the clutch when making a complete stop.

Whenever it becomes necessary to slow down quickly, release the clutch first; that alone will have an immediate slowing-down effect on the movement of the car, because it disconnects the power. If additional checking is needed, apply the foot brake, or, for a quick stop, the foot and hand brakes together. To make it plain, **the clutch pedal goes down first, the brake pedal next.**

If a full stop is not desired, assuming that the emergency has passed, release the brake pedal first, then let the clutch pedal come up. If you did the reverse, the engine would be compelled to pull against the brake, with a consequent rapid wearing down of the brake lining. (See also "Brake adjustments," under the discussion of the repair subject.)

No motorist is qualified to give his car the best care until he has mastered the control of the gears and of the brakes.

Slipping brakes are usually caused by oil working out the rear axle on to the brake lining.

If a grade is long and steep, use the foot and hand brakes alternately. This equalizes the wear on them, and also gives them a chance to cool.

If the Brakes Fail

If the engine stops while descending a hill, the brakes should be thrown on at once to keep the car under control. If poor adjustment of the brakes renders them insufficient for this, then place the gears in low speed. This will tend to check the car. It is then a matter of steering the car to the best advantage.

If, when ascending a hill, the engine stops and the brakes fail, try putting the gears in reverse. This will then turn the engine in the right direction, and ought to start it. It may be possible to steer it—owing to its extremely slow speed—off the road into a bank or other obstruction that will stop the car without much damage to it or to its occupants.

Situations such as this require a cool head and a steady hand, and the more experience in operating that the driver has, the greater are the chances for handling it in the right way.

Stopping a car on an up-grade and starting again requires skill, for the brakes must be withdrawn and the clutch let in at the same instant with one movement.

On a long descent, when you find it necessary to use the brakes constantly, apply the hand and foot brakes alternately, to avoid burning out the brake linings.

On extremely steep hills, when descending, the maximum of resistance and the best control may be obtained by shifting into first gear, switching off the ignition, and applying the brakes at intervals. Just before reaching the bottom of the hill, with the car still moving at a fair pace, close the ignition switch and the engine will start firing again.

Note. There is a disadvantage in opening the ignition circuit. When it is closed at the bottom of a hill, the gas drawn in may have accumulated in the exhaust pipe and muffler. Cases have been known where this gas was ignited and disrupted the muffler. When throwing on the ignition, don't open the throttle too wide.

When the Car Skids

Although the driver feels helpless at first, a little experience will soon give him confidence. Most skids can be corrected by the manipulation of the steering and brakes. An expert driver can keep his car straight under almost any conditions, but it is impossible to explain just how he does it. Usually the rear end skids first, and in the right-hand direction, this being caused by the crown of the road. Under such conditions, the skidding action will be aggravated if the brakes are applied, and the car may be ditched or continue to skid until it hits the curb.

In an emergency of this kind the correct action is to let up on the accelerator pedal to shut off the power, but not entirely so, or it will have the same effect as putting on the brake. If the car seems to right itself, the power may be applied gradually, and it will be advisable to steer for the center of the road again. However, if the car continues to skid sideways, steer for the center of the road, applying the power gently. This will aggravate the skid for the moment, but will leave you with the front wheels in the center of the road and the car pointing at an angle. By so doing, you can mount to the crown of the road again, and the momentum of the car will take the rear wheels out of the ditch on the right-hand side. It is customary to advise turning the front wheels in the direction in which the car is skidding, in order to correct the action, but this can hardly be said to be true in all cases. It holds good where there is unlimited side room, but usually the car hits the curb, or is in the ditch, before you can straighten it out with the steering wheel.

INSTRUMENTS, CONTROL LEVERS, PEDALS, AND GEAR SHIFTS OF SOME OF THE LEADING CARS

The following illustrations show the hand levers, foot pedals, dash or cowl with instruments, and also the gear-shift movements of some of the leading cars.

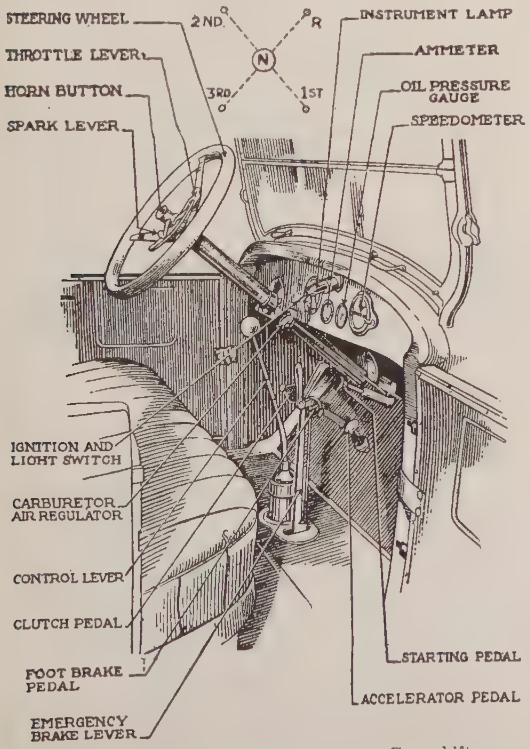

Fig. 9. **Buick, 1921, six-cylinder car.** Gear-shift movement is shown at top of illustration. Firing order of engine is 1, 4, 2, 6, 3, 5.

The purpose of these illustrations is to familiarize the reader with the gear-shift movements and the location and purpose of the control members.

Most cars now use the "ball-and socket type of gear-shift" lever.

The "gear-shift movement," or the direction in which to move the gear-shift lever to obtain various speeds, is shown in each illustration.

Most of the **gear shift movements** are, what is termed the S. A. E. standard gear-shift movement as illustrated in Fig. 19, page 29. Some are different.

The make of electric system used on these cars, as well as on other makes of cars, can be found by referring to the Index for "Specifications of leading cars."

The make of carburetor, steering device, rear axle, engine, etc., can also be found in these specifications.

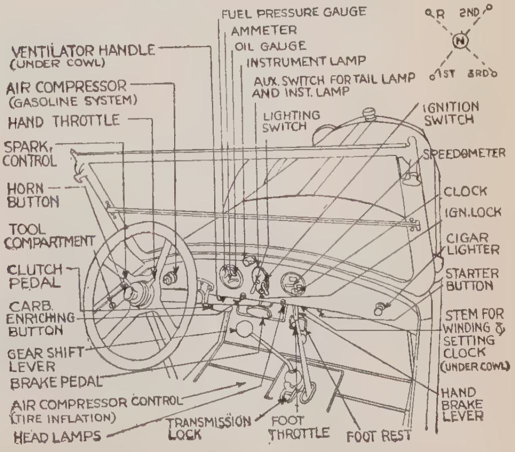

Fig. 10. **Cadillac type "61."** Note the **short spark and throttle levers,** and also that the fuel pressure gauge, the ammeter, and the oil gauge are in one unit on the cowl.

Gear-shift movements shown above. The firing order of the engine is shown on page 84.

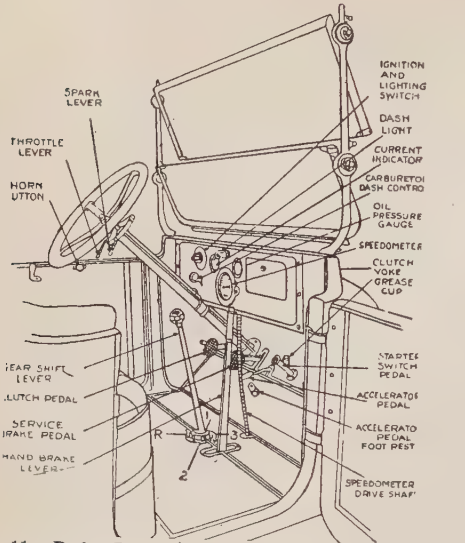

Fig. 11. **Dodge Bros.** Gear-shift movement is shown on floor board. Firing order, 1, 3, 4, 2.

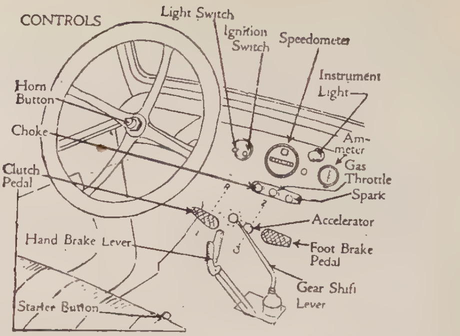

Fig. 14. **Overland "4."** Note that the spark and throttle control is on the cowl board. Firing order, 1, 3, 4, 2. Gear-shift movement is shown.

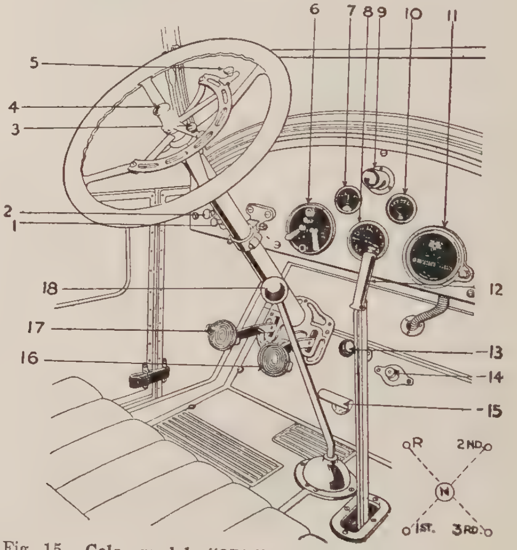

Fig. 15. **Cole model "870."** Gear-shift movement is shown. Firing order is 1-8, 3-6, 4-5, 2-7. Parts: 1, carburetor choke button; 2, carburetor adjusting button; 3, spark lever; 4, horn button; 5, throttle; 6, ignition switch; 7, ammeter; 8, clock; 9, cowl light; 10, oil gauge; 11, speedometer and odometer; 12, hand-brake lever; 13, accelerator; 14, starting-motor switch; 15, accelerator heel rest; 16, foot-brake pedal; 17, clutch pedal; 18, gear-shift lever.

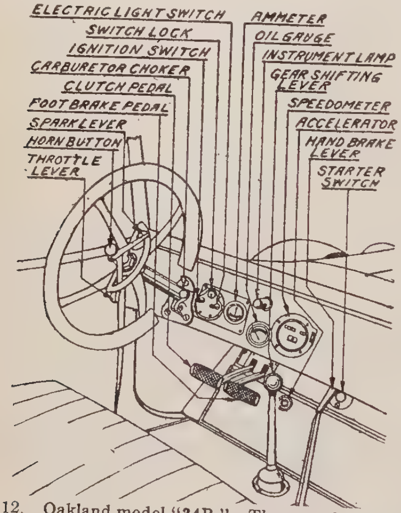

Fig. 12. **Oakland model "34B."** The gear-shift movement is standard S. A. E. three-speed, as shown in Figs. 14 and 15. Firing order, 1, 5, 3, 6, 2, 4.

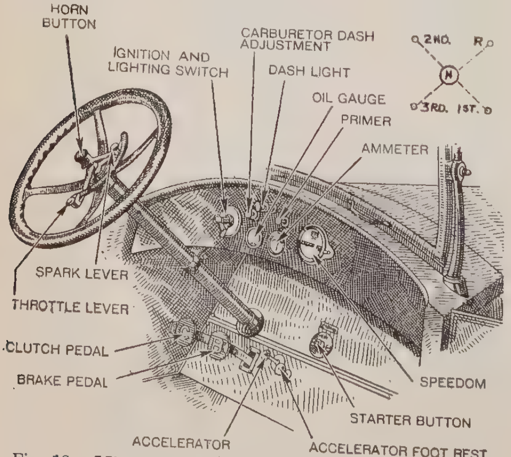

Fig. 13. **Mitchell model "F."** Gear-shift movement is shown at top. Firing order is 1, 5, 3, 6, 2, 4.

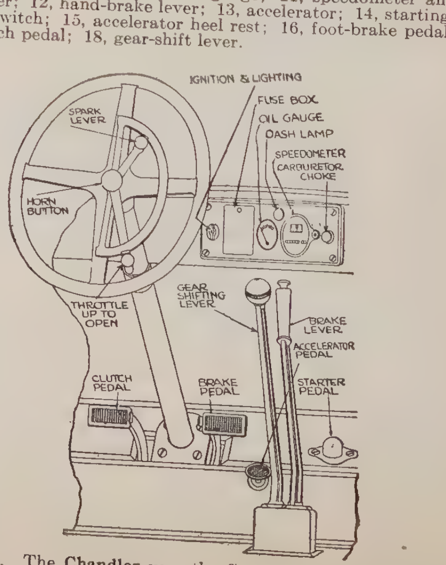

Fig. 16. The **Chandler** uses the S. A. E. standard three-speed gear shift (see pages 27. 29).

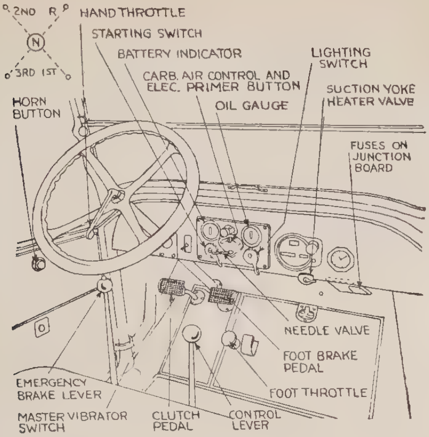

Fig. 17. **Franklin series "9-B."** Gear-shift movement is shown. Firing order is 1, 4, 2, 6, 3, 5.

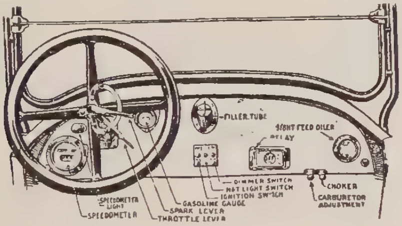

Fig. 18. Briscoe.

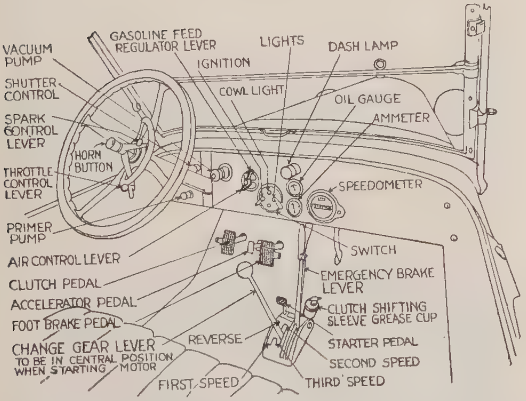

Fig. 19. **Hudson model "O."** To start the Hudson engine: Place the spark lever near the top; open the throttle slightly; place the gasoline feed-regulator lever a little to left of center position; when the engine is cold unlock the primer pump by turning knob until it releases. Give the plunger two slow strokes. Lock again by turning the knob until the pin lines up with the slot. Then press in and give a quarter-turn. Notice that the primer must always be locked when driving; turn on the ignition switch; press the starting pedal and release it when the engine starts.

If the engine does not start immediately, turn the air control lever, or choke to the right for a few revolutions, and then let it go back again. Firing order, 1, 5, 3, 6, 2, 4.

Ammeter: Shows whether the storage battery is discharging or being charged by the generator. It should always show charge when the car is traveling over 10 m.p.h. with the lights out. See page 397 for wiring diagram.

Oil-pressure gauge: Simply an indication as to whether the oil pump is delivering oil or not. It should always show pressure when the engine is running. It does NOT register the quantity of oil being delivered to the motor. That is governed by an adjustment of the pump itself. See page 163.

Carburetor control: The upper lever adjusts the amount of fuel allowed to enter the motor. The lower one is a choke to facilitate starting in cold weather or when the motor has been idle for some time. See pages 136, 137 for Hudson carburetor.

Vacuum pump: Used for filling the vacuum tank (see (14), Fig. 1, page 113) when it has become emptied. Ordinarily the motor supplies the vacuum necessary to deliver the fuel.

Spark lever: Controls the distributor and spark timing. The distributor is controlled by an automatic adjusting mechanism, but to obtain all-around efficiency, the spark must also be controlled manually to a certain extent. If the engine shows a tendency to knock on a heavy pull, gradually retard the spark until the knock ceases. It is a good rule always to carry the spark advanced as far as possible without the engine exhibiting any tendency to knock. See page 397 for electrical wiring diagram.

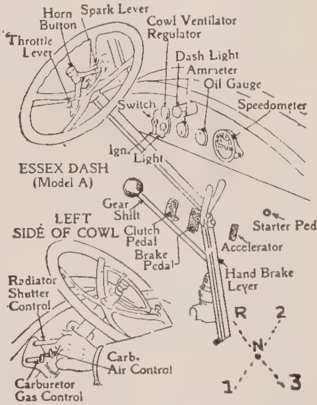

Fig. 20. **Essex model "A."** Firing order, 1, 3, 4, 2.

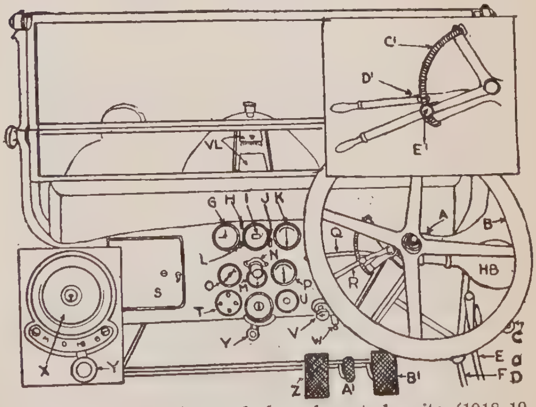

Fig. 21. **Pierce-Arrow dash and control units** (1918–19 model): (A) gasoline regulator on column; (A1) accelerator pedal; (B) steering wheel; (B1) brake pedal; (C) dimmer button; (D) Klaxon horn button; (E) hand-brake lever; (F) gear-shifting lever (see page 27); (G) clock; (H) handle to operate ventilator (VL) on hood; (I) autometer or odometer; (J) knob for setting tenths of a mile; (K) speedometer; (L) knob for setting odometer trip figure back to zero; (M) gasoline gauge; (N) dash lamp; (O) oil gauge; (P) ammeter; (Q) spark lever (see top illustration); (R) throttle lever; (S) left-hand dash cabinet door; (T) lighting switch; (U) starting button; (V) hand-pressure pump handle (arrow pointing to the right for "off" position; arrow pointing to the left for "vent" position); (W) plunger for priming; (X) starting switch (lock above); (Y) starting-switch handle; (Z) clutch pedal.

On some of the Pierce-Arrow models of cars as shown above, the switches (X) and (Y) are two lever switches: ignition and lights, with starting button (U) mounted above the two levers and a Klaxon horn button in the top of the steering column. Note that on this model and on prior models of the Pierce-Arrow car, the throttle and spark levers are placed under the steering wheel. See page 27 for the four-speed gear shift of this model.

Pierce-Arrow 38 and 48 h.p. cars each have four speeds forward, and one reverse; direct on fourth. **The rear-axle gear ratio** on the 38 h.p. is 3.78 to 1, and 3.53 to 1 on the 48 h.p.

		38 h.p.	48 h.p.
1st speed	(trans ratio)	3.88 to 1	4.1 to 1
2d speed	(trans ratio)	2.22 to 1	2.15 to 1
3d speed	(trans ratio)	1.65 to 1	1.65 to 1
4th speed	(trans ratio)	direct	direct
Reverse	(trans ratio)	4.66 to 1	4.93 to 1

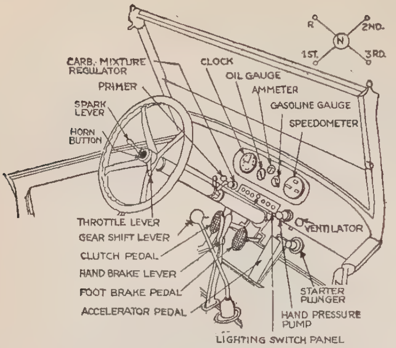

Fig. 22. **Pierce-Arrow "series 32," 1921.** Note the short spark and the throttle levers on the steering wheel. See Index for the rear-axle ratio of Pierce-Arrow "series 32" car. Three forward speeds and one reverse are used on this car. Radiator capacity is 7½ gallons; gasoline tank, 26 gallons; engine oil in crank case, 18 pints. **To start the Pierce-Arrow engine:**

1. Be sure the gear-shift lever is in neutral.
2. Insert the switch key and turn one complete turn to the left. Pull out the ignition button stamped "Double."
3. Advance the throttle (right) lever 1½″.
4. Advance the spark lever about halfway on the quadrant for starting and about two-thirds when driving under normal conditions or up to 50 m.p.h.
5. Prime the engine by pulling out for an instant on the priming button.
6. Press firmly on the starting plunger and release as soon as the engine starts under its own power.
7. Close the throttle until the engine runs slowly.
8. If necessary, move the dash carburetor regulator until the engine runs evenly without missing, by turning to the left.
9. Allow the engine to run a few minutes until it warms up. It will run a great deal smoother and pull better when it starts to move the car.
10. When the engine is thoroughly warmed up, turn the dash carburetor regulator back to normal (center) position. Firing order, 1, 5, 3, 6, 2, 4.

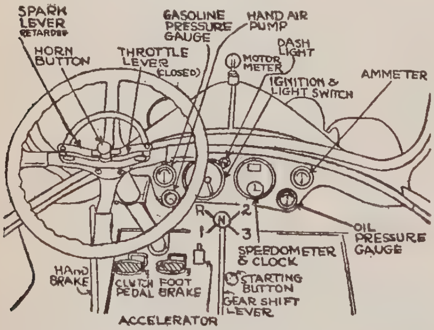

Fig. 23. **Packard Twin-Six,** models "3-25" and "3-35", instrument board and controls and gear changes.

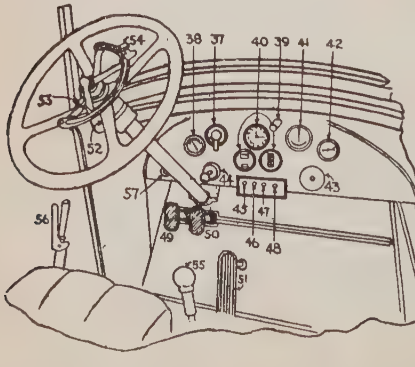

Fig. 24. The **Locomobile** instruments and control members: (37) ignition switch; (38) gasoline pressure gauge; (39) dash light; (40) speedometer and clock; (41) voltmeter; (42) oil gauge; (43) locking switch; (44) hand-pressure pump; (45) starting button; (46) panel-light button; (47) side and tail-light button; (48) head, tail-light button; (49) clutch pedal; (50) brake pedal; (51) accelerator pedal; (52) carburetor adjustment; (53) throttle lever; (54) spark advance lever; (55) gear-shift lever; (56) hand-brake lever; (57) dimming button.

Locomobile 48, series seven, rear-axle ratio is 3.85 to 1. Transmission gear ratio is as follows:

1st speed	15.40 to 1
2d speed	7.39 to 1
3d speed	5.38 to 1
4th speed (direct)	3.85 to 1
Reverse	21.75 to 1

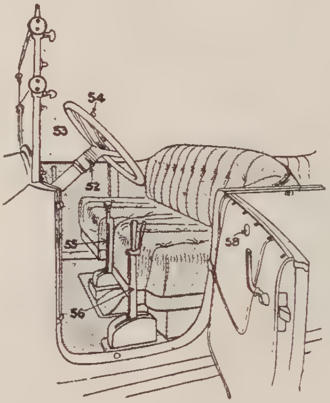

Fig. 25

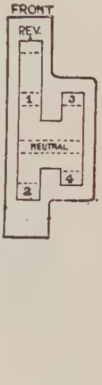

Fig. 26

Fig. 25. **Locomobile** operating levers.

Fig. 26 shows the **four-speed "gate" type of selector,** giving the movements of the lever for 1st, 2d, 3d, 4th, and reverse. See Fig. 17, page 100, for the Locomobile **steering device.** See page 70 for Locomobile **valve timing.** Firing order, 1, 5, 3, 6, 2, 4.

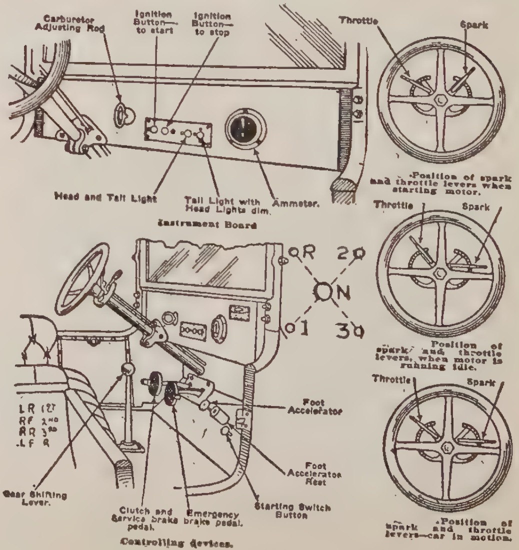

Fig. 27. **Chevrolet "490."** Firing order, 1, 2, 4, 3. The gear shift is shown.

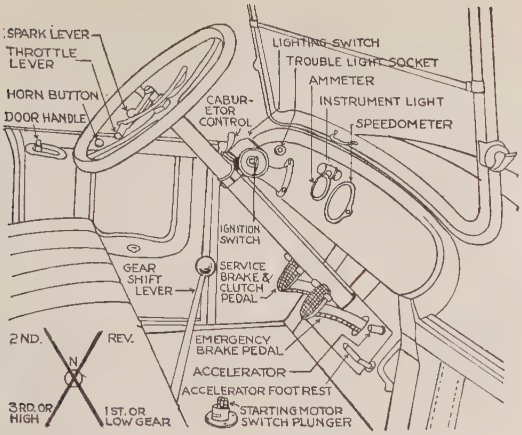

Fig. 28. **Reo models "T6" and "U6."** Note that the combination switch for the ignition, lighting, and carburetor control is mounted under the steering wheel. The carburetor control, when moved towards "Start," enriches the mixture by lifting the nozzle needle of the carburetor. The model "LL3P" Rayfield carburetor is used.

The North East model "L," third-brush regulated generator is used, as also the North East ignition unit. Spark-plug gaps are set at .030″, and the firing order is 1, 4, 2, 6, 3, 5.

The clutch pedal operates the external brakes on the brake drum on the rear wheels, and the emergency (foot brake) pedal (right) operates the internal brakes in the brake drums on the rear wheels.

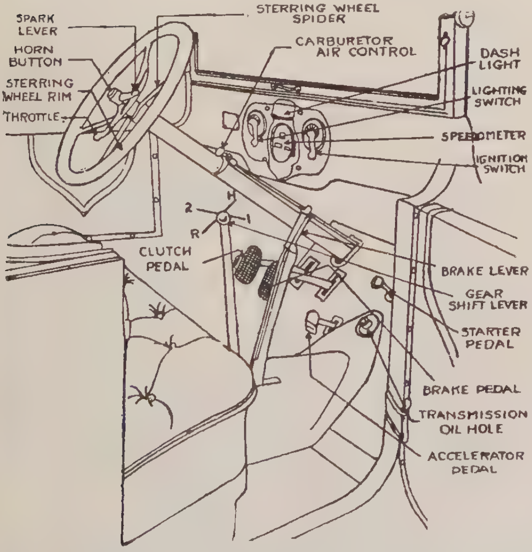

Fig. 29. Hupmobile instrument board and gear shift. Firing order, 1, 2, 4, 3.

As an example of the information concerning a car, which can be obtained from the "Specifications of Leading Cars" (see Index), the data (below) concerning the Hupmobile are taken from same as follows:

Model, R; **wheelbase,** 112″; **engine make,** own; **cylinders,** 4; **bore,** 3¼″; **stroke,** 5½″; **piston displacement,** 182.5; **cylinder shape,** L; **cylinder head,** detachable; **cylinder cast,** in block; **cam-shaft drive,** chain; **cooling,** thermo-syphon; **lubrication,** force through hollow crank shaft; **oil pump,** gear; **carburetor make,** Stromberg; **ignition,** Atwater Kent; **electrical system,** Westinghouse; **rear axle,** own; **rear axle type,** three-quarter floating; **steering-gear make,** Jacox; **hand brake,** internal on rear wheel; **foot brake,** external on rear wheel; **rear-axle bearings,** roller; **front-wheel bearings,** roller.

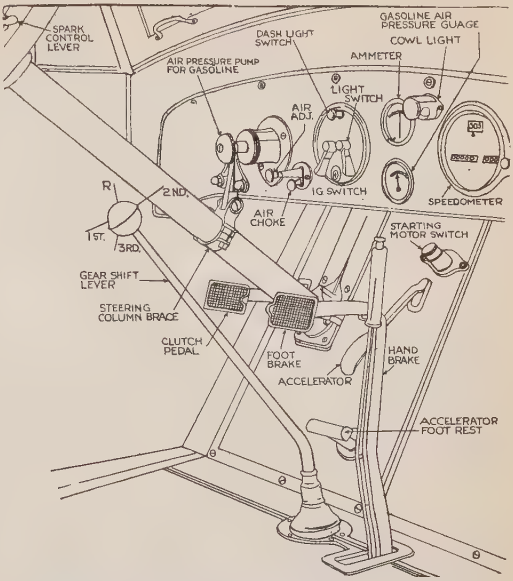

Fig. 30. **H. C. S. series 2 and 3 instrument board and gear shift.** The spark-control lever is the one on the outside of the sector of the steering wheel. Firing order is 1, 3, 4, 2.

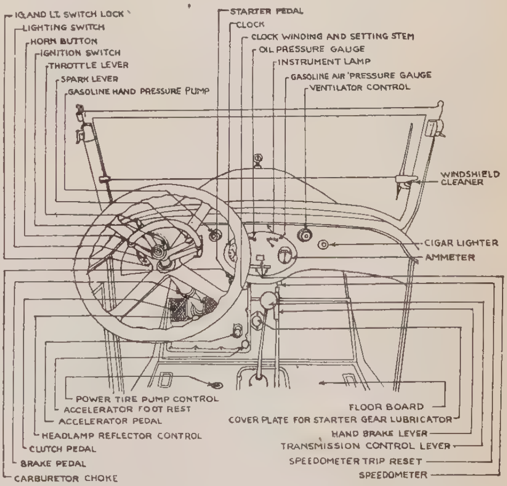

Fig. 31. **Lafayette instrument board and control members.** Gear shifts are as follows: for 1st gear, lever is moved to the left and to the rear; for 2d gear, right side forward; for 3d or high gear, right side, rear; for reverse gear, left side, forward.

The number of teeth in the differential ring gear and the drive pinion is represented by either of the following combinations which would give a **rear-axle ratio** as below:

54—11—4.9 to 1
55—12—4.58 to 1
54—13—4.15 to 1

Note that the 54 is the number of teeth in the master or differential ring gear, and that 11 is the number of teeth in the drive pinion. **To find the rear-axle ratio,** divide 54÷11=4.9. Therefore the drive pinion or propeller shaft would revolve 4.9 times to 1 of the rear wheels or axle shafts.

Engine: Bore, 3¼″; stroke, 5¼″; S.A.E. h.p. rating, 33.8; actual h.p. developed, in excess of 100; valve lift, ⅜″; valve diameter, 1¾″; valve-stem diameter, 5/16″; valve-seat angle, 45°; carburetor, 2″; piston displacement, 348 cubic inches; angle between cylinders, 90°; firing order, 4, 2, 6, 8; 1, 7, 3, 5.

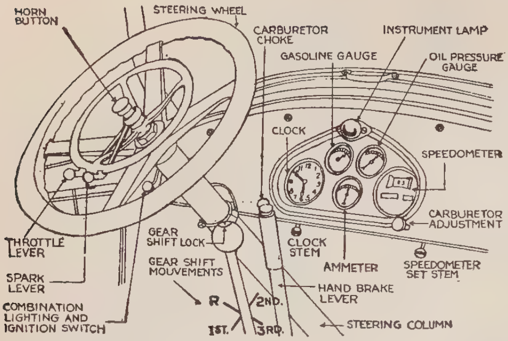

Fig. 32. **Marmon 1922 instruments and controls.** The controls and instruments will be found grouped conveniently about the driver's seat, as shown in the illustration. The clock, speedometer, ammeter, and gasoline and oil pressure gauges are centrally located in the **instrument board, being attached to a die-cast frame which is covered with one piece of glass.** The instruments have no individual glass over their respective dials.

The speedometer trip mileage can readily be set at zero with the adjusting pin. The season mileage can be changed only by returning the instrument to the manufacturer.

The combination switch, on the instrument board just to the left of the steering column, controls the lighting and ignition circuits. The ignition lever has two positions, the "ON" and the "OFF." The lighting lever has three positions. Firing order, 1, 5, 3, 6, 2, 4.

The location of control members not shown in the illustration: The clutch pedal is the left foot pedal; the foot-brake pedal is the right foot pedal; the accelerator pedal is between the two pedals; the starter-switch pedal is just above the toe board.

The **gear-shift movement** is the standard S. A. E. three speed, as shown in the illustration.

The **rear axle** is shown on page 16. The **steering device** and its adjustments are explained under "Adjustment of steering devices" (see Index).

The **engine** is a six-cylinder engine with overhead valves, the principle of which is shown in Fig. 92, page 53. Note in this illustration that the valve push rods are shown on each side of the cylinder, in order to explain the action of both valves in the head, whereas, all of the push rods are on one side of the cylinders.

The **pistons** used in this engine are of a different design from other pistons; see Index under "Marmon pistons."

The **bore and stroke of the engine** are 6¾″x5⅛″, and the piston displacement is 339.7.

POINTERS ON SELECTING A NEW CAR

Power: This is determined by the number of passengers to be carried and the condition of the roads. If the country is a flat district, a low-powered car will do efficiently and infinitely more economically what in a hilly country would necessitate perhaps nearly twice the power to do the work on high gear. For hilly country a car with a low reduction to the rear axle should be selected in order that the engine may take the hills on high gear.

Body: This is not much a matter of choice nowadays, as the cars are all built in large quantities and to a standard type. Putting aside for the moment the case of those who, from consideration of price alone, would confine themselves to a car of power and size suited for a two-seated body only, it is best to have a "touring car" body of 5-passenger type. Though the back seats may be used only once in a while, they are nevertheless too often wanted if not there, and the advantages of being able to give friends a lift and of having plenty of room for luggage and parcels are well worth the slight difference.

Enclosed bodies: The touring-car body is equipped with a very serviceable top, and, in combination with a glass front or wind shield and suitable side curtains, this type of body can be converted into a fairly weatherproof vehicle.

The coupe and cabriolet body (page 5) is a very popular type for business purposes, as it protects one from the dust and weather, and is a very comfortable type of body for winter use.

The sedan type of body is a very popular type for family use, and can be fully enclosed for winter and opened for summer use. This type of body is adapted for those who drive their own car. A suggestion to those who are considering a closed car, yet really prefer an open car, is to purchase an open car and fit the rear with a tonneau wind shield as described on page 649. The difference in cost of an open car and a closed car is quite a sum, and the low cost of the tonneau wind shield will save quite a sum of money, and yet will give the open car a nifty appearance as well as being comfortable. A closed car requires more power and gasoline, and there is usually a greater depreciation in its value. A closed car is generally geared lower than an open car, thus relieving the strain on the engine.

The limousine is a more elaborate type of body and is used where a chauffeur is employed, as the driver's seat is separate from the other seats.

The price with many fixes itself; that is to say, their means enable them to decide in a very short time how far they can go. In any event, to arrive at a maximum figure one must include in the calculation a sum not less than, say, $75.00 to $100.00 for a small car, and so on in proportion to the size, in addition to the purchase price, in acquiring those accessories, spare tires, and tubes, which are necessary.

Service: When purchasing a car don't forget that in time you will need parts and your car will require expert attention. Investigate this feature and find out if the agent carries parts in stock and if he gives his other customers satisfactory service and if he is reasonable in price.

Constant attention is necessary: Whether you intend to employ a chauffeur or to look after the car yourself is a point to consider. There is a limit to the size of car which the owner can (if the car is kept in pretty constant use) attend to himself, unless he be a man of great leisure, and moreover keen enough to put up with the drudgery involved. It is useless to conceal the fact that a car will require constant attention, and while a man may find the time to do justice to a moderate-sized car, a large car might be too much for him.

Cost of running—or up-keep: Here lies the crux of the whole matter. Closely allied with the important question of original outlay is that of the running cost, which must be taken into consideration to a certain extent, when buying. The size of the bill for up-keep bears, of course, a direct proportion to the mileage run. As regards the fuel consumption, this item will not be a large one in any car up to, say, 25 h.p., unless there is some radical defect in the system, or a temporary want of adjustment. In large and heavy cars the gasoline bill quickly mounts up.

Tires are the largest item in the cost of up-keep, and this charge becomes heavier as the speed increases and is again directly proportionate to the mileage run.

There are two kinds of pneumatic tires in general use: the "fabric" tire and the "cord" tire. The "cord" type is the best. The initial cost may be greater, but there is a saving in the long run.

The non-skid tire should be selected for rear wheels. This extra cost is well worth the difference, as the extra wear from the extra amount of rubber, to say nothing of the non-skid feature, is worth a great deal.

Small, light tires spell constant trouble, not to mention short life. Be sure the car is equipped with tires of **ample size** to sustain the weight and speed; also **determine if the size of tire is a standard size,** and if it can be obtained readily. Many of the former sizes have been discontinued (see page 594 for standard sizes).

Also determine if the **rim** is a popular type. The "straight-side," quick-detachable, demountable rim is the rim now used most. One should always carry a tire inflated on a spare rim to replace a damaged tire. It can be mounted on the rim of the wheel by loosening a few bolts and without having to use an air pump at all. There is also an advantage in having the tires the same size on all four wheels.

Which is the best car to buy? This is a question we hear daily. After determining the size of car you want, I will tell you how I would settle the choice, if I were unable to decide otherwise. Go to a used car concern and ascertain which car brings the best price or what make of car sells more readily than others. This may help to answer this question.

Selecting a Commercial Car

There is a distinction between a truck and a delivery wagon. Some of the important points to be decided are:

What type of car is required for your particular needs—gas or electric?

What horsepower?

How many pounds capacity shall it have?

Should several cars be used, or one big one?

Will the use of trailers result in economy?

Shall it be equipped with pneumatic or solid tires?

Can an inexperienced man be given charge of the running and repair work?

Is there any special equipment necessary for greater efficiency?

Should the car always be loaded to capacity?

Should the truck have a long or short wheel base?

Today there are motor trucks and delivery wagons of every conceivable size and design. Therefore, it is the problem of the prospective purchaser to choose carefully the kind of a car best fitted to serve his purpose with the greatest efficiency. It is a very common sight to see a heavy type of delivery wagon make a trip of several blocks and sometimes miles to deliver one or two small packages or baskets of groceries, when one of the smaller types of commercial cars could have done it just as well and with greater efficiency, reducing materially the overhead cost. On the other hand, we have often seen a light delivery or a very heavy type of truck making a trip with an overload. This is just as impractical as an underload, for it will ruin the expensive motor equipment, making the car depreciation very considerable.

A very good rule to stick to closely is to have the car filled nearly to capacity on every trip that is made. A motor truck or delivery wagon should not be chosen with either a maximum or minimum load in mind, but an average load. To get the greatest efficiency out of a commercial vehicle, keep it loaded and moving the largest possible number of hours during the working day.

The manufacturers of large trucks (1½ ton and above) usually sell the chassis only; the body is usually built by some local concern specializing in this work, and is designed to meet the individual requirements of the user. The design of a suitable body is a very important factor; a reliable truck dealer can materially aid the purchaser in making the correct selection.

If electricity is produced in your own plant at a very low cost, and it is possible to secure a man who understands and can care for storage batteries, then it may pay to investigate the electric vehicle.

JUDGING AND TESTING A SECOND-HAND CAR

In order that the purchase of a second-hand car may be attended with some degree of safety, as to its condition, the following tests should be given. It will no doubt be impossible for the purchaser to make all of these tests, but what follows will give a general idea of what should be done to testing or overhauling any car.

General Condition

Ascertain the age, make, and type, and also the horsepower of the engine (see Index under "Horsepower"). If the car is an obsolete model or of antiquated design, it will be a difficult matter to dispose of it later on at any price. Find out if the manufacturer is still in business, in order to know whether parts can be obtained if required. **Do not judge a car by its outside appearance alone.** Paint is ordinarily cheap.

Tires and Rims

Many sizes of tires on some of the older cars have been discontinued (see page 594 for sizes now being made). You may have difficulty in obtaining tires.

Also learn the make of rim. The old-style "one-piece clincher" rim is obsolete, except on the Ford, Chevrolet, Maxwell, and the Overland model "Four." **The modern rim** is the "straight-side," demountable type.

The best tire is the "cord" tire (see page 609). The "fabric" tire is explained on page 608. Examine the condition of the tires after reading page 610, and test for "stone-bruises."

Engine

1. **Test the compression of each cylinder** (see Index under "Testing compression"). Firs learn what compression means (see Index). The compression test will indicate the condition of the rings and cylinder walls and valves. **If the cylinder walls are scored or cut,** then this is an expensive job to repair (see Index under "Cylinders scored"). **If the valves leak,** then this is not so expensive (see Index under "Grinding valves"). **If the rings leak,** this is an item worth noticing (see Index under "Piston rings").

   If there is considerable smoke from the exhaust pipe when running the engine (see page 168), and the smoke is blue or light in color, there is too much oil in the crank case of the engine, or the pistons are pumping oil as explained on page 168, or the rings are loose, or the cylinder walls are scored. If smoke is heavy and black, the carburetor is feeding too much gasoline and should be adjusted. Many new engines have had the cylinders scored by running the engine at too high a speed during the first 1,000 miles and from lack of oil.

2. **Test the bearings.** The best method for doing this is to make a long run, taking at least one or two fairly steep hills, and noting if the engine knocks. By studying the subject (knocks), you can learn to distinguish the cause of different kinds of knocks (see Index under "Knocks").

   When testing for knocks, make allowances if the engine is a four-cylinder, especially of small size, and when taking hills slowly. Many four-cylinder engines must get the engine up to a fairly good speed to take a steep hill, as the power depends upon the momentum of the fly wheel, whereas the six, eight, or twelve-cylinder engine should take a hill with less speed, without pounding or knocking, if the spark is retarded properly.

3. **Test the cooling system.** After making the run suggested above, note if steam comes from the radiator at the vent or overflow tube or filler cap. If so, the engine runs hot, and the trouble is attributable to one of the causes explained on page 152 under "Engine overheats." Understand that an engine runs best at about 170° temperature, but should not steam. Also observe if there are leaks. Usually the leaks are at the hose connections and can be tightened, but if the hose is worn, replace it.

The Clutch

1. **See if the clutch slips** when taking a hill.
2. **See if the clutch drags when released.**
3. **See if the clutch "grabs" or is "fierce"** (see Index under "Clutch grabs").
4. **Ascertain the type of clutch used** in the car by referring to the Index for "Specifications of leading cars." Then turn to Index under the appropriate titles, and note the construction and troubles and remedies.

Transmission

1. **Test the gear shift while the engine is running,** by shifting from reverse, 1st, 2d, 3d speed, to see if the gears can be changed without a clashing noise. If not, then the trouble may be due to the clutch pedal not being thrown far enough "out," or the clutch "drags" or "spins," or the transmission or clutch shaft are out of alignment, owing to worn bearings, or the teeth of the gears are burred.
2. **Test for worn or broken gear teeth:** With the engine running slowly, place the gears in 1st speed; place the finger on the gear lever—if there is a worn place at one point or all round the gear, it can be felt by the vibration. Try this on all speeds and on reverse.
3. **If the transmission is noisy,** and there is plenty of oil in the transmission case, the trouble is probably due to a broken ball or roller bearing or a worn bearing.

If oil leaks out of the transmission bearings, see Index under "Transmission-oil leaks."

Drive Shaft and Universal Joint

1. **Test for looseness** (see Index under "End play in universal joint"): If this is excessive, the looseness is in either worn gears or bearings in the transmission, or there are loose universal joints or loose adjustment of the drive pinion to the differential driven gear (see Index under "Differential gear adjustments").

Rear Axle

1. **Test adjustment of drive pinion** (see Index under "Noisy rear axle"). On some cars, Ford for instance, there is no adjustment, therefore a new drive pinion must be fitted.
2. **Examine the differential by removing the cover,** if a "full-floating" type (see Index), or remove the axle housing, if a "semi" or "three-quarter floating" type (see Index), in order to ascertain if any of the nuts are loose or small differential pinions are worn.
3. **Test wheels for alignment** (see Index).
4. **Test for wobbly wheels** (see Index).
5. **See if axle shaft is bent**—usually at the hub, which would be indicated by the wheel wobbling.
6. **See if oil is working out of the rear hub** into the brake lining.
7. **Test brakes** (see Index).

Steering Device

1. **Test for play,** and for loose bolts and nuts (see Index under "Steering devices, testing of").

Miscellaneous Tests

1. **See if engine will idle** without missing.
2. **Test the battery:** if a coil and battery ignition system (see Index).
3. **Test the magneto:** if a magneto system of ignition, by idling and speeding up the engine to see if there is a missing of explosion.
4. **Examine the wiring** and see if it is oil soaked and ragged.
5. **Test the carburetor** by idling and speeding up the engine to see if explosions are even and if the engine picks up readily under load. Also note if the carburetor air intake and the carburetor mixture are heated.
6. **Examine the spark plugs,** to see that the gap distance is correct at the points (about .025"), and that the porcelains are not cracked.
7. **Run the car and test the mileage gained per gallon of gasoline.** This will require at least a 20 or 25-mile run. Many 6, 8, and 12-cylinder engines will not average over 9 to 14 miles per gallon—depending upon the condition of the rings, or whether there is leakage of gasoline into the crank case, as well as on the size of the cylinders and whether the roads are hilly or level.
8. **Examine all bolts and nuts** on the engine, springs, etc.
9. **See that the engine is properly oiled** and that all parts of the car are greased.
10. **If parts have been replaced,** such as the steering knuckles and spindles in the front wheels, etc., see that they are not made of castings instead of forgings.
11. **The storage battery** is another part which should be examined. Have it tested at a battery station. You can tell if the battery has been repaired by looking at the connectors. Figures are usually stamped at the factory at each end of the connector where they are burned to the post. If there is a bright spot with no figures, it indicates that the battery has been repaired since leaving the factory. The battery should be tested by testing each cell, as explained under "High-amperage tests" and "Cadmium tests of storage batteries."

INSTRUCTION No. 57

CARE OF CAR: Pointers on Driving; Washing, Polishing, and Cleaning Car; Home-Made and Other Polishes; Painting a Car at Home; Pointers on Shipping a Car

GENERAL POINTERS ON DRIVING THE CAR

The driver must keep his eyes and ears open, watching the other occupants of the road as well as the running of the car. See Index relative to "Traffic ordinances," "Rules of the road," etc.

The ear is the best judge of the running of the engine, as it shows any defect by a change in its steady throb. With practice, it becomes easy to recognize a new noise, and the cause should be located and remedied at once. A squeak or rattle that comes at regular intervals may be located in one of the revolving parts; if not regular, it comes from something that is not revolving—the springs, brakes, or a similar part.

Irregular running of the engine may not be serious, but rather the result of a rough road or loose ignition connections. **Knocks or pounds should be located at once,** for they may lead to a serious breakdown.

Know Your Car

Remember that in the care and operation of a motor car, **much must be left to the judgment of the operator,** who should study the construction of his car and thoroughly acquaint himself with its mechanism, the functions of its various parts, and the "why" of everything connected with it.

Learn the speed at which the car will take a turn on mud or wet asphalt, without skidding or side-slipping, and never exceed it. Learn the grade of a hill that the car will climb easily; on steeper grades do not wait for the engine to labor before changing the speed.

Learn the turn that the car will make for every position of the steering wheel, and always make the broadest turns that the width of the road will permit. A sharp turn is more likely to strain and injure the tires, running gear, and steering mechanism, than a broad turn, and, if the car is speeding, is more likely to cause an upset.

Learn the distance that the car will travel before it becomes necessary to refill the tanks—not from the catalogue, but from your own experience, so that a hold-up on the road for supplies may be prevented.

Learn the rapidity with which the car will pick up speed after a slow-down, as it will help when running through traffic, or when it is necessary to dodge another vehicle.

It is important to learn the shortest distance in which the car can be stopped for its different speeds, and the exact extent to which it slows down for each application of the brakes. Learn to use the brakes so that the motion becomes automatic, and can be done without wasting time thinking about it. Learn to judge distance, and the speeds at which the car travels; ability to estimate speeds may prevent arrest.

Learn to recognize the noises of the engine when it is running smoothly: the click of the valves, the hum of the timing, pump, and magneto gears, the puff of the exhaust, so that unusual noises may be easily recognized.

Learn the feel of the compression, by cranking the engine, so that leaks may be detected. Learn the effort required to push the car on a smooth floor by hand, or how freely it will coast down a hill, so that a binding brake or a tight bearing may be felt. In short, get in tune with your car—be part of it—make it part of you; that is, if you want to get good service from it, and save on the repair bills.

Important Points to Remember

The flashy driver, who makes quick turns and sudden stops, attracts attention, but ruins the car. The more smoothly a car is operated, the longer it will last, and the less often it will get out of order. Driving is not a thing to worry about, but to be taken easily.

Easy turns, gentle stops, the running of the engine as slowly as possible for the speed desired, proper adjustments, and constant care, mean long life to the car and freedom from trouble.

When the engine is not acting right, do not rush in and readjust the ignition or the carburetor without first being sure that the trouble has been correctly located. Throwing the carburetor out of adjustment on a guess makes it all the harder to get going again, for its readjustment must be added to the trouble already present. An automobile is not difficult to handle, but neither is it so simple that brain work is not necessary. Get all of the facts possible before doing anything to the mechanism—the noise that the engine made in stopping, the way it stopped, the reasons for the unnatural noises, and the bolts from which nuts may have dropped off. An automobile is constantly in a state of severe vibration, and almost any part is liable to work loose when least expected.

Some accessories are convenient, and others are nuisances. Do not load the dash up with devices that are not of practical use, for they only add to the parts that must be watched and taken care of. Provide the car with a good horn, and use it well when necessary, but never needlessly.

The lubrication is important and must be watched carefully; it takes only a little running without oil to cut the cylinder walls and piston rings. Excessive oil in the crank case means fouled spark points, and should never be permitted; however, it is better to have too much than not enough.

When running, keep to the right, and in meeting another vehicle turn farther to the right, so that it will have room to pass. In passing a vehicle going in the same direction, pass so that it is on your right, and do not swing back to the right side of the road too close in front of it. The other vehicle may speed up as you pass, and be closer than you realize.

Get thoroughly familiar with the different speeds so that there will always be time to stop when necessary. Keep your eye on the people alongside of the road, for they may start to cross without warning. Children are liable to run out of a gate or to cross the road when they are least expected. Cross-roads and cross-streets must be watched, for vehicles or people may come along them.

It is dangerous to run over a dog. It is far safer to slow down when one is barking in front of the car than to try to push it out of the way.

Blow the horn when approaching a turn in the road, for another car may be coming. Do not run on the low speeds if it is possible to run on the high.

Don'ts for Drivers

Don't drive a car until you are old enough to have good ordinary "horse" sense. Don't look around when your hat blows off. Don't try to kiss the lady in the seat beside you. Don't go to sleep while driving. Don't trust one hand to do the guiding. Don't try to make up lost time by speeding down hill. Don't run at night without lamps. Don't delay putting on the chains when the roads get greasy. Don't forget to "STOP, LOOK and LISTEN" before crossing a railway track—Safety First, Last, and All the Time.

Rattling Noise

A disagreeable rattle can often be traced to the hood where it rests on its seat. Strips of rawhide or other anti-friction material should be installed to prevent any squeaks or rattle.

Right Side of an Automobile

Q.: Which side of an automobile is referred to as the right side?

Ans.: The side to the right of the driver when seated in the car.

Why the Engine Runs Smoother at Night

Q.: I have always noticed that my engine runs smoother or better at night. Why is this?

Ans.: Experiments with stationary internal combustion engines have shown that water vapor—steam—injected into the combustion chamber gives an advantage, but the reason is not clear. On the same principle an engine runs better at night when there is more moisture in the air. It may be that the additional oxygen supplied by the small amount of water aids in the combustion of the fuel.

Meaning of 25-35; Engine Rating

Q.: What does 25-35 horsepower mean? I note many manufacturers rate their engines with two ratings.

Ans.: The "25" means the horsepower according to the Society of Automobile Engineers' formula at 1,000 r.p.m. The "35" means the actual block test the engine is capable of developing at full speed. It is taken for granted that the engine will develop 25 horsepower continuously, and will stand an overload of 35 horsepower for short periods. Most electric generators will stand a considerable overload for a short period but will heat if run overloaded continuously. The same applies to the automobile engine.

Save the Tires

If a tire blows out, do not jam on the brakes—cut off the power and let the car coast to a stop. Jamming on the brakes might cause a skid, and that would fatally ruin the tire.

In crossing loose or broken stone, as on a new road, do not drive the car over, but get up speed, and as the car strikes the stones throw out the clutch so that it will coast. If the car has not enough momentum to cross, let it go as far as possible before again throwing in the clutch. Driving across sharp stones forces the wheels to grind against them, while if the car moves without being driven, the tires roll over the stones, and are not so liable to injury.

Jamming on the brakes grinds the tires, and wears them as nothing else does. Letting in the clutch quickly, so that the wheels spin before taking hold of the road, has the same effect.

Tires that are not sufficiently inflated will rim cut, and are more liable to puncture than if blown up hard. Oil rots rubber; therefore, keep the tires clear from it. If they get oily, wipe them with a cloth soaked with gasoline.

If the car is to be idle for a week or more, jack up the wheels to take the weight from the tires—it will be better for them.

Rusty rims cause rim cuts; therefore keep them smooth. When the rims rust, scrape them or rub with emery cloth and give them a coat of shellac or lead paint to prevent them from rusting again.

In applying new tires, put them on the rear wheels, moving the half-worn, one to the front wheels. This will give them a longer life. In applying a single new tire, put it on the right-hand rear wheel, as this is the one that has the hardest work, and needs to be stronger than the others.

Skidding ordinarily occurs only on slippery surfaces and in rounding turns at high speed. In skidding, the wheels of the car slip on the ground, especially on wet asphalt, although the car will occasionally slide on dry surfaces, like loose gravel, etc. See Index for "Skidding."

A Few Words about Gasoline and Fire

Gasoline must be handled with care and common sense. It is dangerous if handled carelessly, but need not be so if the operator uses judgment. Gasoline vaporizes easily, and as the vapor is heavier than air, it sinks to the ground.

When filling the tank, be sure that there are no open lights near, or a fire. If the tank is to be filled at night, don't use a lamp; use a pocket electric flash lamp instead. Have a funnel for gasoline and do not use it for anything else. See Index under "Gasoline" and "Fire, how to extinguish."

In case of fire, do not try to put it out with water, for the burning gasoline will float and spread the fire. Always keep a pail or two of sand handy, and smother the flames with it. In case of fire, the first thing to do, if it is possible, is to turn off the supply cock from the tank to the carburetor, and then push the car away from the blazing gasoline on the ground. Do not let a pool of gasoline drip from the carburetor when priming it, as a chance short circuit may give a spark that will set it on fire. See also Index under "Gasoline fire; how to extinguish."

Fires are usually caused by gasoline dripping from the carburetor and a stray ignition spark. Be careful to see that the carburetor does not drip.

WASHING THE CAR

First, dust off the car and top. Do not wipe it off; this simply rubs the grit into the varnish and makes scratches on the body, fenders, hood, etc.

When washing the car, use only clear water. Warm water is best, but only lukewarm water should be used, otherwise it will soften the varnish. If soap is used, get a good carriage soap that has **no alkali in it.** If it contains alkali, it will take off the varnish.

Mud should not be rubbed off, for the varnish would be scratched. Let the water run gently out of the hose (using no nozzle) and flow over the mud, so that it washes away slowly.

The full force of the water may be used to remove **mud from the under side of fenders, but not from any varnished part.** If a hose cannot be used, pour the water on so that the mud is carried away. Dry mud is more difficult to remove, but if the varnish is to be kept bright, use only the method described, and take time to it.

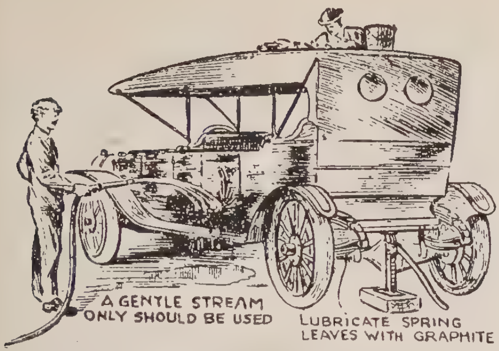

Fig. 1. Washing a car and cleaning the top.

When the body is clean, go over it with a soft sponge, using plenty of water, and dry it with soft, clean chamois skin or wash leather. It is advisable to have a sponge and chamois skin for running gear, a separate sponge and chamois skin for the body.

After the body has been washed, it should be gently dried with a piece of clean chamois skin. Wash out and wring out the water from the chamois as the car is wiped with it.

For removing grease, a sponge with castile soap and tepid water should be used and then body polish applied.

A car ought to be washed and chamoised off immediately if rained upon, otherwise spots will remain if rain is left to dry.

Fig. 2. A flexible wash-hose nozzle.

Wash-rack hose is usually a 4-ply hose of ¾″ inside diameter. A **flexible wash-hose nozzle** (Fig. 2) is best to use for washing cars, instead of a metal nozzle. The nozzle shown is known as the Conqueror brand.

Home-Made Washers

Supply houses can supply complete equipment for washing cars. Below are shown home-made devices.

Supplies for cleaning the car: Two good, clean, soft "wool" sponges, two ten-quart pails, several clean soft chamois, a quantity of canton flannel, a quantity of ivory or pure castile soap, clear running water, a soft wool duster, gasoline for use in extreme cases.

The two sets of pails, sponges and chamois are recommended, so that the pail and sponge used for the first washing may be kept separate from those used in the final washing. See Index under "Sponges"; for the kind of sponges and chamois to use.

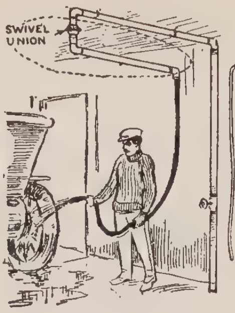

Fig. 3

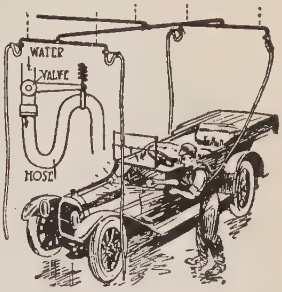

Fig. 4

Fig. 3. **Portable hose swing-rack for washing cars.** This rack is made of standard ¾″ galvanized iron seamless pipe and fittings. The illustration gives an idea of its construction. Large garages usually have means for heating the water..

A washstand is usually made about 12 or 14 ft. wide and about 15 or 18 feet long. It is made of granitoid, so arranged that the water flows to a trap in the center for draining.

Fig. 4. **A washer with several hose outlets,** which meets all requirements and is not likely to get out of order is made out of four lengths of hose suspended from pipe connections at the four corners of the wash rack. Each hose is connected to a plug valve which is spring-closed and opened by a slight pull on the hose. The advantage of the four-hose construction is that it is simple, not likely to get out of order and allows more than one man to work on a car.

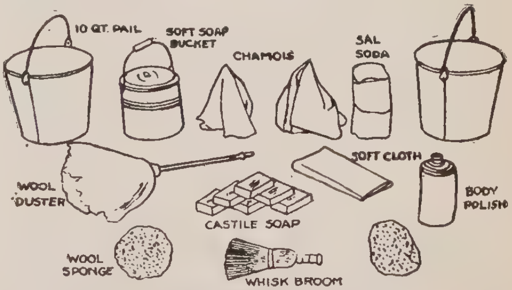

Fig. 5. Supplies necessary for cleaning a car.

Washing Radiator

When it is necessary to clear the radiator spaces of accumulated mud, you should flush the radiator from the rear, not from the front. In that way you avoid getting water into the magneto or ignition system, which is often short-circuited when moisture enters it.

Sponge Off Your Hood

Particular attention should be given to the hood after the car has been run in a heavy rain, inasmuch as after a long run it becomes fairly hot. If raindrops are left to dry upon it in this condition, they will stain it much more than the body. The car should be washed down at once, or if this is not possible, the hood should be sponged off and wiped dry immediately.

A good body polish will remove grease and rain spots from a hood or body.

BODY, METAL, AND GLASS POLISHES

Cleaning and polishing dull varnish: In most cases, dull varnish is not "dead," but is simply coated with a deposit of dirt. When this deposit is removed, the original luster of the varnish can be restored. The following method will give excellent results. The necessary materials are a clean sponge, automobile soap, chamois skin, soft waste, cheesecloth, rotten stone, linseed oil, and Percival automobile polish.

Cleaning: Wash the car thoroughly with automobile soap. Wash small sections of the body at a time, and do not permit the soap to dry on the varnish. Dry the car with chamois skin.

If the finish is very dull after washing, saturate a small pad of selected soft waste (there must be no grit or thread cards in this pad) with water, and dip lightly into fine rotten stone. Do not make a mistake and use pumice stone, for it will completely destroy the finish. Rub with the pad and rotten stone until the surface shows a bright luster. Continue over a complete panel. Be sure to keep the pad saturated with water while rubbing.

Rotten stone has relatively no abrasive effect on gum varnish, but does rapidly abrase the imbedded deposit if the varnish is free from oil and grease. As fast as this deposit is cut away the varnish acts as a lubricant, as the easy sliding of the rotten stone pad will indicate. Remove all rotten stone with damp cheesecloth.

If the finish is only slightly dull or gray, rub with a mixture of 1 oz. rotten stone and 3 oz. linseed oil instead of rotten stone and water. Shake the mixture while using.

Polish: After cleaning as above, polish with Percival automobile polish. The formula follows:

24 oz. wood alcohol....... (By weight)
48 oz. raw linseed oil...... (By weight)
40 oz. white vinegar...... (By weight)
3 oz. aqua ammonia..... (By weight)
3 oz. spirits camphor..... (By weight)
6 oz. butter antimony.... (By weight)

It is imperatively important that these ingredients be **mixed together in the order given,** and that they be shaken thoroughly.

To the formula given above add a mixture of 2 oz. grated beeswax and 3 oz. turpentine, which have been mixed and allowed to dissolve thoroughly for 48 hours. When added, the whole mixture must be shaken. Always shake before drawing from the main supply and while using.

To use the polish: Saturate a pad of fine cheesecloth with the polish and rub the varnish briskly until a full luster appears. The luster can be determined by wiping the parts occasionally with a clean cloth or with the palm of the hand, and looking at the surface as into a mirror. A perfect reflection should be obtained. If dullness appears after the car is used, it will indicate that the deposit was not entirely removed with the rotten stone, or that the polishing was not thoroughly done. Hard, consistent rubbing will invariably bring the desired results.

After thoroughly polishing, wipe off all polish carefully with cheesecloth that has been washed and dried. Then dampen a piece of cheesecloth with alcohol (wood alcohol will be satisfactory), and shake the cloth until no free alcohol is left on its surface. The cloth will then feel cool to the face, but not damp. Wipe over the complete job, occasionally dampening the cloth as described above. This operation removes all traces of oil and polish and leaves the original varnish clean and brilliant. Be careful not to spill alcohol on the finish, and do not use a moist cloth, as the alcohol will dissolve and soften the varnish.

After polishing, the car should be treated as if it were newly painted, with the added advantage that there will be no danger of spots appearing as with a newly painted job.

As it is absolutely necessary that the polish be neutral in its action upon the varnish, use the Percival formula and nothing else.

This process will not be satisfactory on varnish which has been oiled or waxed repeatedly, or on which ordinary furniture polishes have been used.

Another polish for the body for removing rain spots and grease: A much-recommended polish is made by mixing the following ingredients: turpentine, 1 gallon; paraffine oil, 1 pint; oil of citronella, 3½ oz.; oil of cedar, 1½ oz. This should be applied after the car is washed and dried. Apply this with soft, clean cotton waste and rub dry with a clean flannel cloth. If it is not rubbed dry the dust will collect. This preparation in most cases will remove rain spots and grease.

Another method is to use a mixture of boiled linseed oil and turpentine, applying it sparingly and rubbing absolutely dry. The use of these polishes will restore even an old car to a degree of brightness that will surprise you.

Another body polish that is highly recommended is made by using 1 gallon of soft water, 4 oz. ordinary soap, 1 lb. white wax in shavings. Boil well and add 2 oz. of pearlash. This may be diluted with water and laid on with a paint brush, and then rubbed off with a cloth. Another formula often used is 3 oz. shellac, ½ oz. gum mastic, and 1 pint methylated spirits of wine, dissolved. In our opinion, however, better results will be obtained by using some one of the varnish polishes that are on the market and that can be found at almost any hardware or paint store.

A good cleanser for enameled parts of the car, when parts are greasy and very dull, may be made of the following: 1 lb. washing soda crystals to one pail, or 2½ gallons of water. This should be very briskly applied with a soft rag. Then polish with canton flannel.

The solution, before being applied, should be carefully inspected to see that all crystals have been dissolved, as any remaining will scratch the surface.

This solution should be used only on enameled parts of the car, as it will ruin varnish or paint. The enameled parts of the car are the radiator, radiator splashers, bonnet, front and rear fenders, gasoline tank, tire carriers, steering column, shifter lever, black engine parts, and the enameled part of lamps.

Brass

Any good brass polish will work satisfactorily. All these preparations contain some fine abrasive, for which reason care must be taken not to let the polish come in contact with the varnish body surfaces.

Nickel-Plated Parts

All nickel-plated parts may be cleaned with regular silver cleaner paste. Use only the softest flannel rag or chamois to rub with.

Do not clean lamp reflectors except when absolutely necessary, and then use Putz pomade, applied with a very soft clean chamois skin. Reflectors are often silver plated and are very easily spoiled by frequent polishing.

Nickel trimmings should be rubbed over with an oily rag; this will keep them bright without polishing. Before going out for a run in damp or rainy weather, it saves labor to give the brass work a light coat of vaseline to protect it from tarnishing, and put rubber bags over the lamps. When there is little time to give to cleaning the brass work, paint it with black or colored enamel, which looks better than uncleaned brass.

Metal and Glass Polish

Mix one part wheat flour, five parts of dry powdered fire or potter's clay, and use with a damp woolen cloth. This will be found the finest polish ever used, and is cheap. It cannot be beaten for cleaning fly specks, grease, paint, and other stains from glass or metal.

To Clean Glass and Reflectors

For cleaning glass—windows, windshields, lamp lenses, mirror lenses, etc.—there is nothing better than a mixture of half alcohol and half water, which will readily clean off dirt and leave a bright polish. With a soft cloth, or a piece of tissue paper, the work can be done expeditiously. See Index for "Cleaning and polishing reflectors." Putz pomade applied with a very soft, clean chamois skin is also excellent for cleaning reflectors.

To prevent rain or snow from sticking to glass: A trade magazine gives the following mixture to use: 2 oz. glycerine and 1 oz. water with 1 dram salt. Apply to the windshield with cheesecloth—wiping up and down, or in a vertical direction.

CLEANING TOPS, UPHOLSTERING, ETC.

To clean top—outside: A top that has been in use for some time can be cleaned by using the following mixture: ½ pint raw linseed oil; 4 cups water; ½ cup turpentine. Apply with clean rag and rub dry.

A dressing for leather tops: A very good recipe for the purpose is: One part liquid asphaltum to two parts castor oil, to which add ½ oz. ivory black to each pint of the mixture. Apply with a soft brush. This dressing is excellent for a rubber top.

Mohair tops should be frequently dusted and brushed off.

If the top is mohair, a pail of tepid water and a bar of castile soap should be used. Place the soap in the pail and work with the hands until a good lather is obtained. A large clean sponge is dipped into the water and the top is then thoroughly washed.

Pantasote tops and curtains are best cleaned with a soft brush dipped in water in which a little ammonia has been added. Afterwards rub dry. Never attempt to clean top and curtains with gasoline or kerosene.

Do not fold the top until it has become thoroughly dry, because any moisture remaining in the folds is prone to cause mildew, besides making the top leaky and unsightly with spots. When the car is not used for some time, it is best to open the top, which keeps it well stretched and smooth.

If the top is dirty, use a broom first. After it has been cleaned with soap, go over it with clear water so that no alkali spots will appear.

Cleaning Leather Upholstering

Do not use gasoline for cleaning leather upholstery. Plain water with a little ammonia will remove the dirt, and a brisk rubbing with a clean woolen or flannel cloth will do the rest. For still more careful treatment, use a regular leather dressing on all leather.

Recipe for a dressing for leather upholstery: Raw linseed oil and turpentine, mixed in proportions of two of the former to one of the latter, is a time-honored formula.

For cleaning cloth upholstery use clear water and a mixture of ¾ oz. common salt and 2 oz. of either grain or wood alcohol, simply rubbing the cloth with a sponge dampened in the mixture.

To remove ordinary dust from cloth upholstery, beat the cushions and backs lightly with a stick or carpet beater; then remove the dust with a whisk broom or brush. (The vacuum plan is best.)

Grease or oil may be removed by the application of a solution of lukewarm water and ivory soap, applied with a woolen cloth. Any of the approved methods for cleaning woolen cloth may be used with success on this upholstery. Gasoline and benzine have a tendency to spread instead of to remove the dirt. We do not, therefore, recommend their use, although they work no injury to the fabric.

A certain repair shop made a reputation by having **their mechanics wear clean dusters** when working on the interior of a car, thus protecting the upholstering from grease.

PAINTING RADIATOR, ENGINE, CYLINDERS, MANIFOLD, ETC.

To paint the radiator, mix 3 oz. boiled linseed oil, 4 oz. lamp black, 1 oz. turpentine, and thin down with turpentine to the proper consistency. In applying, the radiator must either be dipped into the solution (in this case a great deal more must be mixed), or sprayed (see also, Index under "Painting radiator"), or the radiator can be placed on boxes, face up, and the thin mixture can be applied plentifully so that it will run through the cellular parts of radiator. A camel's hair brush can be used to reach places not covered.

To paint cylinders: Mix 8 oz. white lead in oil, 6 oz. boiled linseed oil, 2 oz. turpentine, and ½ oz. lamp black. If too heavy, thin down with turpentine. This will make a gray paint sufficient for six cylinders.

Aluminum mixed with bronzing liquid can also be used.

To paint the intake manifold: Use regular aluminum, which can be secured at any drug store.

To paint the exhaust manifold: Use aluminum. No paint has as yet been found which will remain on hot exhaust pipes; here is a recipe suggested:

Heat-proof paint: Use 2 parts of black oxide of manganese, 3 parts of graphite, and 9 parts of Fuller's earth, thoroughly mixed, to which add a compound of 10 parts of sodium silicate, 1 part glucose, and 4 parts of water, until it is of such consistency that it may be applied with a brush.

Tire paint: Liquid rubber is a preservative and beautifier of tires. It gives the tire a white coating. It is made of pure unvulcanized rubber in solution. It can be applied with a brush, and if used at regular intervals, it will, it is claimed, prolong the life of the tire because it penetrates and runs into any small cuts or holes and seals them over, thus in a measure preventing moisture from reaching the fabric. It is also suitable for golf balls, rubber mats, and is a highly satisfactory rust preventive for rims. Secured at supply houses.

A very satisfactory tire paint for finishing the inside of a tire after repairing may be made by mixing thoroughly 1 gal. gasoline, ½ pint Firestone rubber C-35 cement, 1½ lbs. soapstone and ½ lb. whiting. Many successful repairmen are using this formula with the best of results. See also page 612.

SUGGESTIONS FOR REPAINTING A CAR AT HOME

In some cases the car owner may feel disposed to do some of the work himself, and then pass it on for the professional painter to put on the finishing coats.

He may, for example, give the car as thorough and complete a washing up as the painter will do. Then by getting the car up on stout wooden horses, so that he can work under it conveniently, the grease and dirt may be removed from the chassis. This is a somewhat smeary job, but anyone who is not afraid of work can save some money by doing it. Saturate the greasy parts with one-third turpentine and two-thirds kerosene or crude oil, and let the applied mixture stand for several hours to soften up the hardened oil and dirt.

Then take a ½″ putty knife and a couple of mowing machine knives and some pieces of coarse burlap, and proceed to cut and scrape the accumulations off, and wipe the parts up. It may take two or three applications of the oil and turpentine mixture, and a lot of rubbing with the burlap, to get the surface clean, but it is all necessary work.

If the surface is worn and the paint beaten off, and the bare metal or wood is disclosed, these pieces will need touching up with a paint mixture containing at least one part raw linseed oil and two parts turpentine. Mix thoroughly some ground white lead and lamp black and add a little at a time to the oil and turpentine. Apply with a small round brush.

Next get some dry white lead and a small quantity of finely ground whiting, using one part of the whiting to two parts dry white lead. Knead it to a good working body in equal parts of coach japan and rubbing varnish. Then, with your putty knife, putty up all the holes and surface fractures, filling them smooth and level with the surrounding surface. While this class of work is somewhat difficult to do well, with care and some practice it may be taken care of.

If the surface is in a condition suitable to sandpaper, apply the color without any further surfacing. The professional painter may then, if desired, be called in to sand this putty and the surface down smooth and apply a coat of color to the car. If any striping is to be applied, the lines may be run on this coat of color, after which apply one or two coats of varnish, according to the class of finish desired.

In case the car needs simply a coat of varnish, with perhaps a few worn or bruised spots touched up with a bit of color, it should first receive a thorough washing and cleaning. The body surface will need going over with water and pulverized pumice stone to lay down the gloss and fit it for the varnish. Then touch up with the color where necessary, and apply a coat of body-finishing varnish. Likewise, give the chassis a stout coat of varnish.

In this connection, it may be stated that the amount and kind of work to be applied to the car depends altogether upon the condition of the surface at the time the work is to be done, and naturally, also, upon the sum of money that the owner wishes to expend upon the work. Generally speaking, if the car is kept well varnished, it will not need heavy painting repairs except at long intervals.

Pointers on Cleaning a Car and Removing Old Paint[1]

Having stripped the car, run it on to the washstand and hose off the mud.

Clean the upholstery and the inside of the car with a good stiff brush, or a vacuum cleaner; if an open car style of top, brush it out well on the inside and outside; and if the outside is very dirty, hose it off and scrub with a stiff brush.

Then clean off the chassis with gasoline (kerosene may be used for cleaning a job that is to be burned off, but is too greasy where only repainting is intended), using a gasoline brush or an old worn-down paint brush for the purpose—scraping off any hardened grease or dirt with a putty knife. Next make up a suds of soap and water and sponge off all of the dirt that has become loosened by the gasoline. Then hose off.

Hot water may be used where the job is to be burned off afterwards—as hot as desirable; but where repainting only is intended, it should not be so hot as to soften any of the paint coats; and where revarnishing only is intended, the water should not be more than lukewarm. After washing a job that is to be repainted or revarnished, hose off thoroughly with plenty of water, and make sure that all soap has been removed from the surfaces. The stripped parts can be similarly cleaned, where necessary. Sponges and chamois used in washing should not be used elsewhere, and it is best to have one set for use on the chassis, which is always the greasiest, and another set for use on the body parts.

Cleaning preparatory to burning off need not be so thorough as when done before repainting, etc. If there is any body polish on the surfaces, wash it off with gasoline preparatory to the washing with soap and water, whenever the job is to be handled without burning off.

Cleaning with no washstand available: In this case clean out the inside and top as described, and then scrape off the caked mud and grease with a putty knife. If the job is to be burned off, the paint remover can be depended upon for removing any remaining grease or dirt.

If burning off is not intended, the surfaces should be further cleaned with gasoline on the chassis, etc., and if necessary with a warm water suds on the body—doing the work from a pail—and then sponging off with clean water. The sanding that the surfaces will receive must free them of any remaining dirt. Wash off all body polish with gasoline.

Cleaning the chassis with a spray: A very quick and effective method of cleaning is that where a spray is used. Such a device cannot be used without compressed air, but where this is to be had, a simple spray nozzle can be rigged up with a few pieces of brass pipe, patterned like that of a garden or orchard spray, and the cleaning solution can be sprayed on the car from it.

A mixture of hot water, soap, and kerosene can be used in cleaning a chassis for burning off; while for repainting, warm water, gasoline, and soap would be used first, and clean water afterwards. There are many cleaning solutions to be had on the market that can be advantageously used in cleaning a car preparatory to burning off, but most of them are too strong for use otherwise.

Materials for use in automobile painting can be had from: Valentine & Co., Chicago; Murphy Varnish Co., Chicago; Chicago College of Auto Painting, Chicago. Brushes can be obtained of Mishawaka Auto Specialty Co., Mishawaka, Ind.

For undercoating a good primer should be used, that is suited for use on both wood and metal, with roughstuff, sanding surfacer, and stiff putty. Colors and color varnishes can be stocked in the most popular shades, and the odd ones can be made as desired with the color and rubbing varnish. A free working and flowing finishing varnish will be best suited for general purposes, especially for body work, but for chassis work use one that is a little heavier bodied. Spar varnish can also be used on the wheels or other small surfaces where there is no danger of laps or runs showing.

The subject of application would require a volume in which to discuss it properly.

Selection of brushes: Brushes are often cheapened in such a way that it does not show. Good hair is placed on the outside and the poor grade is placed at the center. In the best grades, the hair will be found uniform from the center to the outside. The "filled" brushes are not bad ones to work with, but the "pure" ones will outwear them, and as brushes improve with use, it is not desirable to have one start wearing out just at the time when it should be getting good.

It takes some little time before the badger-hair finishing varnish brush can be brought to its maximum efficiency; and, properly cared for, it should last for years. So it would be nothing but false economy to buy anything but the "pure" badger-hair brush for such a use. Brushes that are used for finishing must be absolutely clean, and as this is a condition that can be acquired and maintained only by use and care, these brushes improve in value and usefulness in direct proportion to the care and use given them. Nearly all automobile painters, who make a specialty of finishing, that is, applying the finishing varnish, own their own brushes, and they accord them the very best care and attention.

The following table will show the types and sizes of brushes used in automobile painting:

Brushes for Car Painting

Primer: 2½″ ox-hair or soft bristle for large surface; 1″ ox-hair or soft bristle for small surfaces.

Filler: 2″ flat bristle; 1½″ oval bristle.

Color: Body, 1″ camel's hair for small places; 3″ camel's hair for large panels; chassis, 1½″ camel's hair.

For the automobile colors that are applied in thicker coats, like the whites, creams, and grays, a 1½″ ox-hair brush can be used.

Touch-up: ½″ camel's hair for bolt heals, lugs, etc.

Color rubbing varnish[1]**:** Body, badger-hair, double thick, 1″ for small places; badger-hair, double thick, 2½″ for large panels. Chassis, badger-hair, double thick, 1½″.

Finishing varnish: A set of three, the same as for color-rubbing varnish. For touching up the finished job with an air-drying enamel, irons, running gear, etc., a small brush known as a sign painter's brush is a handy tool. It is a ½″ ox-hair, with the hair about ⅝″ long, and has a long handle. A 1½″ bristle or ox-hair brush will also be required for enameling rims.

Striping, monograming, lettering: Sword stripes, sizes No. 2, No. 3 (stripe up to ⅛″); broad stripes (stripe ⅛″ to ⅝″); monograming and lettering pencils, assortment.

Brushes for Truck Painting

Truck work is harder on brushes, and a high-class finish is not so essential. The surfaces are rougher and do not call for so high-grade a tool.

---

[1] From *Motor Age*.

Primer: Body, 2″ bristle for any kind of primer; chassis, 1½″ bristle for any kind of primer.

Filler: 2½″ bristle body.

Color: Body, 2½″ ox-hair; chassis, 1½″ ox-hair.

Varnish:[1] Body, 2½″ bristle (one set for color rubbing varnish); Chassis, 1½″ bristle (one set for finishing varnish). A bristle brush is required for this work because larger surfaces require a longer working or brushing of the varnish, and the longer it is worked the stiffer it gets. Also the heavier bodied varnishes are used on trucks, where so fine a finish is not required. Larger brushes would be required for moving vans, or a number of men could work on a panel at the same time.

POINTERS ON SHIPPING AN AUTOMOBILE

An automobile will be received for transport by freight only when either crated or set up. The usual method in shipping by freight is to ship it complete, and run it right into the car. See that the railroad company blocks the wheels so that the auto will not pitch forward or backward. It is also well to see that the machine is braced from the side.

Get a clear bill of lading from the railroad company, so that you have something on which to base a claim for damages in case of the car being smashed. It is well to box the cushions and all loose parts separately. The charge for conveyance must be ascertained from the railway company.

Place the vehicle in the car parallel with the sides, and see that the front wheels are in line with the back wheels. Wrap the lower third of the tires with burlap to prevent chafing; and set the brakes.

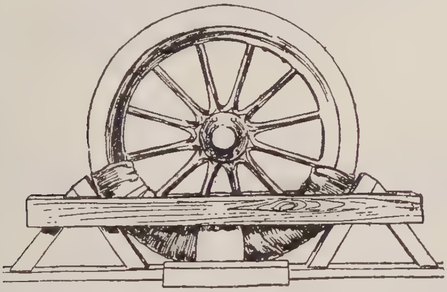

Fig. 6

To block the wheels, fasten each wheel to the floor with a strong band of canvas or several layers of burlap of the width between two spokes. Secure the band to the floor on each side of the wheel with blocks 2″ by 4″ by 12″. Place these blocks parallel with the wheel, using plenty of nails or spikes.

Use blocking in front and behind each tire one-third as high as the diameter of the wheel, and at least one inch wider than the tire. Fasten this securely to the floor, and tie together with one or two-inch lumber from block to block. Have the blocking of sufficient width so that the boards used to tie the blocks together will clear the tire at least a half-inch on each side.

In packing the auto, empty the gasoline and water tanks and disconnect the batteries. In the case of electric cars, remove the batteries.

The tires should be tightly inflated; and the edges of the boards and blocks next to the tire should be rounded or beveled, so that if they should become deflated or in any way come in contact with the boards or blocking, they will not be so liable to chafe. Place the covering over the vehicle to keep off dust. Also remove the lamps to prevent damage to them.

Freight cars should be carefully inspected to see that they are fit for loading. If there are nails or other projections in the floor or sides of the car, they should be removed. If the roof appears to be leaky, or its fastenings for the doors, both end and side, are not complete or ample, the car should be refused, and a car suitable for loading demanded. Failure on the part of the shipper to do this renders him liable for the damages resulting from having loaded the vehicle in a car manifestly unfit.

USEFUL ACCESSORIES

The J. H. tonneau windshield shown in the illustration (Fig. 7) will give to the open car the comforts of the closed car. In the summer it permits of driving in comfort with the top down or up, and in the winter it will close the rear of a car up as comfortably as a limousine or closed. car.

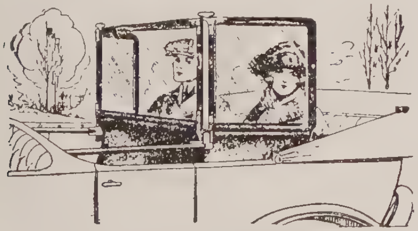

Fig. 7

To those who are debating the question of whether to purchase an **open** or a **closed car,** this device will no doubt prove of advantage in assisting in reaching a decision. The expense of a closed car is considerably more than that of a touring car and less power and wear can be had from it. With this device a considerable sum can be saved. The tonneau windshield is handsomely constructed, and will add greatly to the appearance of a car. Manufactured by the J. H. Tonneau Windshield Co., 1777 Broadway, New York, N.Y.

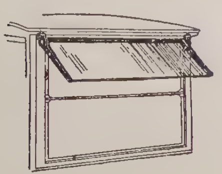

Fig. 8

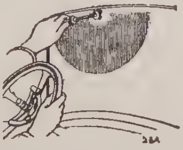

Fig. 9

The Gemco visor for Dodge sedans and coupes is shown in Fig. 8. It is made of heavy plate glass 11″ wide, ¼″ thick; nickel plated trimmings, black enameled frame; the brackets are screwed to the extension of the car; and it is provided with a ratchet for quick adjustment to any angle. With this attachment sleet, rain, and snow cannot obscure the driver's vision. Made by the Gemco Co., Milwaukee, Wis.

Windshield cleaners are made in a number of different forms. Fig. 9 shows a half-circle cleaner which is fitted to the windshield by drilling the glass. It will instantly remove rain or snow in this half circle.

An "automatic" windshield cleaner is another type used. This consists of a small metal cylinder, about six inches long, mounted on the top frame of the windshield. The metal cylinder contains a small piston attached to a scraper arm fitted with a rubber strip. A piece of special rubber tubing is connected to the inlet manifold of the engine, and the scraper is thus operated by the suction from the inlet manifold. When once turned on, the cleaner swings constantly, and removes the rain or snow until stopped.

Fig. 10

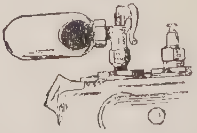

Fig. 11

A mirrorscope for placing on the fender (Fig. 10) will enable one to see the cars in the rear.

A compression whistle is shown in Fig. 11. This device is screwed into the cylinder in place of a relief or priming cock, and is operated from the seat. To those who have difficulty in keeping the battery charged this device will serve instead of the electric horn and thus save electric current.

A good clock is a very necessary cowl-board equipment. Not all clocks on automobiles are good ones. A clock for automobile use should be of the best in order to withstand the vibration. As cars are driven in all seasons of the year, the clock should have a compensating balance so that it will not be affected by extremes in temperature.

---

[1] The Columbus Varnish Co., Columbus, Ohio, and the Boyer Chemical Co., 940 N. Clark St., Chicago, supply varnish and paints with instructions as to their use for repainting and touching up cars.

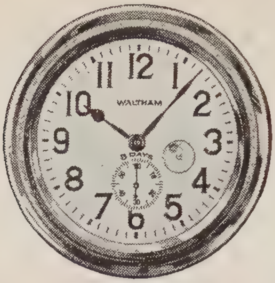

Fig. 12

Fig. 12. Automobile clocks are made in many designs by Waltham Watch Co., Waltham, Mass. The one shown is the model "F." Note the "O" on dial. A red signal will appear three days in advance of the time when winding is necessary.

Experienced automobile drivers advise a clock to do away with the inconvenience of referring to their watch when clothed for cold or stormy weather, as even the few seconds required for this might result in an accident to the machine or passengers.

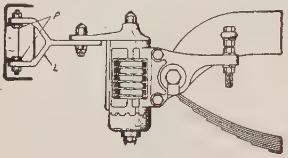

Fig. 13

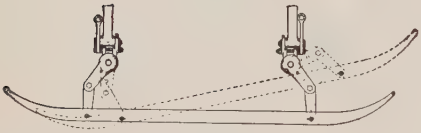

Fig. 14

Fig. 13. The Ramspring bumper, shown above is based on a principle that is different from other principles and constructions. One side may be deflected without materially deflecting the other side. The action of the coiled spring may be varied by changing its tension, which is done by loosening the nut on the bottom and winding up the bottom cap. It will be noted that the bottom cap which holds the spring tension is serrated with heavy square teeth.

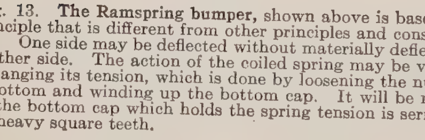

Fig. 15

Action: Heavy coil springs cushion the impact and absorb the shock. Fig. 14 shows the bumper taking a blow from the side; solid lines indicate normal position of the bar; Fig. 15 shows the bumper taking a heavy blow head on. Manufacturers are the Ramspring Bumper Co., 624 W. Adams St., Chicago, Ill.

A bumper for the rear as well as the front of the car will often save the lamps, fenders, body, and radiator. Insurance rates are reduced in most policies where cars are equipped with front and rear bumpers.

Fig. 16. **A gasoline gauge which can be placed on the dash** and which will indicate the amount of gasoline in the tank in the rear of the car is a very handy and serviceable device. A gauge known as the Petrometer, sold by the Porter Carburetor Co., Knickerbocker Bldg., Forty-second Street and Broadway, New York, N.Y., is shown in the illustration.

The glass tube in the gauge of the Petrometer contains a special red fluid which indicates by different levels and the markings beside it the quantity of gasoline in the tank. It is applicable to all motor vehicles or other fuel or liquid tanks which are open to the air—all automobile fuel tanks using gravity or vacuum systems.

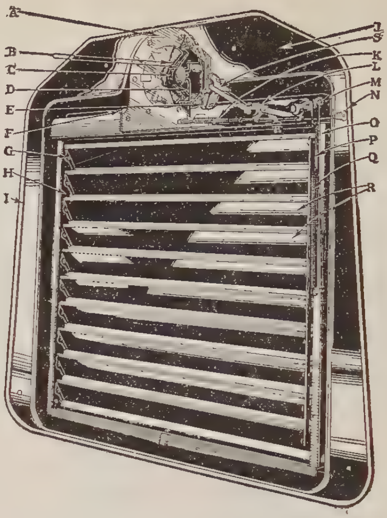

Fig. 17. **The Winterfront radiator shutter** could be classified as a very necessary device for regulating the temperature of the cooling system, thus conserving the heat of the engine, making starting easier, and enabling the engine to warm quickly, as explained with another principle on page 149. The device (Fig. 17) is one which can be secured for any make of car, and fits over the outside flat surface of the radiator core.

Operation: The shutters (R) are ribbed and turn in brass trunnions (G). All shutters operate in unison and are connected with a thermostat.

The **thermostat** consists of a pair of thermo-wafer cells (B) with a spacer (C) and an aluminum heat-conducting flange or plate (A). The thermo-wafer cells are filled with a liquid mixture which forms gas proportioned to make the cells expand or contract at the desired temperatures. For ordinary requirements they are filled to begin expansion at 130° F., and fully expand at 175° to 180°. The heat is derived from the radiator core, through the aluminum heat-conducting flange (A) which rests against the core of the radiator, and as it warms up the heat is carried to the thermo-wafer cells (B), causing them to expand. As the cells (B) expand, they turn the double bell crank (D) which is connected with the shutters (R), opening them gradually as the heat of the radiator rises above 130°, and fully at 175° to 180°. When the temperature drops below 130° the thermo-wafer cells (B) contract and automatically close the shutters (R).

If desirable to close shutters when stopping the car, the exposed closing button (N) can be pressed, which instantly locks them shut. The automatic release (L) restores the shutters to operating position when the engine is started.

Adjustment of the releasing attachment can be changed with a small wrench enclosed with the attaching bolts, etc. It fits the brass bolt projecting through the upper tie bar. This brass bolt can be reached through the space above the top shutter, when the shutters are open. Turning the wrench to the right will make the adjustment more sensitive, and to the left less sensitive.

If shutters should fail to open fully when the engine is heated up, the thermostat disks (B) may have become porous, or the soldering leaks. The disks are replaceable.

Names of parts: **A,** aluminum heat-conducting flange; **B,** thermo-wafer cells; **C,** cell spacer; **D,** double bell crank; **E,** thermostat insulator; **F,** frame insulator; **G,** brass trunnions; **H,** composition bearings; **I,** cushion cord; **J,** shell; **K,** safety spring; **L,** automatic release; **M,** shutter lever; **N,** closing button; **O,** shutter rod; **P,** shutter operating bar; **Q,** closing spring; **R,** shutters. (Manufactured by Pines Mfg. Co., 408 N. Sacremento Blvd., Chicago, Ill.)

To Prevent Steam and Water Collecting on Windshield

A solution suggested by a trade magazine to prevent steam and water collecting on the windshield is as follows: 1 ounce water; 2 ounces glycerine; ½ spoonful of salt. This can be applied by wiping up and down with a cloth saturated in the solution.

INSTRUCTION No. 58

TRAFFIC REGULATIONS: Rules of the Road; Pointers on Driving

STREET, TRAFFIC AND PARKING REGULATIONS

The driver of a car should be careful to observe the rules of the road, for damages are not so likely to be collected, if he can prove that he was where he should have been.

Throughout the United States, **the invariable rule is to keep to the right;** in England it is just the opposite.

The following is a fair example of traffic rules which may vary slightly, but practically represent the ordinances in different large cities.

St. Louis traffic laws and regulations are **cited as an example of ordinances which are substantially similar in all large cities.** Compiled by Mr. J. F. O'Donnell, Atty., under direction of Mr. C. M. Talbert, Director of Streets, St. Louis, Mo.

Definitions

"Vehicle" includes animals that are led, ridden, or driven, and every horse-drawn or motor-driven conveyance except a street car. (Sec. 1294, Rev. Code, 1914.)

"Driver" includes the rider and driver of a horse, the rider of bicycles and motorcycles, and the operator of any other vehicle. (Sec. 1294, R. C. 1914.)

"Congested district" consists of the following described streets, to-wit: (Sec. 1333, R. C. 1914).

"Street" designates every highway and place used by or laid out for the use of vehicles. (Sec. 1294, R. C. 1914.)

"To park" means to stand or store any vehicle on a public highway when it is not being loaded or unloaded. (Sec. 1294, R. C. 1914.)

Authority

Drivers shall at all times promptly obey all reasonable directions of a police officer engaged in directing traffic as to stopping, starting, approaching or departing from any place; the manner of taking up or setting down passengers, and loading or unloading goods in any place. (Sec. 1288, R. C. 1914 amended by Ord. 30174.)

License

State license plates shall be conspicuously displayed and firmly fixed on the front and back of every motor vehicle, except motorcycles and motor tricycles, which shall display a State License Plate permanently fastened to the back only. (State Law, 1917.)

License plates to be kept reasonably clean. (State Law, 1917.)

Lights

Motor vehicles, while on the public highways, whether in operation or otherwise, from a half-hour after sunset to a half-hour before sunrise, and when fog or other atmospheric conditions render the operation of vehicles dangerous to traffic, shall carry at the front at least two lighted lamps, not exceeding 36 candlepower each (except that motorcycles shall carry one lighted lamp), showing white lights visible at least 500 feet ahead and revealing objects 150 feet ahead, adjusted and directed so that on level ground the main shaft of light shall be projected straight forward, no portion of it being above the level of the lamp nor more than 42 inches above the ground. Electric headlights shall, in addition, have their door glasses etched, ground, or so formed that the lighted filament shall appear blurred. (State Law, 1917, and Sec. 1314 R. C. 1914.)

Red light on rear. At all times when lights are required there shall be carried at the rear a lighted lamp exhibiting one red light, plainly visible for 500 feet toward the rear. (State Law, 1917; and Sec. 1315*a*, R. C. 1914.)

Sidelights, or substitutes therefor, may be used with electric bulbs not stronger than 10 candlepower each, provided the condensed light is projected forward and if possible downward below the level of the lamp, and provided the glass openings emitting light are etched or ground as required of headlights. (State Law, 1917; and Sec. 1314*a*, R. C. 1914.) Ground-glass bulbs may be used instead of having glass opening etched, ground, etc.

Spotlights shall not be used on the public streets except in emergencies or when headlights are inadequate owing to rain or fog, and then only providing the shaft of light is directed well downward and at no time into the eyes of other persons. Outside of the city, they may be used if directed well downward and not into the eyes of other persons. (State Law, 1917; and Sec. 1315, R. C. 1914.)

Horsedrawn vehicles from one half-hour after sunset to one half-hour before sunrise during the months from October to March, inclusive, and from one hour after sunset to one hour before sunrise during the months from April to September, inclusive, shall carry at least one light showing white from the front and red from the rear, visible for a distance of at least 300 feet. (Sec. 1308, R. C. 1914.)

Lights and warnings upon extensions shall be placed when any part of the load projects more than five feet beyond the rear of the vehicle. Such extra light or warning must be placed at the extremity of the projection and be visible from both sides and from the rear. (Sec. 1311, R. C. 1914 and penalty; See 1312, R. C. 1914.)

A vehicle being towed shall have separately displayed thereon the lights required on vehicles of the class to which it belongs. (Sec. 1310 and 1312, R. C. 1914.)

Bicycles while on public highways, whether in operation or otherwise, at the times and under the conditions specified for **motor vehicles** shall carry one lighted lamp showing a white light, visible at least 200 feet to the front, and also one red light or one red reflex mirror plainly visible from the rear. (State Law, 1917; and Sec. 1308, R. C. 1914.)

Color of lights: No vehicle shall show any other than a white light to the front and a red light to the rear. (State Law, 1917; and Sec. 1308, R. C. 1914.)

Rules of the Road for Vehicles

How to drive: All vehicles shall be driven in a careful manner, with due regard for the safety of other vehicles and persons (Sec. 1301, R. C. 1914.)

Rights of vehicles: Two vehicles, which are passing each other in opposite directions, shall have the right of way, and no other vehicle to the rear of either of such two vehicles shall pass or attempt to pass such two vehicles. (State Law, 1917.)

Overtaking, meeting and passing: If overtaking another vehicle (except a street car), pass it on its left. (Sec. 1267, R. C. 1914.) In meeting another vehicle, pass it to the right. Keep to the right side of the street. (Secs. 1300 and 1266 R. C. 1914.)

Vehicles to pass other vehicles—how—except street cars: A vehicle overtaking another shall, in passing, keep to the left, and shall not pull over to the right until entirely clear of it, nor shall it leave the line on the right unless there is a clear way of at least one hundred feet in advance on the left. (Sec. 1267, R. C. 1914.)

Right of way: Vehicles in the service of the Police and Fire Departments and United States Mail, underwriters' salvage corps, emergency repair vehicles of public utility companies, and ambulances, when in the course of their regular duty, shall have right-of-way over other vehicles. (Sec. 1278, R. C. 1914.) East and west-bound vehicles shall have right-of-way over north and south-bound vehicles. (Sec. 1280, R. C. 1914.) Excepting where controlled by traffic regulations of a city, the driver of a vehicle approaching an intersection of highways shall yield the right-of-way to a vehicle approaching on his right. (State Law, 1917.)

Stop back of street cars: The driver of every vehicle shall stop at the rear of any street car which has stopped to take on or let off passengers, and shall remain at a standstill until such street car has resumed motion; provided that on streets in the congested district vehicles may pass street cars so stopping if they clear the running board, or lower step by six feet. (Sec. 1283, R. C. 1914.)

Stop back of building line: When so signalled by traffic officer, vehicles shall stop back of the building line, leaving the crossing clear for pedestrians. (Ord. No. 30174.)

Vehicle likely to delay traffic: No one shall drive any vehicle in such condition or so loaded as to be likely to delay traffic, or cause an accident. (Sec. 1285, R. C. 1914.)

Width of vehicle and load: No person shall drive through the streets a vehicle the width of which, with its load, shall exceed ten feet, except on permit from the Director of Streets and Sewers. (Sec. 1287, R. C. 1914.)

Left side to curb not permitted: No vehicle shall stop with its left side to the curb. (Sec. 1289, R. C. 1914.) See special rules for One-Way Streets and Alleys for exception.

Stopping alongside another vehicle not permitted: No vehicle shall stop abreast aonther vehicle lengthwise of a public street except in an emergency. (Sec. 1290, R. C. 1914.)

Slow up on approaching a pedestrian: A driver of a motor vehicle shall slow up on approaching a pedestrian who is on the traveled part of the roadway and signal audibly. (State Law, 1917, see Secs. 1276 and 1277 R. C., 1914.)

Slow up on approaching intersecting highway, curve or corner: The driver of a motor vehicle, on approaching an intersecting highway, curve, or corner, where his view is obstructed, shall slow up so as to stop readily. (State Law, 1917 and see Secs. 1276, 1277, and 1301, R. C. 1914.)

Safety zones: No vehicles shall cross or enter safety zones as designated by the signs. (See Secs. 787 to 789, R. C. 1914.)

Turning: A vehicle wishing to cross from one side of the street to the other in a business district, except in the congested district, shall go to the next intersecting street before making the turn. (See Secs. 1271 and 1272, R. C. 1914, and Sec. 1334 Cong. Dist.)

Vehicles turning into another street to the right shall keep as near the right-hand curb as possible. (Sec. 1269, R. C. 1914.) See special rules for One-Way Streets and Alleys for exception.

Vehicles turning into another street to the left shall turn around the intersection of the center lines of the two streets. (Sec. 1270 R. C. 1914.) See special rules for One-Way Streets and Alleys for exception.

Signals on leaving curb, slowing up, stopping, or turning: The driver shall give an advance signal to those behind by holding out the hand or by some approved signaling device, so as to indicate intention to slow up, stop, or turn. In approaching an intersecting street where other vehicles are approaching, or where a traffic officer is located, the drivers of vehicles shall designate the direction in which they wish to proceed by signals or words. (Secs. 1273 and 1274, R. C. 1914.)

Backing: The driver shall give ample warning to those behind by hand or by some approved signaling device before backing, and constant care shall be exercised to avoid a collision while doing so. (Sec. 1275, R. C. 1914.)

Stop on approach of fire apparatus: The driver of a vehicle, on approach of a fire engine or fire apparatus, shall immediately draw up said vehicle as near as practicable to the right-hand curb, parallel thereto, and bring it to a standstill. Street cars shall immediately stop between intersecting streets and keep stationary on the approach of a fire engine or other fire apparatus. (Secs. 1281 and 1282, R. C. 1914.)

Vehicles to keep near right-hand curb—exceptions: All vehicles shall keep to the right and as near the curb as possible, except when passing vehicles ahead. (Sec. 1266, R. C. 1914.)

Taxicabs and other vehicles regulated by permits shall comply strictly with the provisions set forth in their respective permits. (See Secs. 525 to 554, R. C. 1914.)

No one under 16 years old to drive: No one under sixteen years old shall drive any public, numbered, licensed, or business vehicle on a public highway. (Sec. 1286, R. C. 1914.)

No chauffeur under 18 years old: No certificate of registration of a chauffeur shall be issued to any person under eighteen years old. (State Law, 1917.)

Keep to right drive on divided parkway: On a street divided longitudinally by a parkway, vehicles shall keep to the right of such subdivision. (Sec. 1268 R. C. 1914.)

Vehicles to stop near curb: No vehicle, unless in an emergency, or to allow another vehicle or pedestrian to cross its path, shall stop in any public street or highway, except near the right-hand curb, and so as not to obstruct a crossing, and shall not stop or stand within the intersection of any streets. (Sec. 1292 R. C. 1914.) See Reg. of one-way streets.

Accidents: In case of an accident due to the operation of any vehicle, the driver thereof shall stop and render such assistance as he can, give his name and address to the person injured, or to any other persons who question him, and report the same immediately to the Police. (State Law, 1917.)

Intoxication: No person while under the influence of intoxicating liquor shall drive any kind of vehicle on the public highways. (State Law, 1917.)

Processions: No vehicle shall be driven through a funeral procession except Police, Fire Department, Salvage Corps, emergency repair vehicles of public utility companies, United States mail, and ambulances when on duty. (Sec. 1199, R. C. 1914.)

Obstruction by vehicles and interference with street cars. No vehicle shall so stand on any street as to interrupt or interfere with the passage of street cars or other vehicles. (Sec. 1325, R. C. 1914; see Sec. 1292, R. C. 1914.) This applies particularly to vehicles standing near the corner so as to interfere with street cars rounding curves.

No automobile shall be left unattended with machinery in motion: No automobile shall be left upon any street unattended while any portion of its machinery is in motion. (Sec. 1291, R. C. 1914.)

Vehicles not to obstruct mail boxes: No vehicle shall stand opposite a United States mail box so that convenient access thereto is obstructed. (Sec. 1326, R. C. 1914.)

Length of tow lines: Any vehicle being towed shall be so connected as not to leave more than 12 feet between vehicles.

Glass on street, alley, or driveway: No person, firm, or corporation shall throw or place any glass upon any public street, alley, or driveway. Penalty up to $100 for each offense. (Secs. 1208 and 1209, R. C. 1914.)

Rules of the Road for Pedestrians

Observation of the rules: Pedestrians by observing the rules will facilitate the movement of traffic and minimized danger to themselves. While they have the right to cross the roadway in safety, it is intended, primarily, for vehicular traffic.

Look before stepping from the curb: Look first to the left and then to the right for vehicles.

Use the regular crossing, and cross at right angles and not in the middle of the block or diagonally at intersections.

Stand on sidewalk when waiting for street car until the car approaches.

Obey traffic officer's signals and commands.

Do not cross behind street cars: When alighting from street cars, be sure the way is clear before crossing behind the car.

Congested District

Between the hours of 7 A.M. and 7 P.M. the following regulations shall be enforced in the "Congested District." (Sec. 1330, R. C. 1914 and Sec. 1333.)

Not to park longer than one hour: No vehicle shall remain continuously at the same place in the congested district for a longer period than one hour. Disabled vehicles and vehicles for public hire, operating under proper permit are exempt. (Ord. No. 30405.)

Vehicles for advertising not to stop: Vehicles for display advertising or public inspection shall not stop within the congested district, except on direction of a traffic officer or on approach of fire apparatus, and shall move at not less than three miles per hour. (Sec. 1330, R. C. 1914.)

"No parking" spaces: The Director of Streets and Sewers is authorized to designate spaces on either side of any street where no vehicle shall stand for a longer period than is necessary for the discharge or receipt of passengers or freight, and not longer than fifteen minutes while so engaged. These spaces shall be designated by official signs. It shall be unlawful for any person to place any sign designating any portion of a street as a place at which vehicles shall not be parked except the signs authorized as above. (Sec. 1335, R. C. 1914.)

Entrance to public buildings: No vehicle shall park before any entrance to a building for a longer period than thirty minutes. (Sec. 1331, R. C. 1914.)

Complete turn at intersection prohibited: No vehicle shall make a complete turn so as to face in the opposite direction on any street in the congested district, but such vehicle, in order to turn around, shall be driven around the block. (Sec. 1334, R. C. 1914.) The owner or driver may be a misdemeanant, under this section.

Fire hydrant reservation: No vehicle unattended shall be left standing at any time within 6 feet of a fire hydrant. (Sec. 1330(c) R. C. 1914.)

Speed

Vehicles on the public highways shall be driven in a careful manner and at such speed as not to endanger the safety or injure the property of anyone. (State Law, 1917; Sec. 1301, R. C. 1914.)

Ten feet between vehicles at crossing when pedestrian about to cross: No person in charge of a vehicle shall allow it to come within ten feet of any vehicle in front of him when approaching and passing over a crossing when a pedestrian is about to pass. (Sec. 1276 R. C. 1914.)

Special Rules for One-Way Streets and Alleys

One-way streets have been designated to facilitate the movement of traffic. Vehicles move in the same direction as street cars and on the dead side. Parked vehicles stand on the live side of street cars, leaving space for safety zones. Thus vehicle traffic is not interrupted by stopping while street cars take on and discharge passengers, and the latter are not endangered by moving vehicles. In parking at an angle, autos are required to back in. Thus the top, when down, overhangs the walk, while if headed in, the tops of the larger machines would not clear the street cars.

Sixth Street and Eighth Street between Washington and Market, southbound: Vehicular traffic shall move south on the east side of the street. Waiting vehicles shall stand on the west side, facing south, at an angle of 30 degrees with the curb.

Seventh Street, between Washington and Market and Ninth Street between Washington and Pine, northbound: Vehicular traffic shall move north on the west side of the street. Waiting vehicles shall stand on the east side, facing north at an angle of 30 degrees with the curb.

Vehicles stop with the left to the curb: Since traffic is moving ahead on the left side of the street, vehicles may stop with left side to the left curb, long enough to load or unload, but if intending to park, must take up a position on the right-hand side of the street.

Turning: In turning to the right into a one-way street, the center line of the latter must be passed before making the turn. In turning to the left into a one-way street, the center line of the latter must not be passed before making a turn.

Alleys in business district: In all east-and-west alleys, vehicular traffic shall move west; and in all north-and-south alleys it shall move south.

Signs

"Safety Zones": (Secs. 787 to 789, R. C. 1914.) These signs are placed to designate the space reserved for pedestrians waiting for street cars and through which vehicles must not be driven.

"Congested District" signs are placed at all street corners within the congested district.

"No Parking" signs are furnished and placed by the Department of Streets and Sewers on the curb to designate the ends of the space within which vehicles must not be parked, in accordance with the congested district regulations. (Sec. 1335, R. C. 1914.)

"One-way Traffic Street." These signs are placed at each street corner on a one-way traffic street, designating the direction in which traffic must move.

"In" or "Out" signs are placed at the entrance to one-way alleys in the downtown district, to designate the direction of traffic through the same.

"School Zone" signs are placed on either side of and 100 ft. from school buildings as a warning to drivers to use exceeding care for the protection of children crossing the street.

"Zones of Quiet" signs are placed in the neighborhood of hospitals and similar institutions, where particular care is to be exercised in preventing unnecessary noise. (Secs. 1196–1198, R. C. 1914.)

Pedestrian lines: At certain street crossings in the downtown district, white lines are marked on the roadway pavement, within which pedestrians are expected to stay when crossing the street.

Equipment of Motor Vehicles

Brakes: Adequate brakes must be provided and kept in good working order at all times. (State Law, 1917.)

Warning signals: Every motor vehicle operated on the public highway shall be equipped with a warning device capable of emitting a sound adequate in volume to give warning of the approach of said vehicle. Every person operating a motor vehicle shall sound the warning device whenever necessary, but not at other times. (State Law, 1917; see Secs. 1323 and 1324 R. C. 1914.)

Mufflers shall be attached to the engines of all motor vehicles and shall be of such capacity as to quiet the maximum possible exhaust noise as completely as practicable. (State Law, 1917; and Secs. 1317 to 19, R. C. 1914.)

The muffler cut-out shall be completely closed and disconnected from its operating lever so that it cannot be opened while said vehicle is in motion. No vehicle shall be driven in such a manner as to produce unnecessary noise. (State Law, 1917; and Secs. 1317 to 19, R. C. 1914.)

Locks: Motor vehicles should be provided with good and sufficient locks, installed in a manner that will allow the moving of the car, when necessary, by the Police and Fire Department.

Copies of traffic ordinances similar to these are provided free to motorists in every large city. When touring, one should secure a copy for each large city he enters.

One-way streets are usually those in which street cars run in one direction only. Alleys in business districts are also one-way.

Sec. 1335, under **"Congested District"** above, has been amended. For instance, "No Parking" space, would apply to other than congested districts, if in the judgment of the Director of Streets such spaces are necessary, for the interests of a business firm in loading and unloading freight, etc.

RULES OF THE ROAD AND POINTERS ON DRIVING

The following illustrations show how to make turns, pass other vehicles and street cars, etc.

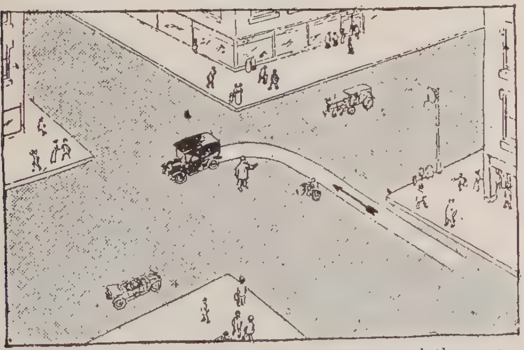

Fig. 1. **When turning to the left,** pass around the center of the intersection of two streets.

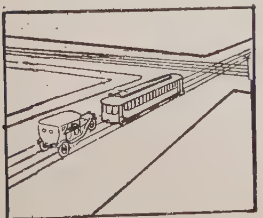

Fig. 2. **Passing a street car on the left** is a violation of the law.

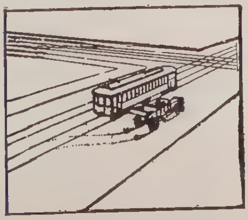

Fig. 3. **The right way to pass a street car is on the right,** and if passengers are getting on or off, stop.

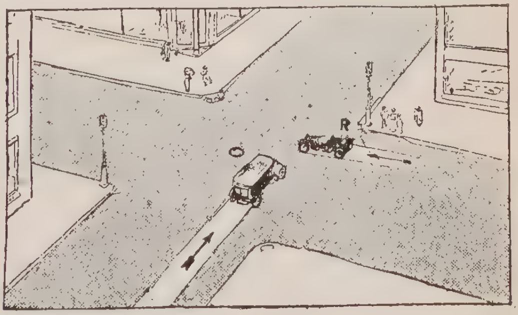

Fig. 4. **When crossing a street,** the right-hand vehicle has the right-of-way.

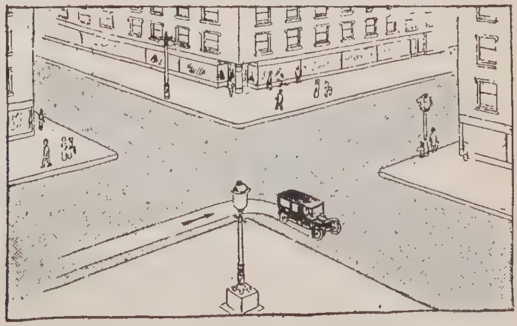

Fig. 5. **When turning to the right,** keep near right-hand curb.

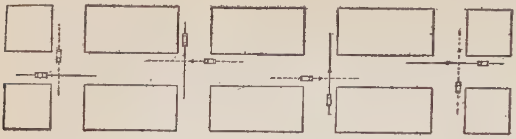

Fig. 6. It is the rule in many cities that **when two vehicles approach a street intersection simultaneously** in the manner illustrated, the vehicle at the right, as indicated by the heavy lines, shall have the right-of-way, regardless of the direction traveled.

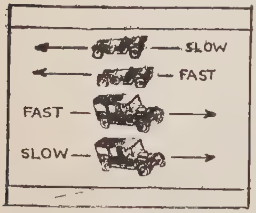

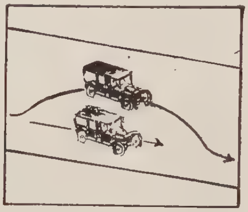

Fig. 7. **Slow-moving vehicles** should keep close to curb.

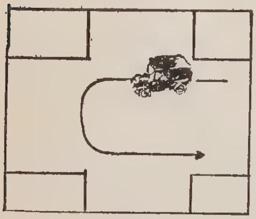
Fig. 8. **One car passing another going in the same direction,** should pass on the left of the car ahead. Do not cut directly in front of the car which you pass.



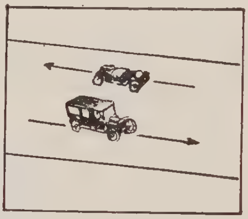


Fig. 9. **When turning,** go to the far corner, then make a wide swing.

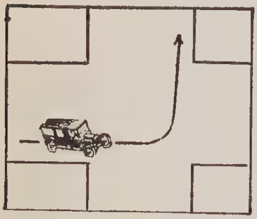
Fig. 10. **Keep** over as near as practicable **to the right-hand curb when driving slowly,** so as to leave the center of the street free and open for faster traffic—the slower the speed, the nearer the curb.



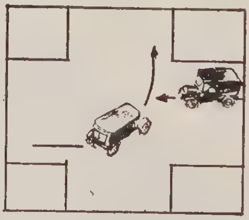


Fig. 11. Clear the center intersection of the street when making a turn.

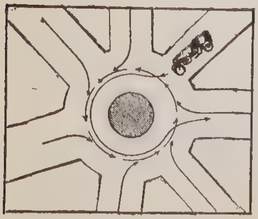
Fig. 12. **In turning corners, with a car coming,** give a signal with your hand to indicate the direction in which you intend to go and as a hint for him to slow up. Always observe a central point in the intersection of streets, and clear it when turning.



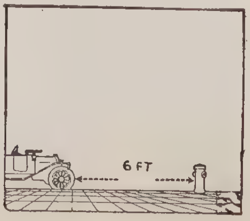


Fig. 13. **Approaching a circle;** arrows point the way in which to enter and leave.

Fig. 14. **Don't park closer than 6 ft. to a fire hydrant.** The distance varies; in some cities 10 and 15 feet is the limit.

Precautions

Approaching railroads: When approaching a railroad crossing, especially if there is an incline or grade, the car should be dropped back into second speed and the approach made carefully, first so that the driver may be in a position to determine whether to make the crossing or not, and second, to be in position to accelerate the car suddenly with very little chance of stalling the engine.

Many accidents have happened because inexperienced drivers have become confused and stalled their engine. On noting the approach of the train, they have thrown on their power, or let in their clutch suddenly, with the result that the egnine is stalled, and it is then too late to move out of danger.

When crossing street-car tracks and climbing out of ruts, skidding can be prevented and accidents avoided, and the life of your tires can be lengthened, if you will learn how to turn your car out of tracks and ruts. Make a sharp turn of your front wheel. Do not allow the wheel to climb along the edge of the rut and finally jump off suddenly, and do not attempt to climb out of these conditions at speed.

Rounding corners at speed: Driving a car around a sharp corner at twenty-five miles an hour does more damage to the tires than do fifteen or twenty-five miles of straight road work. This is an economical reason why one should drive around corners cautiously and slowly. The other reasons are obvious.

Excessive sounding of the horn is proof that the motorist is a novice. No accepted rules exist in regard to the meaning of horn blasts, but it is reasonable to assume that prolonged honking indicates that the car behind is going to pass and desires a clear road.

Headlight Courtesy on the Road and Signals when Stopping, Slowing down, or Turning

You know how very difficult it is to see when you are approaching another machine with glaring headlights. You are simply blinded, and cannot tell whether you are running off the road, are too close to the oncoming machine, or are striking obstructions. It is a peculiarly helpless feeling to be directing a car when confronted by the other fellow's glaring lights in this way.

If your headlights are on and are not equipped with non-glare devices, he is in just the same predicament, however, and the least either of you can do is to dim the headlights while passing. This is a safety factor as well, for it protects each from running into the other, or off the road. In most states a law prohibits the use of glaring headlights.

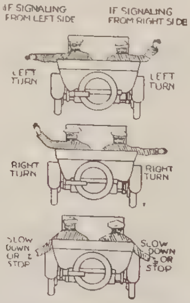

Fig. 15. Signals when turning or stopping.

If you are standing still on the side of a street and intend to start and turn out into the street, signal in the manner shown in Fig. 15, and look before you turn into the street. Many accidents have occurred from a failure to do this.

When you intend to slow down, stop, or turn, signal as suggested in Fig. 15. In many states the law requires closed cars to be equipped with a **stop signal** in the rear of the car, such as a red light which is automatically thrown on when the car slows down, or turns.

Stop Signals

In a number of states there are laws providing that all closed cars shall be equipped with a rear signal device which will indicate to the driver of the car in the rear that the car is going to slow down or stop.

There are a great number of devices on the market for this purpose, one of which deserves special mention, and is called the Neo-Lite. It derives its name from the fact that Neon is used in a glass tube which is subjected to static electricity, thus giving an orange-red glow which can be seen at a great distance.

Neon is an element of the air. When air is split up into its component parts: oxygen, nitrogen, argon, etc., Neon is one of the elements segregated, and it is this Neon that is used in a glass tube shaped like a hand, which is used as a stop signal. Neon is one of the air's rarest gases. There is only 1 cubic inch of Neon in approximately 100,000 cubic inches of air.

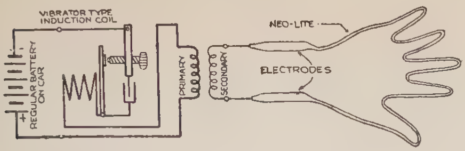

Fig. 16. The Neo-Lite; a stop signal.

An examination of Fig. 16 will show that a small induction or secondary coil is used, something like a vibrator type of spark coil. This is used to intensify the low voltage to a high voltage.

The glass tube (shaped like a hand) is filled with Neon, which has 75 times less resistance than air. For this reason, when connected with the secondary terminals of the coil and contact is closed, the Neon glows, giving an orange-red glow.

The connection for closing the circuit can be attached to the brake pedal, so that when the car is slowed down, the current from the battery is connected. The device is enclosed in a metal case mounted on the fender. Owing to the low resistance offered by Neon, the current consumed is approximately one-eighth less than that of an electric bulb generally used. Experiments have proved that Neon offers so little resistance to the passage of electricity that, where a 15,000-volt current is required in air, a 200-volt current will suffice in pure Neon. In other words, a spark that will jump 1 inch in air will jump 75 inches in pure Neon. The manufacturer of this device is the Federal Signal Co., Albany, N.Y.

Join the A. A. A.

"**A.A.A.**" stands for The American Automobile Association, which is the national organization of motor-car users. It was organized in 1902, and has a membership of over 200,000.

You should join your local club if it is affiliated with the A.A.A.; otherwise join the national body direct.

The A.A.A. is striving for a federal highways system; urging the adoption of uniform traffic laws; advocating federal registration; and mapping the roads of the country.

Members can always obtain exact and detailed information from the national bureaus of the Touring Board in Washington, D.C., and New York City, and also from the local clubs in practically every important city throughout the United States. Address; The American Automobile Association, Albee Bldg., Washington, D.C., or 501 Fifth Ave., New York City, N.Y. Mention Dyke's *Automobile Encylopedia* when writing.

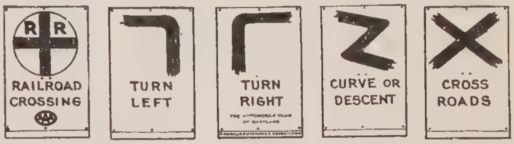

Fig. 17. The A.A.A. international road signs.

INSTRUCTION No. 59

TOURING: Touring Equipment and Pointers

A TRANSCONTINENTAL TOUR—THE LINCOLN HIGHWAY

The following offers full suggestions regarding the equipment necessary and other details incident to a long tour. A short tour, of course, would not require such an elaborate equipment as that suggested below, and it can, of course, be reduced accordingly.

The transcontinental tour is now comparatively easy and decidedly worth while to anyone who can possibly arrange to take it. We use the term "now," because such has not been the case in the past. Until very recently, a trip across the continent has been more or less of an adventure, a somewhat hazardous as well as an expensive and lengthy undertaking, requiring some measure of endurance.

The following is taken from an article which appeared some time ago in the *Motor Age.*

One can drive for nearly 2,000 miles across the country without once being more than half a mile from the familiar red, white and blue Lincoln Highway markers.

The only thing which might make a coast-to-coast automobile trip a hardship would be a lack of proper equipment and perhaps attempting the trip at the wrong time of year.

The greatest asset on a trip of this kind is "common sense." The next greatest asset is "efficient equipment."

The time required for the trip, with easy driving, will be nineteen days, driving approximately ten hours per day. This will make an average of approximately eighteen miles per hour, during the driving time.

Dress: White collars and cuffs are impossible in camp, and soiled linen looks a thousand times worse than a flannel shirt. The khaki and flannel are much more welcome in a hotel.

Make ready before starting—not after. Fit yourself as well as your car.

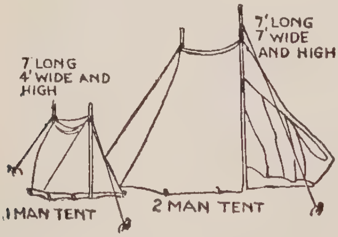

Fig. 1 Fig. 2

The tent: If a one-person affair where two sleep together, it should be a balloon silk tent, 7 x 7 x 7 feet, A-shaped, with waterproof canvas floor sewed in, and loops along the ridge to which to tie the rope when stretched between trees or in using poles. (See Fig. 1.)

The one-person tent (Fig. 1), called the Trego tent, can be A-shaped, 7 feet long, 4 feet high by 4 feet wide, with a ridge rope sewed on and extending about 10 feet beyond each end. Floor, waterproof canvas sewed into the side walls, which hang over slightly.

At the head end is a little window covered with mosquito netting sewed in, and outside of this is a curtain which may be raised and lowered at will from the inside of the tent. At the foot are two flaps, overlapping each other when closed, and equipped with snaps and rings for fastening, either open or closed. Sleep with the flaps and window of your tent open, unless it is storming. A rope loop is attached to each corner for stakes, but, as a rule, the stakes will not be necessary, as the bedding holds down the floor.

This tent may be slung between two trees. If not used in this manner, the ropes at each end should be led over 4-foot stakes of some kind, and the corners of the tent must then be staked down, so that the walls will act as cross-pieces to keep the end poles upright.

This size tent will take blankets folded once over, and all of the extra clothing, etc., can go under the blankets at the head, and serve as a pillow.

The blankets are to be pinned across the foot of the head end, with horse-blanket safety pins, procurable at any harness store, spacing them about 8 inches apart. There should be two pairs of heavy blankets, and one cheap cotton quilt. Fold this last mentioned over once, and place under blankets to serve as a mattress.

Always keep a small whisk broom handy.

Sleep with clothes on, unless the weather is warm; simply remove your shoes, leggings (use only canvas leggings, not leather), hat, and handkerchief.

Camp location: Pitch where natural drainage will carry water off in case of rain. In the forest, cut a lot of small pine branches, no thicker than your finger, and rip-rap these with the stems to the foot, making a pad the full width of your tent, and about a foot thick, before you lie upon it. If there are no trees to furnish this, dig a trench about 3 inches deep by 8 inches wide just where your hip will come when you lie upon your side. This will add wonderfully to your comfort.

It makes no difference how the tent is placed, except that care should be taken not to get the foot or open end toward the wind.

Protection from the wind: Try to get the camp out of the wind, on account of cooking. Alongside of the woods is much better than in them, on account of the mosquitoes, flies, bugs, etc. Get near running water, if possible, although by carrying a 5-gallon milk can on the running board you are independent of this.

Drinking water: Should be selected and carried in a 5-gallon milk can, which can be held in place by a wood circle placed on the running board, and by straps made on the order of a harness. Don't be dependent upon other water—keep a supply on hand.

When stuck in the mud[1]: If the rear wheels are stuck in the mud, dig holes in front of the front wheels for them to fall into, to give the initial start, and, if the car does not continue, then block the rear wheels instantly and repeat the operation. Place brush in front of the rear wheels and turn them as slowly as possible to keep from churning. If one rear wheel is on a good road, try putting on the handbrake fairly tight to destroy the action of the differential, or fasten the mired wheel so that it cannot turn, and the other wheel will do the work and slide the mired wheel along the ground.

The instant you realize you are getting stuck in sand or mud, stop right there and look over the situation, instead of fighting the car and burying it deeper and deeper.

Start early and stop before dark to select the camp site.

Use the windshield to keep the hot, dry air from burning your face, and have the top up all of the time for like protection.

Get all of your guide books before you start.

In asking directions, always apply to a garage or livery stable, but do not depend upon farmers, as their knowledge of the road does not extend very far.

In a party of four, let one do the cooking, another gather firewood, another put up the tents, and the fourth go over the car with oil can, turning up all grease cups, adjusting brakes, etc.

The Car Kitchen

This outfit is designed for four people and weighs about 10 pounds. All items marked* may be purchased at Von Lengerke & Antoine, Chicago, or Abercrombie & Fitch Co., New York, and the unmarked items may be obtained at almost any store dealing in such goods.

1 Arizona camp grate, 24″ by 12″.*

1 set pot hooks.*

1 aluminum folding baker, 8″ x 18″.*

1 canvas case for baker.*

The following Armorsteel pieces of cooking outfit may all be purchased of the firms mentioned above:

1 frying pan, 9⅞″ wide, with patent handle.

1 cooking pot, 9⅜″ wide.

---

[1] Pull-U-Out Sales Co., 2024 Market St., St. Louis, Mo., manufacture a device suitable for this purpose, see Index.

1 cooking pot, 8⅛″ wide.
1 cooking pot, 7¼″ wide.
1 coffee pot, 6⅜″ wide.
4 soup bowls, 4⅜″ wide.
5 cups, 4″ wide.

Don't use aluminum cups.

6 plates, 8¾″ wide.
4 forks, with four prongs, 7¼″ long.
4 knives, 8¾″ long.
6 teaspoons.
2 cooking spoons.
1 carving knife, 10¼″ long.
1 sharpening stone.
1 set tin lids for the pots and frying pan.
1 pancake turner, 3″ by 4½″.
1 3-prong cooking fork.
1 collapsible wash basin, 12″ by 3″.*
1 camper's carbide lamp (Abercrombie & Fitch Co. No. 3A937; be careful to read the instructions).
1 lb. carbide for lamp.*
2 canvas duffle bags, 10″ by 24″ (use for food only).*
1 doz. food bags, 9″ by 9″.*
2 food bags, 9″ x 14″.*
1 agateware milk can with tight lid—2-quart. Use for stewed fruit only.
2 patent egg carriers.
1 tin bread pan, 10″ by 4″. Use also for washing dishes.
1 Inspirator, for camp fire (2 feet of small rubber hose, one end of which is slipped over one end of a 3″ piece of copper tubing, and the other end of this tubing is flattened to make a slit about 1/32″ opening). This is a wonderfully handy thing for getting a balky fire going.

Read matter under head of "The Car Kitchen" above. The Prentiss Wabers Stove Co., 34 Spring St., Grand Rapids, Mich., manufactures camp stoves. Marshall Field Co., Chicago, supply complete camping outfits.

Car Equipment

This equipment is suitable for a transcontinental trip or for a shorter one:

2 extra tires mounted on demountable rims.
2 extra tires with tubes, covers on them.
4 extra tubes in bags, under rear seat.
5 gallons good water.
60 ft. 5/16″ flexible steel cable.[1]
1 medium-size shovel, strapped to running board.
2 gallons engine oil, in 1-gallon cans. Under front seat.
1 set Weed chains, heavy type.
6 extra cross-chains.
1 set spring chain tighteners.
1 set regular tools for car.
1 car jack.
1 pair good cutting pliers.
1 piece hardwood 1½″ by 4 ft. by 10″.
1 2-quart canteen. Buy west of Missouri River.
1 blow-out patch for casing.
3 extra spark plugs.
8 ft. high-tension wire.
8 ft. low-tension wire.
1 extra valve and spring complete.
1 medium-sized axe. Strap to running board.
1 small can LePage's glue, for mending camera, etc.
1 hose, upper radiator connection.
1 hose, lower radiator connection.
1 canvas folding bucket for water; 9″ by 12″.
1 can cup grease; under front seat, and so packed that it cannot upset when melted.
1 set extra electric lamp bulbs.
1 set extra fuses for electrical system.
2 packages small, cheap towels, for wiping machinery, etc.; one dozen in each package.
150 feet ¼″ best Manila rope, for packing, etc.

Personal Equipment

When on a camping motor trip, the first thing of importance is common sense. The second is proper equipment.

Now for the list. This is the minimum for a long trip, and, of course, may be added to according to the tastes and ideas of the individual, but more is entirely unnecessary and should be avoided, if possible.

1 pair tan shoes, light-weight. Don't wear new shoes.
3 pairs light cotton lisle socks.
1 pair canvas puttees, light-weight. Don't wear leather.*
2 pairs khaki riding breeches, laced below the knee. Don't wear corduroy.*
2 pairs light wool drawers.
2 light-weight wool shirts to match above.
2 pairs B. V. D. under suits.
2 U.S. Army officers' brown shirts with patch pockets. These are twice as warm as $2.50 flannel shirts, and are practically wind-proof.*
1 light-weight khaki coat, to wear in towns.*
1 heavy mackinaw coat with shawl collar, for driving when it is cold at high altitudes, and by the camp fire.*
1 pair light-weight gauntlets, for driving.
1 pair old street gloves, for wear around camp.
1 khaki hat with narrow brim. Cut ½″ ventilating holes on each side.*
2 blue and white bandanna handkerchiefs. Tie up snug to your neck, and don't wear loose like the pictures of cowboys.
6 pocket handkerchiefs.
1 pair light-weight moccasins, for wear around camp and to sleep in.*
1 toothbrush.
1 hair comb.
1 pocket knife, three blades and strong.
1 pocket compass.*
1 safety razor and two extra blades.
1 can shaving powder.
1 shaving brush.
1 mirror, small.
1 Ingersoll watch, with fob.
1 pair yellow goggles; don't forget these.
1 pair white goggles.
1 tube toothpaste.
1 package bachelor buttons.
1 pair scissors, small.
1 set needles and thread.
1 pair manicure scissors; don't forget these; hangnails are a great source of trouble on long trips.
1 narrow leather belt.
1 stick camphor ice; much better than any form of cold cream and very handy in package. Use it only at night unless riding in the shade of the top, as the hot sun will blister the lips on account of the beads of moisture acting as lenses on the lips after using the camphor ice.
2 doz. cathartic tablets.
1 package gauze.
3 rolls gauze bandages, 2″ wide.
1 tube vaseline, for burns, guns, etc.
2 pairs 5-lb. wool double blankets.
1 cotton quilt.
1 tent (Trego sleeping tent). Purchase at Von Lengerke & Antoine, Chicago.
1 camera.
12 rolls film for camera.
1 Welcome photographic exposure record. This is a red book bought at any photo supply store.
1 small whisk broom, for use in tent, etc.
1 silk sleeping cap, to pull down over the ears.
2 coarse towels.
2 pipes, if you are a smoker, and plenty of your favorite tobacco.

* Items marked (*) may be purchased at Von Lengerke & Antoine, Chicago, or Abercrombie & Fitch Co., New York.

What to Cook and How

Bacon: This is the standby of all camping parties and is really the best meat to carry, as it keeps well and is easy to cook. It should be placed on bread and eaten as a sandwich; thus you will not miss butter. Fresh meat should be attempted only by the expert cook. There is a science in cooking bacon, and but few people seem to catch the idea. I will try to make it as clear as possible.

---

[1] A good auto tow line (flexible wire) is manufactured by A. Leschen & Sons Rope Co., St. Louis, Mo. It is called "Hercules Wire Rope Towing Line," and is 25 ft. long between end fittings.

In the first place, do not buy the sliced bacon under any circumstances. Buy the bacon in the slab, as lean as possible, and of the very best quality. Buy one full slab at a time as you go along, and cut this into three pieces to go into one of the larger food bags. Now, when slicing the bacon before each meal, cut the slices at least 3/16″ to ¼″ thick. Bacon which is sliced thin cannot possibly be fried properly, as it will curl up in spite of you and burn one end while the other end is raw.

Cutting the bacon: After cutting the slices down to the rind, cut this off by passing the knife under the slices horizontally, with the slab lying flat. Lay the slices in the frying pan, putting in as many as may be required. regardless of whether they rest on top of each other or not. Set the pan on the grate, and, after the grease begins to form, tilt the pan this way and that, so that the grease flows all through the slices. Watch it carefully, and turn the slices frequently with your fork. In the meantime, have a plate warming on one corner of the grate, and as the slices become fairly brown on both sides, pick them out with the fork and pile them up as closely as possible on this plate. As soon as all are done, cover the plate with another, and set where it will be kept warm. This will keep the slices moist with the heat and grease left in them, and they will not become brittle and dry. The remaining grease in the pan can now be poured into one of the cups for future use, or for that meal, for **frying eggs,** etc. Eggs fried with bacon grease have a fine flavor.

It is astonishing how **few cooks know how to cook rice** so that the grains will be soft, and yet stand apart and separate. Boiled rice is a great dish for camp, if properly cooked, but is miserable stuff if cooked into a thick paste.

Take next to the largest pot and fill it about three-quarters full of cold water, and add about one half-teaspoon of salt; then put in three-quarters of a cup of rice and put on the lid, placing the pot over the fire on the grate where it will get a good heat to boil. The rice should boil for about 30 minutes, and, if desired, it may be tested by gathering a little in the spoon and chewing it, to see that the grains are soft. Stir frequently, and scrape the bottom of the pot with the spoon.

After the rice is done, take the pot to one side of the camp and pour off all the water you can by holding the lid in place and turning the pot almost upside-down. Now set it to one side with the lid on until needed, and the rice will steam so that the grains will stand apart. You will find this a delicious dish, which should be served with evaporated milk and sugar, or with a sauce of fruit juice. Cook a fresh lot for each time served, and do not try to save it for the next meal. If you have too much rice for the quantity of water, it will produce a mixture like glue, and is poor stuff to eat.

Fifteen-minute bread: Most campers will shy at making bread, but really it is very simple and is made in about 15 minutes. The patent baker is a marvel, and will brown the loaf equally on top and bottom, no matter how the wind blows. A special kind of fire is required to bake bread, so do not attempt it at the regular cooking fire.

To build the correct fire[1], drive two stakes in the ground about 2 inches apart, and 2 feet from there drive in two more likewise. Between the vertical stakes, lay a wall of sticks about 1″ to 1½″ thick, preferably green sticks, and against this wall set a lot of fire stuff which will burn rapidly and make a high flame with little smoke. You must have a high flame. This should be kept going brightly until the bread is done. (See Fig. 4.)

Test the bread by piercing the loaf with a sliver of wood. If no dough sticks to the sliver, then the bread is done. Of course, it should be fairly brown on top before testing. Leave the pan in the baker and remove from the fire, setting to one side where it will receive a little heat from the regular fire to keep warm. The aluminum baker will retain the heat for quite a while.

Carry whole wheat flour only, and in the larger food bag. Of this take one and one-half cups and put it into the bread pan for mixing. Add to this one and one-half heaping teaspoonfuls of baking powder, one level teaspoon of salt, three teaspoons of sugar, and one and one-half cups of water. Stir gently until thoroughly mixed, but do not beat. Warm the baking pan, and then grease it all over the bottom and around the sides and corners with a strip of bacon rind. Then pour in the batter you have made, and place the pan in the patent baker. Set this before the baking fire quite close, say one to two feet. It will begin to rise immediately, and will bake into a loaf about one to one-half inches thick, which will be just right for four hungry people. This bread is great, and will stick to your ribs on the long hike. It is so much better than baker's bread, and very little trouble after you once get the hang of it.

Dessert à la tour: You will find that stewed fruit is far ahead of the canned goods, and much better food. In the food list you will notice that peaches, prunes, and apricots are specified, dried. These will all be mixed together and used that way. The flavor is much better than when used separately.

Fill your 2-quart milk can about one-third full of this dried fruit, and then fill up with cold water, adding three tablespoons of sugar the day before you start, and then at the first night stop, place the can on the grate over the fire and allow to simmer, first loosening up the lid to let the steam escape. After serving the fruit, you can put in more fruit, add more water and sugar, and carry it with you to the next stop, repeating the simmering process. In this manner the mixture will become quite syrupy and of fine flavor. About every three days empty the can and wash out with hot water, beginning over again as you did in the first place.

The breakfast drink: Use 3 teaspoons of ground coffee to one cup of cold water in the coffee pot. Set on the fire until it comes to a boil; then pour one half-cup of cold water over the top, going round and round, and a little down the spout. Set the pot aside until served, and then pour carefully and slowly, and the coffee will be clear. No egg or anything of that sort is needed to make clear coffee. If the coffee food bag is tied tightly, it will keep in the ground state all right, so do not carry it in the can in which it is sold.

Tea: If tea is used immediately, pour boiling water over the tea leaves and let stand for a few moments only. If it stands very long with the leaves in the pot, it will make a mixture which will absolutely tan the lining of your stomach. If the tea is to be kept for any length of time, put the tea leaves in a piece of cheesecloth, and tie with a bit of string, fishing this out of the pot after the tea has soaked for a moment in the boiling water. Shake out the cloth and put away for the next time. If the cloth is used, you can save the tea for a long time, and serve cold, if desired. This is often handy for the late hunter in camp, if side hunting trips are made away from the car.

The army ration: Erbswurst (pea sausage in English), powdered pea meal, and bacon. This is a very palatable and nourishing food, and is used extensively as the perfect army food by the nations of Europe. It is sold in round packages about 1″ in diameter and 4″ long. Each package is marked in six divisions, one of which is to be used for each cup of water. Boil for 20 minutes. It is already seasoned.

Pancakes are very nice for a change, and should be served with maple syrup, as one craves sweets when living out of doors. Buy the syrup in small cans. For the cakes, buy self-rising buckwheat flour and mix with cold water, with possibly an egg added for richness, until the batter is quite thin and will run readily from the spoon. Rub the frying pan with grass or a rag thoroughly, to smooth its surface; then grease with a strip of bacon rind and pour in a large spoonful of batter at a time, while the pan is piping hot. The pan will hold three cakes of this size at a time. Cut them apart with the pancake turner as soon as you can, and loosen them from the frying pan by slipping the turner under the cake without lifting it. As soon as you can handle them on the turner, flop them over to brown on the other side. If the batter is not thin enough, the cakes will be tough and heavy.

Potatoes are really a necessary article of food on a long trip lasting several weeks, and should be served about once each day, if convenient. Peel the potatoes, and then boil them in the largest pot for about twenty minutes if you are going to fry them, and forty minutes if they are to be served boiled only.

In high altitudes, the boiling process will require much longer, as the water boils at lower temperature. "All that bubbles does not boil" in the high mountains.

To fry the potatoes, first boil them as directed above, and then cut into slices about ¼″ thick. Pour about 1/16″ of the bacon grease into the frying pan, covering it evenly. Heat this on the fire until it sizzles and put in the potatoes. Take a knife and immediately chop the potatoes into small pieces and put on the cover. Stir and turn over frequently with the knife and test them for softness with its point. When nice and soft they are ready to serve, and the bacon grease will give them the desired browning. The bacon grease has a much better flavor than lard.

Canned goods: These are good for a change, where they can be conveniently carried, but are not at all necessary. In all cases of vegetables and soups, simply pour the contents of the can into one of your pots and heat it over the fire. Do not forget to stir it to keep the mixture from sticking to the bottom of the pot.

Water: Be very careful of the water you drink, especially west of the Missouri River. If there is a white deposit around the edge of the lake or pond from which you wish to get the water, it is alkaline and will make you very sick. Fill your big milk can with good water in the towns, and then drink that instead of taking a chance on water found by the roadside. Animals can drink alkali water without harm, whereas it would seriously affect a human being.

This 5-gallon supply of water will be used for all purposes, as it will be required only for the radiator in case of accident. Fill the radiator when you fill the gasoline tank, and you will have all you need.

---

[1] See Figs. 3 and 4 for building a "cooking fire" and "camp fire."

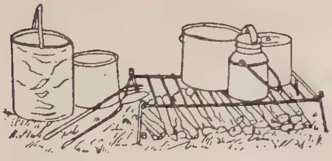

Fig 3.

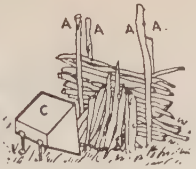

Fig 4.

Fig. 3. Explains the method of making a cooking fire as described. Note the iron rods (B) and iron frame with crossrods.

Fig. 4. Explains the method for building a baking fire, which must be high. Note that the sticks (A) are of green material, whereas the burning material is dry. (C) is the patented baker, made of aluminum.

Cooking fire: This fire is to be built under the grate the four legs of which have been driven into the ground until the grate is about 8″ high. Build this fire of small sticks, from the size of your finger to 1″ diameter, no larger. Have this fire at some distance from the cars and from the main camp fire, and on the lee side of both. The sticks should not be over 14″ long. The smaller the fire, the easier to keep the heat down, so that the cook is not roasted as well as the food. You may build the fire the full length of the grate if you wish, but keep it down. Do not attempt to cook at the camp fire, for the smoke and heat will make it a martyr's job. Fig. 3 shows the proper method.

A baking fire: Build this away from the other two, as shown in Fig 4.

Camp fire: Do not build this near the cars, and be sure to have it on the lee side of them on account of possible sparks. Build a moderate-sized fire only, so that you can gather closely around it and converse easily. "Injun build little fire and sit up close—white man build big fire and sit away off." Build yours the Indian style. Be sure to put out all fires with your shovel before breaking camp. The western forestry laws are very strict about this.

Packing: Packing the outfit on the car is quite important, and it should be standardized at the start, and then everything always should go back in the same place. Much time may be saved if this is carried out, as each member of the party becomes familiar with the location of each item, and the car will be loaded in an astonishingly short time.

Method of stowing is as follows:

Cooking grate—under floor mat in tonneau.
Large water can—right running board forward.
Extra tires not on rims—left running board forward.
2 tent beds—on end, each side of back of front seat. Tie to robe rail.
Cooking utensils—between these beds in tonneau.
1 tent bed—right running board; strapped on.
1 tent bed—left running board; strapped on.
Shovel—left running board behind tires.
Axe—tonneau floor; just back of beds.
Food bag—tonneau floor; passengers can rest feet on it.
Patent baker—hanging where it will not be crushed.

The cooking utensils all go into a canvas bag which is sold with them, and the outfit is very compact.

Food List

2 slabs best bacon—lean.
5 lbs. whole wheat flour.
5 lbs. sugar.
1 lb. salt.
2 lbs. best baking powder.
2 cans maple syrup, small cans
1 can pepper, small.
8 lbs. ground coffee.
12 cans evaporated milk, unsweetened.
1 roll surgeon's plaster 1″ wide—for sealing cans, etc.
5 lbs. dried fruit—apricots, peaches, prunes, in equal portions.
1 lb. tea.
1 can cocoa.
1 lb. self-rising buckwheat flour.
3 lbs. rice.
2 cans tomatoes.
2 cans corn.
2 boxes graham crackers.
4 quarts potatoes.
12 packages Erbswurst.
2 doz. eggs in patent carriers.
2 boxes bouillon cubes.

Some of the Concerns Who Make Camping Equipments

Marshall Field Co., Chicago, camping refrigerators, lunch equipment, tents and complete camping outfits.
Cozy Camp and Auto Trailer Co., Indianapolis, Ind.
Auto-Kamp Equipment Co., Saginaw, Mich.
Ideal Mfg. Co., North Kansas City, Mo., folding shovel.
Peoria Auto Kot Co., Peoria, Ill.
Boyle Mfg. Co., 5101 Santa Fe Ave., Los Angeles, Cal., camp grates, canteens, etc., for touring.

Touring Tents, etc.

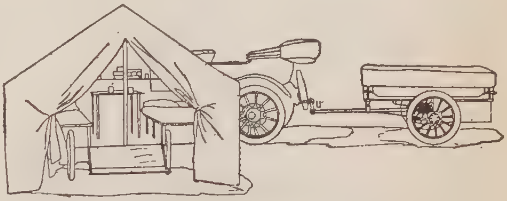

Fig. 7 Fig. 6

Fig. 6. Pictures a new idea of camping. A trailer (Fig. 6) is carried with you, and it is claimed that it will travel 50 miles an hour along with the car. The tent and all parts are placed into this trailer.

Fig. 7. Shows the tent when removed from the trailer, and the trailer used as the floor. The tail gate of the trailer is utilized for a step. This outfit is made by the Auto-Kamp Equipment Co., Saginaw, Mich. Another good outfit is made by the Tentobed Co., 3300 Jackson Blvd., Chicago, Ill.

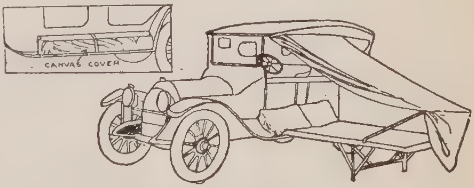

Fig. 8. Shows another principle. Note the compact form of the outfit (shown in the upper corner) when placed in a box on the running board and covered with canvas.

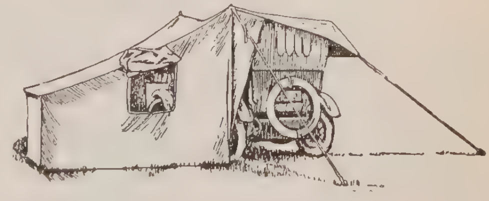

Fig. 9. Another outfit: The tent has a floor 8 feet square, which is sewed in. An extension of about 2 feet on the front edge of the floor can be fastened over the running board of the car. The front wall of the tent is 7 feet high and extends over the top of the car, when the tent is pitched in this way, or it may be used as a straight front for the closed tent when the car is not attached.

The illustration, Fig. 9, shows the arrangement of the tent in relation to the motor car. The tent can be used also without being attached to the car.

Two 7-foot poles prevent undue strain on the car top. The poles are cut with slip joints to be of proper 4-foot length to carry on the running board. The side walls have extensions of about 10 inches on the front edges to fasten to convenient places about the car, making a tightly closed tent in case of storm or cold wind. One side wall has a window, and the other has a door.

The rear wall is about 3½ feet high, and is kept at a convenient height by its location near a fence, tree or other object to which ropes could be attached.

The tent is made of khaki at a cost of $18. Folding camp cots are used. The use of heavy blankets on the tent floor during cool weather is preferred to the cots. The tent is adapted to an Overland by a 6-inch flap sewed to the front wall to make sure of protection for the car. The size given is suitable for a car having a 7½ or 8-ft. top.

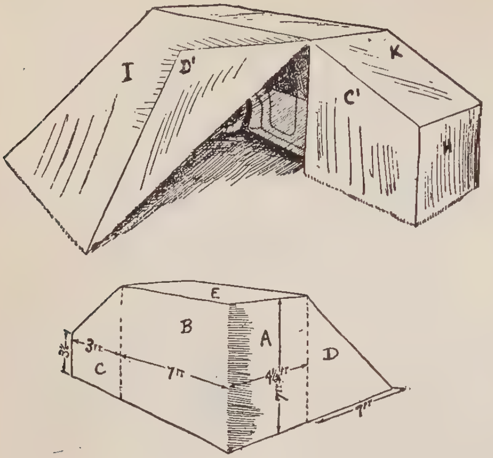

Fig. 10. A serviceable tent for touring. Use 8 oz. duck which comes in 36″ widths and can be purchased at 20c. per yard.

Dimensions of tent in square feet: (A) 4½′ x 7′=31½′; (B) 7′ x 7′=49′; (C) 3′ x 5¼′=15¾′; (C1) 3′ x 5¼′=15¾′; (D) 7′ x 3½′=24½′; (D1) 7′ x 3½′=24½′; (E) 4½′ x 7′=31½′; (H) 4½′ x 3½′=15¾′; (I) 7′ x 10′=70′; (K) 4½′ x 4½′=20¼′; total 298½ sq. ft. or approximately 33¼ yds. at 20c. per yard, making $6.65. (*Motor Age.*)

Note: Symbols expressive of feet (′) and inches (″).

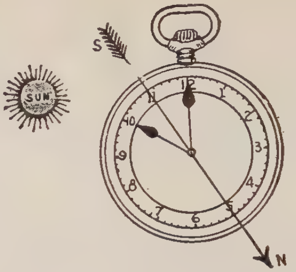

Fig. 11. **To use your watch as a compass:** Point the hour hand of your watch to the sun at any time of the day; then lay the watch flat in your hand. A point midway between the hour hand and 12 on the dial will be due south.

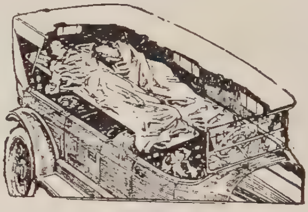

Fig. 12. **The Auto-Kot** is a very serviceable and compact adjustable cot which can be placed on the top of the rear seat, and the front seat of a 5 or 7-passenger car. It can be folded in a very compact form and placed back of the front seats. (Peoria Auto-Kot Co., Peoria, Ill.)

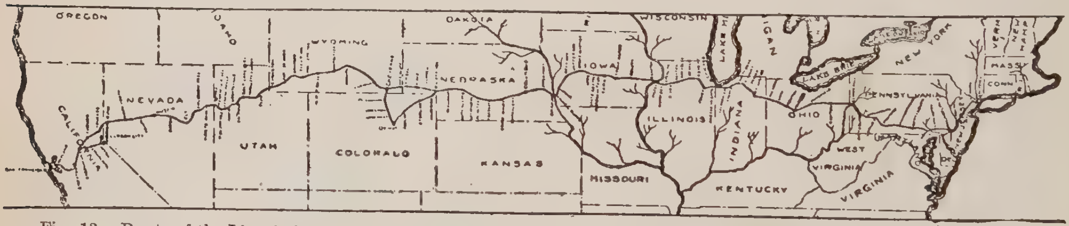

Fig. 13. Route of the **Lincoln Highway.** Further information can be had from Lincoln Highway Association, Detroit.

THE AUTOMOBILE BLUE BOOK, A TOURING GUIDE

These books cover the entire country in **four volumes.** They assist in planning a tour, show detailed running directions, road conditions, points of scenic and historic interest, city maps, and many other details of interest to a tourist.

Volume 1: New York and New England Automobile Blue Book. Complete touring data on New York State, Connecticut, Massachusetts, New Hampshire, Rhode Island, Vermont, Maine, Quebec, Ontario, and the Maritime Provinces of Canada, with extension routes into New Jersey, Pennsylvania, and Ohio.

Volume 2: Middle Atlantic and Southeastern Automobile Blue Book. Complete touring data on Pennsylvania, New Jersey, Maryland, District of Columbia, Virginia, West Virginia, Tennessee, North Carolina, South Carolina, Mississippi, Alabama, Georgia, Florida, and Eastern Louisiana, with extension routes into New York, Ohio, Kentucky, and from Tennessee to Detroit and Chicago.

Volume 3: Middle Western Automobile Blue Book. Complete touring data on Michigan, Ohio, Kentucky, Indiana, Illinois, Missouri, Wisconsin, and Minnesota, with extension routes into New York State, Pennsylvania, West Virginia, and the West, including Port Arthur and Winnipeg.

Volume 4: Western and Transcontinental Automobile Blue Book. Complete touring data on Western United States and Canada, and including main trunk lines to the Atlantic Coast for long-distance and transcontinental travel.

The price of each volume is $3.00. The address of the publishers is: Automobile Blue Books, Inc., 1056 W. Van Buren St., Chicago, Ill.

INSTRUCTION No. 60

THE AUTOMOBILE REPAIRMAN: Pointers for the Beginners; Starting in the Repair Business; Light Tool Equipment for the Auto Mechanician

POINTERS FOR THE BEGINNER

The auto repairman must know how to adjust any part of the car. To know how to adjust, he must first know the principles underlying the construction of the parts, as explained in previous Instructions, and must know when and where to look for trouble. (See Index under "Digest of Troubles.")

About one-half of the work of the automobile repairman is in making adjustments and fitting parts, such as carburetor adjustments, cleaning carbon, grinding valves, fitting horns, muffler cut-outs, diagnosing troubles, and numerous other little details, which do not require a machine shop, but do require a good assortment of tools, and a knowledge of the principles involved in the construction of a car.

A machine shop is not necessary, unless there is sufficient work to keep more than one machinist busy. A great number of small repair shops put in only the tools needed for the average repair work, and when they have a job of machine work to do, they take it to a machine shop. In other words, a machinist and an auto repairman follow two different trades. The auto repairman need not be a machinist; by machinist I mean one who can turn all kinds of metal parts on a lathe and do actual machine work.

System and Order

When beginning work on a car or engine, remember that system and order are two things every repairman ought to learn early. They mean success.

Fig. 1. Don't throw nuts or bolts on the floor. Place them in a box or pan.

There is nothing more disgusting to a man who owns a car, than to walk into a repair shop and find a careless workman dumping nuts, bolts, etc., here and there on the floor. That customer will say to himself: "If that workman is as careless as that, he is careless enough to leave a nut in my crank case and ruin my engine when it is started up, or he will leave off lock nuts or lock washers and cause me expense and damage."

A little piece of metal, such as a piece of a cotter pin or the like, accidentally dropped into a can of grease or oil and subsequently put into the gear case of a motor car has been known to cause much damage, and to cause the driver or owner of the car considerable trouble and expense.

A Careful Workman the One in Demand

If you do your work thoroughly and carefully and always do a little more than you agree to do, you will be sure to make a success.

It's the careful man the auto owner wants to handle his car, not the fellow he can't depend upon.

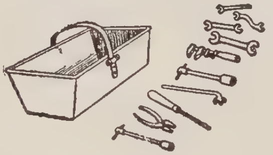

Fig. 2

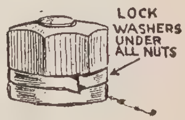

Fig. 3

Fig. 2. Keep your tools in a box or kit, not on the floor.

Fig. 3. Before turning a car over to the customer, be sure that all nuts have lock washers and are tight.

I will give you an example of a careless young man who lost his job. An auto owner had a young man overhauling his car; he told him to fill all the grease cups, and to be sure to see if the valve under the gasoline tank was tight; he had an idea it was leaking. He went away, and when he came back that afternoon he asked the young man if he had attended to the different things he told him to do. He said yes. Next day the auto owner was out on a country road and ran out of gasoline. He found that the young man had not examined the valve carefully, and the leak had exhausted the tank—the valve was in a difficult place to get at under the car, so he simply took it for granted that it was all right and let it go at that. So you see a careless man is worse than none at all—it's the dependable fellow who will win.

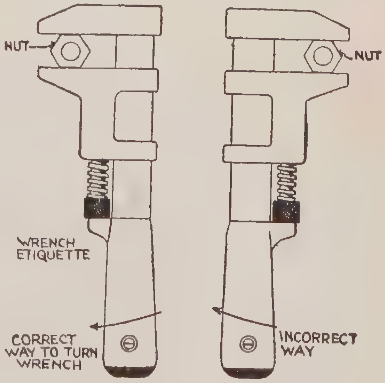

Fig. 4. Monkey-wrench etiquette. When using a monkey wrench or a Stillson wrench, use it as shown above. Most all nuts and bolts turn to the right to tighten and to the left to loosen. The proper method of using a wrench for the desired turn is shown above.

Don't Overcharge

We want to warn you that in the matter of charges, it pays to be liberal. Automobile repairmen, like plumbers, generally have a reputation for exorbitant charges. Make it a rule to do a little more than you agree to. It is well to comment on your work, in talking with the auto owner, like this: "I noticed that some of the nuts were loose around the springs, so I went over all the nuts on the running gear and found that many needed attention. You want to watch those little things, and then you won't need me so often." The owner may not say anything out loud, but he will certainly comment to himself, "There's a good repairman," and that is the most profitable reputation you can establish.

You are building a business for the future when you do your work right, and treat your customers fairly.

Don'ts for the Repairman

1. Don't lay wrenches, hammers, chisels, etc., on the fenders or on the seat cushions. Cover the fenders, and remove the cushions during the work.
2. Don't spill oil, or smear grease over the finish or upholstery.
3. Don't try to squeeze one car past another in the shop, even though the fenders will spring enough to let the car pass.
4. Don't pound the end of a shaft with a bare hammer. Use a babbitt hammer, or deaden the blow with a piece of brass or wood.
5. Don't push a car around the shop with greasy hands on the varnished surfaces. Either wipe your hands, or place a piece of dry waste between your hands and the car.
6. Don't leave a car standing in a pool of grease.
7. Don't use an 18″ Stillson on a ⅜″ nut.
8. Don't sit on the cushions with your greasy overalls. Spread a newspaper over them first, and don't put your greasy hands on doors, body, hood, etc.
9. Don't use the customer's gasoline just because its handier than to get some from the storeroom.

Starting in the Auto Repair Business

We will classify the automobile repair work into two classes: first, will be the automobile repairman who works in a shop under a foreman. His work is laid out for him and he is advised just what to do.

The second, is the automobile mechanician whom we will class as an expert; he will generally be found in the position of a foreman, or operating his own shop. We also find him doing work at the homes of automobile owners.

For the sake of classification and names to distinguish this latter class of work, suppose we call the "auto mechanician" the one who makes a specialty of doing work at the home of automobile owners, in the auto owner's private garage.

The Auto Mechanician—How to Start

Many men have found this work profitable and it has been the stepping-stone for a future. This work also applies to marine engine and stationary gasoline engine work.

In order to engage successfully in this work, it is necessary for the mechanician to provide himself with the necessary tools to do the average work around a car.

It is probably safe to say that nine cars out of ten need greasing; that is, the gears, the differential, the wheels, and the universal joints. This job is one that does not appeal to the auto owner, and the chances are that he is not prepared to grease his car if he wanted to. It is easy enough to put grease in the compression cups and screw them down, but to grease the rear axle parts and universal joints is a different job unless one is supplied with the proper tool. The auto repairman with the Townsend grease gun, as shown in Fig. 9, can do the job quickly and easily.

Then there are the valves to grind, carbon to clean out, lost motion in the valves to take up, compression to test—in fact, a general engine overhaul or a general car overhaul would constitute the work that the auto mechanician could do on these special jobs.

Very likely when the auto mechanician goes to an auto owner's garage to do repair work he will be provided with most material, such as oil, grease, waste, etc., but it is advisable to suggest a good oil and to request that the car be supplied with it, providing the oil in use causes a great deal of carbon. In other words, it will be necessary for the mechanician to be able to diagnose all troubles and suggest their remedy, as well as to make adjustment and overhaul the car.

The Auto Mechanician's Outfit

This is shown in Fig. 5, and is a suitable equipment for general work around a car, testing, etc.

The average workman carries more tools than are necessary to the job, and often finds that even then he does not have the right one. A careful study of the cars handled usually shows that twelve of the common tools will serve to do the ordinary job. It has been found that the following tools are most essential, and are adequate for most jobs: 4 open-end wrenches, Nos. 34, 25, 29, 734; 1 monkey wrench; 1 main-bearing wrench; 1 connecting-rod wrench; 1 screwdriver; 1 pair pliers; 1 valve cap wrench.

Repairman's Tool Kit

A well-assorted tool kit is shown in Fig. 5 Other tools and suggestions are illustrated below.

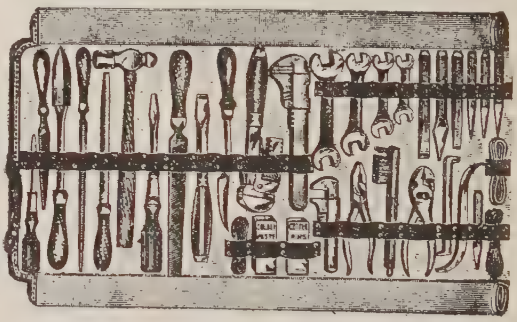

Fig. 5

6⅞″ drop-forged hardened wrench.
5⅞″ drop-forged hardened wrench.
4⅞″ drop-forged hardened wrench.
4″ drop-forged hardened wrench.
4½″ warding file with handle.
8″ square file with handle.
8″ flat file with handle.
7″ round file with handle.
5″ square shank screwdriver, polished.
Machinists' all-steel heavy screwdriver.
½-pound soldering iron with handle.
6″ side-cutting pliers.
6″ adjustable combination pliers, nickeled.
Machinists' bearing scraper.
9″ auto monkey wrench.
10″ Stillson wrench.
8-oz. machinists' hammer.
⅜″ cotter-pin extractor, polished.
⅜″ center punch.
½″ cold chisel.
Box solder paste.
Box cotter pins.
6″ offset screwdriver.
Spark-plug brush.
⅜″ cold chisel.
Bundle wire solder.
Bundle No. 15 copper wire.
Bundle No. 20 copper wire.
5″ bicycle wrench, nickeled.
½″ cape chisel.
⅜″ solid punch, 3/32″ point.
⅜″ solid punch, 3/16″ point.
⅜″ solid punch, ¼″ point.
3″ electricians' screwdriver.

The Vlchek Tool Co., Cleveland, Ohio, manufactures a complete line of tool kits.

A Trouble-Man's Repair Kit

The set shown in Figs. 6 and 7 is not designed for shop use, but for outside trouble calls. A leather-bound ¼ or ½-size suitcase (A) is fitted with four wooden trays made of 3/16″ hard maple. The thickness of the top piece (B) depends upon the

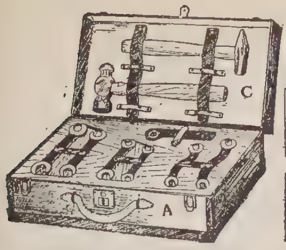

Fig. 6

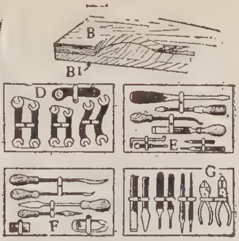

Fig. 7

size of the tools. Outlines are drawn on the wood with pencil and the wood is cut entirely away to permit tools to lie flush. The bottom piece (B1) is then glued on and fastened by wire brads. Buttons holding tools in place are made of sheet brass. General arrangement: hammers strapped in cover (C); wrenches in top tray (D); screwdrivers and punches in tray (E); bearing scrapers, oil stone, Prussian blue, tray (F); chisels, files, pliers, tray (G). (*Motor World.*)

Miscellaneous Light Tool Equipment

Such tools and devices as socket wrenches, large monkey wrench, a grease gun, oil guns, carbon scrapers, etc., are necessary. Electric testing instruments are shown elsewhere. The Weston instrument is shown below. See Instruction 63 for list of small tools for the repair shop.

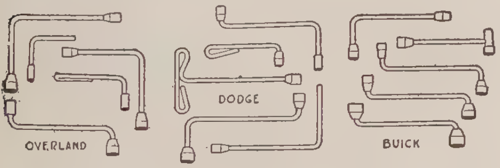

Fig. 8. Walden socket wrenches come in sets for various cars and are accurately made to fit the nuts on each car.

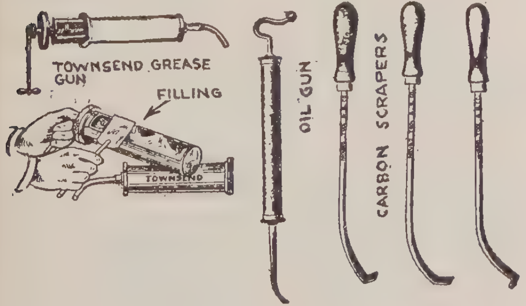

Fig. 9. A good grease gun is very essential. The Townsend grease gun can be obtained of the Townsend Co., Orange, N.J. An oil gun for general use is necessary. Carbon scrapers are shown at the right.

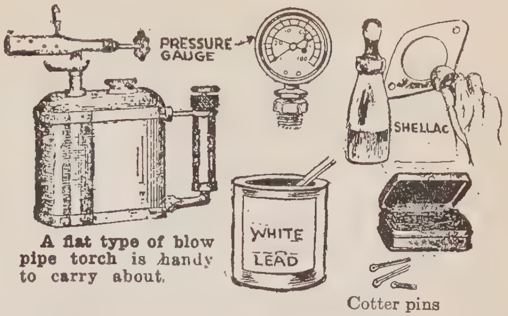
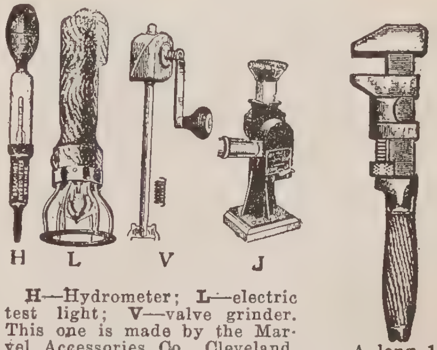


A flat type of blow pipe torch is handy to carry about.

Fig. 10. Miscellaneous tools and accessories are always needed.



H—Hydrometer; L—electric test light; V—valve grinder. This one is made by the Marvel Accessories Co., Cleveland, Ohio. J—jack.

A long 18 or 21 inch monkey wrench

Fig. 11. A hydrometer for testing storage batteries; a trouble light and a good jack are essential as is also a large 18 or 21-inch monkey wrench for removing hub caps, etc. See Index under "Magnet light" for an ideal trouble light.

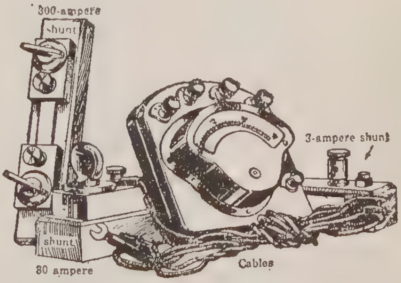


Fig. 12. An electric testing instrument is very necessary as 8 per cent of troubles are electrical. The instrument shown is the Weston model "280." Micrometers and a thickness gauge are also required.

A CAR OVERHAUL AT HOME GARAGES

The following enumerated list gives a detail of procedure in giving a car a general overhauling. Where the automobile owner keeps his car at home and cares for it himself, nine chances out of ten his car and engine need cleaning or greasing, the valves ground, or carbon removed. All of the work mentioned below can be done in the auto owner's private garage. This work then would require but a few well-selected tools, and the auto owner is likely to have most of them. Supplies such as oil, waste, etc., would be furnished by the auto owner. This class of work is well suited for the beginner or auto mechanician.

Cleaning the Engine

1. Clean the engine outside with gasoline.
2. Clean the engine inside.
3. Clean the drip pan.
4. Clean and pack the pumps.
5. Clean and adjust the spark plugs.
6. Clean the gasoline strainer.

Lubricating the Engine

7. Put fresh oil into the engine after cleaning.
8. Oil other parts of the engine, such as magneto, starter, generator, fan, etc.
9. Screw down on all grease cups, and refill.

Cleaning the Car

10. Wash the car (see Index under "Care of a car").
11. Polish the body with body polish.
12. Clean the clutch.
13. Clean the transmission and underneath the car.
14. Clean the steering device.

Lubricating the Car

15. Screw down all grease cups, and refill.
16. Grease the clutch shaft.
17. Grease the universal joints.
18. Fill the transmission with lubricants.
19. Fill the differential housing.
20. Grease the steering device.
21. Grease the front wheels.
22. Lubricate the springs.

Inspection and Adjustment

23. Inspect all bolts and nuts, and tighten. This will require a day's time, if properly attended to.
24. Inspect the gasoline line, and tighten all joints.
25. Inspect the balls of the front wheels when greasing to see if there are any broken balls. Jack the wheel, and listen for a clicking sound.
26. Inspect and tighten all loose water connections.
27. Inspect the tires and see if they are properly inflated.
28. Inspect the steering device and connections, and tighten and grease.
29. Inspect the springs and fenders and nuts, and tighten, and remove squeaks.
30. Inspect the rear wheels; see if loose; if so, draw up on the nut.
31. Inspect the differential; if noisy, take up lost motion.
32. Examine the brakes. If loose, adjust them, and also tighten spring bolts, nuts, and spring clips.

Inspection of Engine and Parts

33. Inspect the water hose on the engine, and replace with new hose if required.
34. Inspect the gaskets on the engine, and draw up on the cylinder head.
35. Inspect the bolts and nuts holding the cylinder to the crank case, and tighten.
36. Inspect all nuts, and tighten on the crank case.
37. Inspect the generator adjustment, and draw up nuts.
38. Inspect the nuts holding the exhaust and inlet manifold, and tighten.
39. Inspect for air leaks at the carburetor, manifolds, and spark plugs. If there is a leak, the engine will not idle properly.
40. Inspect all nuts and cotter pins, and tighten.
41. See that lock washers are under all nuts.
42. Inspect the muffler and clean if necessary, and tighten up.
43. Inspect the timer or magneto, and see if connections thereto are tight.
44. Inspect horn, magneto, switch, generator, starter and battery, and coil connections. See if there are any loose binding posts or connections. Don't forget to tighten all ground connections.
45. Inspect the battery. See if all terminals are tight.
46. Inspect and test the storage battery with a hydrometer.
47. Inspect the starting motor and generator to see if there are loose connections.

Engine Adjusting

48. Test the compression.
49. Clean carbon from the cylinders.
50. Grind valves.
51. Adjust valve clearance.
52. Test for weak exhaust springs.
53. Test the engine for knocks.
54. Take up on any loose bearings.
55. Fit piston rings, if necessary.
56. Check up the valve timing.
57. Clean and adjust the spark plug gaps.

Note. These subjects, as well as how to make adjustments and rep[illegible] are fully treated farther on.

INSTRUCTION No. 61

THE GARAGE: Building and Equipping

Many, after starting in a small way, soon earn enough to start up a shop of their own. We will now lay out a procedure for starting a shop or garage.

A garage is a place where cars are stored and cared for. Most garages also have shops in connection.

If only a shop for repairing automobiles is planned, then figure on enough room to take care of at least four or five cars while working on them.

A repair shop without the garage is profitable, and can be started for much less capital. If the repairman is just starting out and his capital is limited, the best plan is, of course, to start in a small way.

The question to decide is whether you intend to do strictly repair work, or to store cars and repair, and also whether you will conduct an agency for some car, and carry supplies.

Garage

A garage is termed a place for storing cars, but is subdivided into departments: storing, salesroom, auto-supply department, and repair shop.

The garage equipment consists of suitable space for the number of cars you intend to store, bearing in mind that the space devoted thereto should be utilized to the best advantage. For instance, cars which are used frequently and regularly should occupy that space where exit is easy, usually nearest the exit. The wash rack should be in a convenient location, and the garage supplies, such as oil and gasoline, should be where convenient, yet not interfere with the space occupied by the cars.

The salesroom, office, and stockroom should all be carefully planned. The stockroom quite often is utilized for small tools and accessories, but it is better to display the accessories in some sort of showcase or shelves in a space in the salesroom.

Repair Shop

The repair shop can be subdivided into departments as follows: machine shop, tire repair, welding room, electrical apparatus and testing department. The testing department should be a space allotted for the purpose of diagnosing the troubles, before actual work is begun. See also page 691.

The electrical repairs constitute recharging batteries, work on the electrical apparatus, etc.

By maintaining a system of departments in this manner, the parts belonging thereto are easily located, work is turned out quicker, and a higher degree of efficiency is maintained.

An extensive line of repair work can be carried on in even a small garage, and the sale of extras and sundries will add materially to the income.

LAYOUT FOR A GARAGE AND FOR SHOP BUILDINGS

Successful garage operation is largely a question of systematic economy. This holds true for smaller garages even more than large ones, and therefore such an establishment requires great care in its layout, construction, and subsequent operation. The more thought that is concentrated upon the system to be followed, once the building and equipment are ready for starting business, the fewer mistakes will be made and the greater will be the profit derived from the undertaking.

A Nine-Car Garage and Shop

The type of a small country garage, as described in Fig. 1, is designed for the storage and general care of nine automobiles. Besides the space necessary for garage work, the building contains a well-equipped repair shop and an office, which also serves as a reception room.

In the repair shop a limited supply of parts and supplies is kept, the latter being provided for the accommodation of the garage patrons. The supply stock consists of the most important accessories, tires, tubes, and ignition sundries, etc.

This garage is designed with a view to economy. It is a one-story brick building, 60 by 40 feet, with the longer side toward the street; the interior height is 14 feet from floor to roof, and the latter is carried on trusses 40 ft. long and spaced 8 ft. apart.

A skylight (L) 10 feet wide and 50 feet long with windows illuminates the garage during daytime.

Near the middle of the street side (1), 15 feet from one end, is located the main door, which is 10 feet wide. Entering through this door a row of four automobiles is arranged at the right, while at the left is the entrance to the garage office. Adjacent to the office door a board 3 by 3 feet is hung on the wall, on which checking forms, which constitute a part of the garage system, are kept.

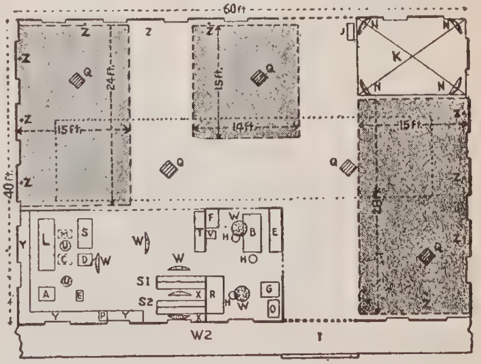

Fig. 1. Floor plan of the garage, showing location of departments, skylight, and arrangement of tools and lamps.

The office is 10 feet wide and 15 feet deep, and besides the entrance mentioned, has one door leading into the repair shop and another into the garage proper, which has a floor space of 1,275 square feet.

The space filled by automobiles is shown by shading, and there is enough room to accommodate nine cars of 124 inches wheel base and standard tread. The space between the dotted portions illustrate the passageway for automobiles driving to or from their assigned positions in the garage. From the garage proper a 10-foot door leads into the back yard, and adjacent to this door the wash rack and charging outfit are located.

The wash rack is formed by a rectangle deepening toward its center (K), whence a pipe for the flushing water leads to the sewer, or other drainage system. The water is supplied either through the medium of the ready-made car washer, or through one which can be readily made from ¾" standard pipe, a stuffing box, four elbows, and about 12 feet of ¾" water hose, at a cost of less than $8.00. The method of assembling the parts is shown elsewhere (see Index under "Wash racks").

The repair shop in this small 9-car capacity garage is but 24 feet long and 15 feet deep, and, besides the door connecting it with the office, has a sliding door between it and the garage proper. This door is sufficiently wide to permit of an automobile being passed through it into the shop, which also contains a small stock of raw material and repair parts stored in shelves (S1) and (S2), and a tool shelf (T). (*Motor Age.*)

A Fifteen-Car Garage

An arrangement and equipment of a garage and repair shop suitable for a town of 3,000 population with good transient and country trade is shown in Fig. 2. The size of the building is 50 by 120 feet, one-story brick or cement block, with the repair shop 40 by 50 feet at the rear.

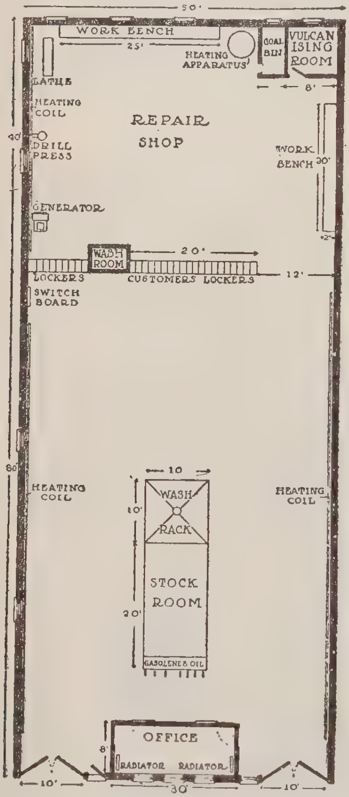

Fig. 2 shows a garage which would suit the requirements stated, beside being convenient and cheaply maintained. It allows of cars entering at one side and leaving at the other, thus avoiding any congestion in getting in and out. Gasoline and oil are handy to the street, beside being under the direct scrutiny of the office.

Posts should be barred and the roof supported by trusses, making the working space much more valuable and saving many accidents to lamps, fenders, and varnish. Heat is supplied by a hot-water apparatus located in the repair shop. It is of the overhead supply type—that is, the supply veins extend from the boiler at the ceiling height, and branches drop down to the coils and radiators and return just above or under the floor. Steam could be used, but the boiler would have to be sunk considerably in a pit before this could be used at all successfully.

A small gasoline-electric generator-set with a suitable switchboard is suggested for electric charging and running the lathe and drill-press, in case the local service is not direct current. Sky or other kinds of roof lights are a necessity if the garage is on an inside lot, and are desirable in any case to make things cheerful and airy and attractive to transients who use it.

Average space to allow for storage of cars: 7 feet is the usual width. The length varies from 13 to 18 feet, according to length of cars stored. (*Motor Age.*)

Another Fifteen-Car Garage

A one-story building for a garage, salesroom, accessory store and shop: The plan is shown in Figs. 3 and 4. The size of the lot is 60 x 100 feet. The building is erected so that another story can be added.

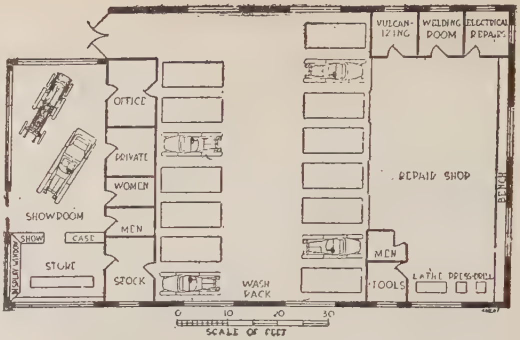

Fig. 3. Plan view. The cars in front, near the shop doors, should be the ones which are away from the garage the most.

The entrance to the garage is exposed so that light can be obtained from two sides into the showroom. Thus the building has practically all the advantages of being on a corner.

There is a small accessory store divided off from the showroom by showcases and an arch, a stockroom, private and general offices, rooms for men and women, garage space for fifteen cars, wash rack, and a shop big enough for five or more cars, and equipped with vulcanizing, welding, and electrical rooms. (*Motor World*, by Harold F. Blanchard.)

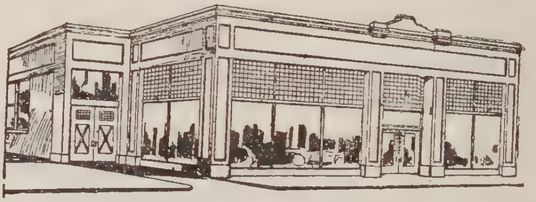

Fig. 4. Front view. Note that the driveway to the garage gives the showroom a corner appearance, and light.

A Twenty-Eight-Car Garage

A one-story corner building with alternative plans for garage, salesroom, accessory store, offices, toilets, garage and shop is shown in Figs. 5 and 6. Size of the plot is 66 x 112 feet.

There are two designs: Fig. 6 is probably the preferable one, considering all the conditions, but Fig. 5 is the one to use in case a front entrance to the garage is considered essential.

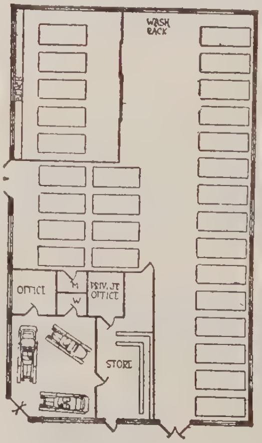

Fig. 5

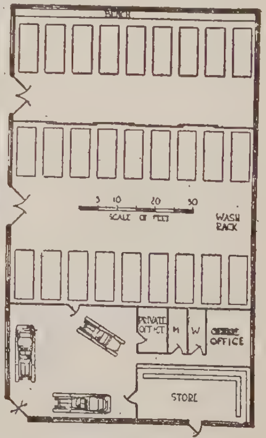

Fig. 6

Fig. 5. Complete establishment located on a corner and with a front entrance.

Fig. 6. Complete establishment, with no front entrance.

The objection to the front entrance is that it restricts the frontage so that the display space for the showroom and accessory store is rather small; but with the entrance on the side, full advantage of the front may be taken. And inasmuch as it may be considered as valuable advertising space, it is essential to use all of it for display purposes. The question to decide is whether the advantage of having the whole front for display more than offsets the disadvantage of having the entrance to the garage on the side street. Even if the garage trade is the most important part of your business, and evidently it is not, the side entrance is not very objectionable, provided there is a large sign at the front stating that the garage entrance is on the side street.

Fig. 5 has capacity for only five cars in the repair shop. Entrance to the garage is from both streets, but when the demand for space is strong, the last cars in at night may be placed in the side entrance-way.

Fig. 6, which has no front entrance for cars, not only is a more attractive building to look at, but also the layout of garage and repair shop is more convenient.

As far as storage capacity is concerned, there is little to choose, Fig. 5 having room for twenty-eight cars, including five in the shop, and Fig. 6 having space for one less, including nine in the shop. The shop in Fig. 5 may readily be enlarged if desired, by lengthening it. (*Motor World.*)

Steam Heating a Garage

The usual plan is to heat by steam, or hot water. The method of assembling the pipes or coils is illustrated in Fig. 8. For garages of larger capacity there would be more coils and a larger boiler.

As an example we will give the dimensions for a garage 48 x 62: It is assumed that it is heated by a steam-heating system working at a pressure of 5 lb. gauge, and for this an ordinary low-pressure steam boiler, such as is used in heating houses is appropriate. (See Fig. 7 for a suggested plan.)

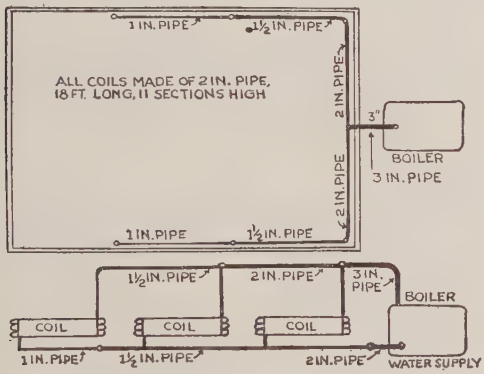

Fig. 7. Steam-heating system for garage 48 x 62. The heating coils are made of steel pipe 2 in. in diameter.

If you intend to place the boiler outside of the garage, you do not want to overlook the fact that it should be suitably housed, so that no heat will be wasted in warming the open atmosphere.

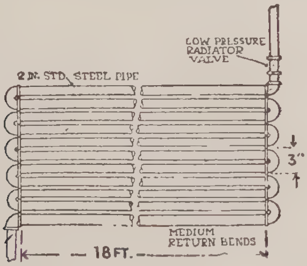

Fig. 8. The boiler must be set so that the water line will be below the level of the lowest radiator or coil, and so that the condensation will drain from the coils back to the boiler by gravity. If this is not done, the heating system will be very inefficient, as you will have to heat cold water up to the steaming point, instead of being able to reclaim some of the heated water. It is best to submit plans to a steam-heating specialist when installing a heating plant.

Lighting the Garage

Lighting the garage: This is a matter of providing the proper electric lights located to the best advantage. The local electrician is posted on this subject.

Artificial illumination of the garage proper is supplied by five 100-watt Mazda lamps, equipped with 12″ steel diffusers with white enamel finish (Fig. 9).

Special lighting provision is made for washing the cars; there are four 25-watt Mazda lamps located at the corners of the wash rack (N) (Fig. 1, page 665), and these lamps are held in Holophane D'Olier steel reflectors, directing the light to the lower part of the automobile being washed.

The repair shop requires even more elaborate lighting facilities than the garage space. It is therefore equipped with five 60-watt lamps and two 25-watt lamps, all of which are of the Mazda (tungsten) type. Three 60-watt bulbs (W), fitted with Holophane D'Olier steel reflectors (Fig. 9), and dropped from the ceiling to illuminate any part of the car being worked on, while two 25-watt lamps (W1) shown in the shaded circles (Fig. 1, page 665), are fitted with the same sort of reflector and are so located as to be useful in seeking parts stored on the stock shelves (S1).

Two 60-watt lamps (U) with Holophane intensive glass reflectors are dropped above the lathe, planer, and drill press, to shed a concentrated light on the work.

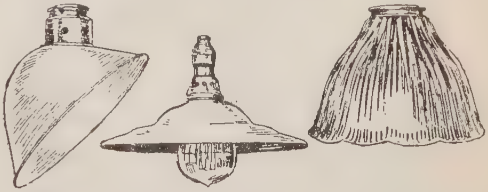

Fig. 9. Three types of reflectors for lighting a garage: Holophane type of D'Olier steel type; 12″ diffuser; Intense type, D'Olier.

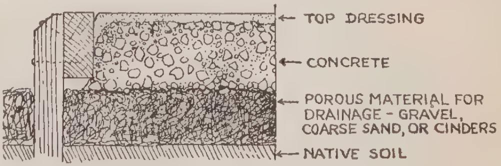
Building a Garage Floor

Cement concrete is the acknowledged material par excellence for the garage floor.

Wood is condemned as being short-lived and usually out of repair. Boards placed as close to the ground as is usual with garage floors rot in a short time. They also tend to warp both transversely and longitudinally by reason of the under sides being damp and the top dry; thus they pull loose from the under-pinning on account of the timber rattling and failing to hold the nails.

Wood blocks make a good pavement, but, unless creosoted, are also short-lived, and the creosote is said to be injurious to rubber.



TOP DRESSING
CONCRETE
POROUS MATERIAL FOR DRAINAGE - GRAVEL, COARSE SAND, OR CINDERS
NATIVE SOIL

Fig. 10. Detail of construction

Before starting a concrete floor it is well to study the situation as regards water pipes and drains. If there is any filling to be done, the nature of the soil must be considered.

It is not safe to lay concrete over clay that has been filled, as the floor will surely settle. Gravel will immediately settle to a solid bed, as will sand if wet down sufficiently to wash it into any crevices that may exist under it. Clay is quite different from sand and gravel, though sandy clay is not quite as bad as gumbo or any of the more sticky clays.

If clay must be used, it should be placed when as dry as possible. After it is laid, it should be soaked with water until virtually soft and incapable of supporting a person's weight. When it has dried, it will be as dense as it can be made without process of time, and will have settled from 10 to 24 per cent of its original height.

The drainage of the floor should also be considered before the work actually begins; a puddle of water on the floor after a heavy rain is never desirable

Sometimes it is convenient to give the whole floor a slight pitch in one direction—towards the side, front, or back. The best method, however, appears to involve making the center the highest point. In a long garage, 50 ft. by 100 ft., this high point would be a line 75 ft. long through the center; from this line the floor should fall off towards the walls at the rate of about one inch to 10 ft. The lowest point may be close to the wall, or it may be four or five feet from the wall, so as to come under the row of cars. Along this low line a tile must be laid below the floor with drains, protected by cast-iron grills entering it every 10 to 14 ft.

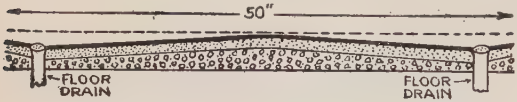


Fig. 11. Cross-section of the floor of a 50-ft. garage.

If the foundation soil is such that it becomes soft with moisture, it should be sloped slightly toward the drain tile, in the same way as the floor, so that no water can collect under the floor. When this is done, the bed material of cinders, coarse sand, or gravel is spread and tamped thoroughly to within three or four inches of the finished floor.

Strips of 2 by 4 are usually used as grounds; they are spaced 6 to 8 ft. apart, and are held in place by stakes and cross-divisions placed the same distance apart as the grounds, forming square blocks. When the filling is started every alternate space is filled; then the cross-pieces are taken out and the remaining spaces filled.

The proportions of cement and gravel for the base of a concrete floor are as follows:

Good quality bank gravel: 1 part cement; 5 parts bank gravel.

Washed gravel or crushed stone: 1 part cement; 2½ parts torpedo sand; 5 parts 1″ gravel.

The proportions for the top dressing are as follows:

1 part cement; 1½ to 2½ parts torpedo sand.

Fill the forms with the base mixture to within ½″ to ¾″ of the top. Tamp well and finish with the top dressing, smoothing and striking off with a perfect straightedge. Never let the base dry out before the top dressing is added, or they are liable to separate and the top to scale off.

After striking off, the dressing should stand an hour or so for the excess water to settle before troweling is started. A wooden trowel is best for use in evening up; then after an hour or more the steel trowel may be used, if a smoother job is desired. Some desire the rougher surface given by the wood float, but there is little chance of cars skidding inside the garage, and the smoother surface is more easily kept clean.

Sometimes, instead of the fine cement top dressing, asphaltic compositions are applied. They make a less harsh and less crumbly surface, but eventually get soft from the constant applications of oil. (*Motor Age.*)

THE GARAGE OFFICE

The illustration shown in Fig. 1, page 665, will be used as an example of a garage office, which is also equipped as a reception room, which contains a desk, table, chairs, safe, and couch. The office is lighted by two 40-watt Mazda lamps with 12-inch diffusers. The price of the office furniture and safe is about $100.

Pointers on Office Work

The system designed to take care of all the business of this garage is exceedingly simple. To carry it out, **only three forms are required:** a monthly checking sheet, a monthly supply sales sheet, and a repair card. In addition to these forms an ordinary ledger is used, in which each customer is given a page on which all his charges and credits are entered.

While it is very important to operate the office in a systematic manner, about seven out of ten neglect this part of the business.

Checking Sheet, Sales Sheet, and Repair Sheet[1]

There are very many different methods for keeping records, books, etc., for automobile garage and repairwork. The *Motor World* of New York supplies books for this purpose. A simplified system of checking sheets, etc., is explained below.

The checking sheet (Fig. 12) is 3 feet high by 11 inches wide, with nine 1-inch-wide columns, allowing sufficient space for checking one car in and out every day of the month. Thirty-one horizontal lines are ruled one inch apart and the dates are printed under the heading "Date." Thus one square inch of space is provided for car "out" and "in." The checking times are entered by the day workman, who spends his time keeping garage and cars in shape. After the end of the month the sheet is filed for future reference.

4—30	8	Havoline	1 gal.

Fig. 13

Fig. 12. Monthly checking sheet for cars housed in garage.

Fig. 13. Monthly supply sales sheet kept with checking sheet.

Gasoline, oil, and other supplies bought by garage patrons are noted on the supply sales sheet (Fig. 13). If this sheet is made as large as the checking sheet, it will last a full month. On the last day of the month the sheet is taken off its board, the sales are entered on the car owner's pages in the ledger, and the stock records corrected in accordance with the sales record. Then the monthly bills are sent to the patrons. Where materials of any kind are sold to any but regular patrons, the price and the notation "Paid" is entered on the sales sheet instead of the number of the car.

---

[1] The "Motor World" simplified system of accounting: A simple method of keeping accurate records of what you pay out and take in, telling how much you made or lost on each department, and showing you how much you received, how much the stock and labor cost, how much your customers owe you, the amount of your overhead expenses, etc. 800 pp., 11½ x 15 ins., leather index, heavy duck leather corners. Price $15. Can be secured of A.L. Dyke, Granite Bldg., St. Louis, Mo.

Date:........................

Fig. 14. Practical repair card, combining repair order, material requisition, and time card of workman.

For the handling of repairs the repair card (Fig. 14) is designed. These cards are used in series and are numbered consecutively. They consist of three portions with perforations between. The middle portion is filled out when a car is brought in to be repaired, the name of the owner, number of the car, and date of the order being written on the blank. Then follow the specifications of the work to be done. The card is then attached to the automobile, and accompanies it to the repair shop.

The upper portion of the card is now used as a time card, the name of the workman and his starting and stopping times being entered upon it. As the work progresses the man checks every item of the work, and finally enters his total working time on the card. If it be necessary to draw upon the repair parts stock or buy material from outside, the lower portion of the repair card is used as a requisition, upon which the needed material is entered. If it is not in stock, and has to be bought, an order is made out after the requisition. In every case the cost of the repair part is entered on the requisition, which is O.K.'d by the owner before an order is sent out. The repair work being completed, a charge covering time and materials of the repair is made out from the parts of the repair card and entered on the ledger page of the car owner. Thus when the monthly bill is made out all charges against a patron come up at once.

Motor World Systems

Fig. 15. **Repairman's Check Sheet.** When quoting prices on repair work, it is advisable to keep a statement of work necessary, marking after each item the cost. Keep the original with the owner's signature, and give a copy to him.

When the repair card is no longer needed it is filed away under its number, the file being kept, with the ledger, in the safe of the office. This makes a very compact system, all parts of which are accessible to the owner of the garage at a minute's notice, thus enabling him to keep his operations on a high plane of efficiency.

Extra equipment: Include here the tools left in his car; then there can be no dispute. Put them in the stockroom. This plan can be elaborated upon. (The check sheet shown [Fig. 15] is an example of *Motor World* system.)

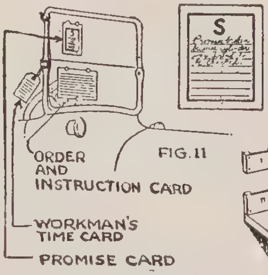

Fig. 16

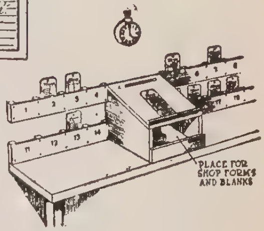

PLACE FOR SHOP FORMS AND BLANKS

Fig. 17

Fig. 16. **A visible promise-recording system** is shown. When the car reaches the repair-shop floor, the work to be done is noted from the instruction card, and the job is promised to be done at a certain time. This promise is recorded by means of a heavy-bordered card, pasted to the windshield and having the initial letter of the day of the promise printed at the top center. For example, if the car is promised for Saturday, a card having the letter "S" is used; if Monday, the letter "M." The foreman can then instantly see what must be got out each day, and what promises are broken, and why.

Fig. 17. **A foreman's desk:** System is essential in the repair shop, but because it is system it does not necessarily mean an elaborate equipment. An old packing box may be made into a foreman's desk, and a few strips of wood and tin may be used to construct a workmen's time and work-card filing rack. The blank cards are always available, and clean. Any of the workmen's cards may be seen at a glance, and are in order. A clock should be hung near at hand, so that the men will not have to guess at the time. (*Motor World.*)

Garage and Repair-Shop Prices for Storage and Repairs

The prices below are not standard but are about as near standard as can be compiled. Note the difference in prices to those who purchase gas, oil, and grease from the company, and who are regular customers and transients.

Per Month—(Regular Customer)

Roadsters, small, list under $1,400	$15.00
Roadsters, large, list over 1,400	20.00
Tour. cars, small, list under 1,400	17.50
Tour. cars, 5-pass., list over 1,400	20.00
Tour. cars, 7-pass., list over 1,400	25.00
Coupes and enclosed cars	25.00
Limousine	30.00

Electric—(Regular)

Runabouts	$30.00
Coupes, victorias, etc.	35.00
Cars with Edison equipment extra	5.00

Transient

Wash, polish, and storage, first night	$2.00
Wash, polish, and storage, each additional night	1.50
Storage only, per night	1.00

Dead Storage

One-third regular rate	Per month
Separate body storage, per month	$5.00

Repairs per Hour

Day labor, according to work	per hour	$1.25
Night work and outside work	per hour	1.25
Sunday and holiday labor	per hour	1.25
Shop room for chauffeurs when owners furnish tools	per day	1.00
Chauffeurs furnished to drive owner's car (day)	per hour	1.00
Chauffeurs furnished to driver owner's cars (night)	per hour	1.00

We will not be responsible for cars left for repairs or storage in case of fire, water, cyclone or other accidents, or if car is damaged in delivery to and from our garage.

We are not responsible for articles left in cars or in the shop.

Note: The foregoing is printed on a heavy card, 14 x 24 inches, framed, and placed in a conspicuous place.

FIXTURES AND SUPPLIES FOR A GARAGE

Fixtures for the repair shop should consist of such things as: shelves and racks for tools, such as stocks, hacksaws, etc.; these should be on the walls at the back of the vise. A set of stout drawers for keeping bolts and screws and brass rods should be provided. Some of the drawers should be fitted with locks and keys, for sometimes tools will disappear. Several shelves should be put up for storing various spare parts, mandrels, etc., but it must be remembered that the shelves when full may have to carry a very considerable weight; they should be stout and well secured.

Fixtures for the garage would also consist of such parts as lubricating oil tanks, gasoline tank, wash hose and washing rack, heating plant, turntable, stock room, etc. See Index under "Care of a car for constructing a wash rack."

A heating plant, either hot water or steam, with coil pipes or radiators must be provided. This plant should be in a cellar or on the outside of the building in a small brick enclosure.

A turntable is very handy for garages, but not altogether necessary. It should be placed in the center of the garage.

A wash rack is very essential.

For the lubricating oils, a small enclosure can be provided made of wire fencing with a lock and key.

Lubricating oils should be carried in about three grades: light, medium, and heavy gas-engine cylinder oil, as well as a supply of gear-case oil and greases. Sixty-gallon tanks are usually provided for lubricating oils, and all are placed near the gasoline pump.

A lubricating oil tank and a pump capable of delivering anything up to the consistency of transmission grease are made by concerns specializing in this work. Smaller and cheaper lubricating tanks can be had.

The gasoline supply should be stored in an underground tank, placed some distance from the building, from which it is piped to a pump located inside of the building near the wash rack. The gasoline tank should have from 120- to 280-gallon capacity.

A gasoline pump can be connected to a tank under the sidewalk or in the rear.

A Western gasoline pump, with the stroke adjustable for ¼, ½, 1, and 2 gallons, and equipped with a 280-gallon tank, is sold by the maker for about $200. A curb gasoline outfit is shown farther on.

Many useful devices, in the way of time-saving additions are shown under "Useful hints, suggestions and devices" (see Index).

An inspection pit is useful, placed at any convenient place where the auto can be run over it. The pit permits the repairman to get under the car and work, and should be installed. The pit can be made about 6 feet long, 2 feet 9 inches wide, and 2 feet 9 inches deep. A mirror is very handy for throwing the light in dark corners when at work in the pit under the car.

A chain hoist or crane, for lifting the engine and other heavy parts, will pay for itself many times over in time and labor.

Fire extinguishers should be kept handy. The only part of the building (if made of concrete or brick) that is subject to fire is the roof. In case of fire, keep two or three buckets of sand handy (or fire extinguishers) to put out a gasoline fire, as water is useless.

Gasoline often drips from a carburetor, and back-firing or a spark from a muffler will ignite the gasoline. Once a gasoline fire is started, it is difficult to extinguish. Never use water; it will serve only to float the gasoline and spread the flame. If a fire extinguisher is not at hand, keep a box of fine earth or sand and dash it over the flame. Flour will also do, if nothing else is handy.

A water connection in the repair shop will be handy, and should be installed.

Electric lamps with wire guards and a long cord for working around the car are very necessary.

There is no end to the number of useful devices which can be installed in a repair shop and garage.

For oil fires, a motor trade magazine advises to keep on hand a mixture of sawdust and soda (about 1 qt. of bicarbonate of soda to a bushel of sawdust).

A chemical fire extinguisher can be made by taking 7½ gallons of water and mixing about 10 or 11 lbs. of ammonia salts and 21 or 22 lbs. of common salts. Put into bottles and keep on hand.

The following few pages will be devoted to equipment and supplies usually required in a garage. By writing to some of the manufacturers, where names are given farther on, and who specialize in garage equipment, and to automobile supply houses useful catalogs can be obtained if this book is mentioned in the request.

Fixtures for Handling Lubricating Oils, Waste, etc.

Below are shown methods of handling lubricating oils. Very elaborate equipments can be obtained for those who desire large outfits. Write for printed matter to the concerns mentioned farther on.

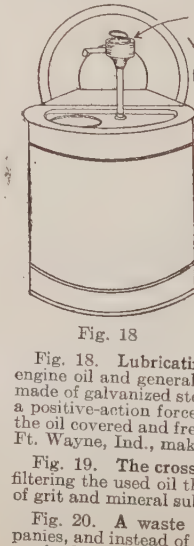

Fig. 18

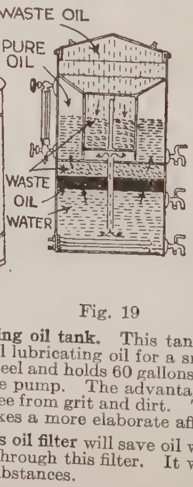

Fig. 19

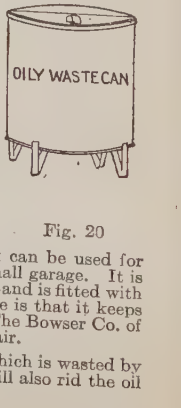

Fig. 20

Fig. 18. **Lubricating oil tank.** This tank can be used for engine oil and general lubricating oil for a small garage. It is made of galvanized steel and holds 60 gallons, and is fitted with a positive-action force pump. The advantage is that it keeps the oil covered and free from grit and dirt. The Bowser Co. of Ft. Wayne, Ind., makes a more elaborate affair.

Fig. 19. **The cross oil filter** will save oil which is wasted by filtering the used oil through this filter. It will also rid the oil of grit and mineral substances.

Fig. 20. **A waste can** is required by the insurance companies, and instead of throwing greasy, oily, inflammable waste on the floor, it is placed in this can. Every garage should have this waste can.

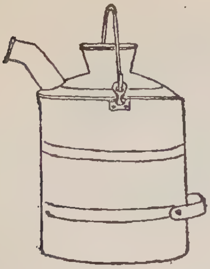

Fig. 21

Fig. 22

Fig. 21. **The Dover gasoline and radiator filler** will prevent spilling, and is very easy to handle. It holds 5 gallons. It is not advisable to put gasoline in the same vessel used for water, but if it is necessary, then place a chamois skin in the funnel, and pour the gasoline through it. No water will then pass into the gasoline tank.

Fig. 22. Illustrates a smaller size of Dover radiator and gasoline tank filler. It is advisable to have one each for gasoline and water. This filler is also suitable for lubricating oil.

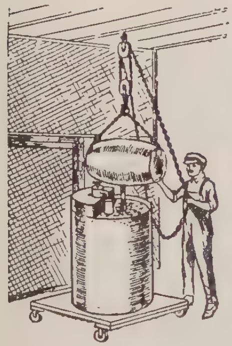

Fig. 23

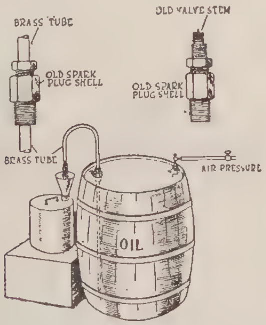

Fig. 24

Fig. 23. **Oil may be most readily transferred from the barrel** to the storage can by the aid of a differential pulley and suitable grab-hooks. The differential pulley may be fastened to the ceiling beams just over the oil-storage-room doorway, and if the storage cans are mounted on casters in the manner shown, they may easily be rolled under the suspended barrel, a hole drilled in the bung, and the oil transferred without further attention. The oil-storage room shown in the sketch has several valuable features. First, the oil may be locked up, and is accessible only to the proper persons; secondly, the upper part contains a shelf on which the surplus stock of heavy oils and greases are stored.

Fig. 24. It is difficult **to transfer oil** from the common oil barrel to a smaller container unless some special outfit is at hand, such as the one illustrated. The oil is forced by air pressure from the barrel. Air pressure is applied through a valve that is an ordinary tire valve soldered into an old spark-plug shell, which in turn is screwed into a hole in the barrel. The oil is delivered through a bent brass pipe, passing through a second spark-plug bushing, also screwed into a hole in the barrel. This pipe must be long enough to extend nearly to the bottom of the barrel, as shown by dotted lines. Packing is placed between the bushing of the plug and the shell, so that the tube may be adjusted to any barrel, and the amount of oil is readily regulated by the pressure applied.

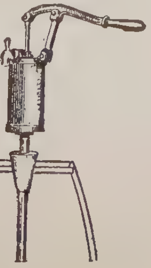

Fig. 24A. Oil pump which can be secured at supply houses for removing oil from a barrel.

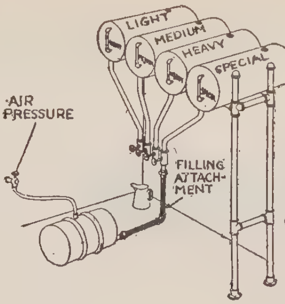

Fig. 25

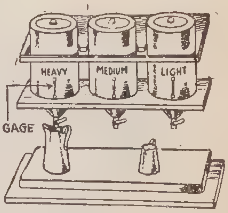

Fig. 26

Fig. 25. **An oil-storage system,** whereby the oil is discharged **by gravity.** It comprises several tanks, as many as there are kinds of oil to be stored, held close to the ceiling on pipe standards, and each pipe connected to its discharge valve. Oil is transferred from the original barrel by air pressure, through a special connection, in the manner illustrated. In addition to facilitating the withdrawal of oil, this method gets the storage tanks up out of the way, and saves much valuable room.

Fig. 26. The common type of oil-storage tanks requires a pump and does not provide a convenient place for keeping the measures. Gravity flow is somewhat handier, and the installation requires less floor space. **A simple method of storing several grades of oil** and having them on tap is illustrated here. The tanks may be made by any tinsmith, and are provided with gauge glasses that show at a glance the amount of oil on hand. The conical-shaped bottoms permit the draining of the last drop of oil, and prevent the collection of any sediment. A shelf provided with a drip-pan offers a convenient place for keeping the receptacles.

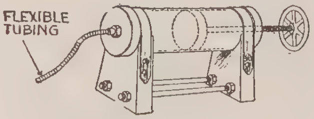

Fig. 27

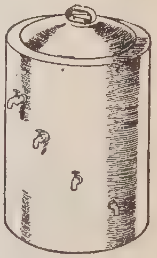

Fig. 28

Fig. 27. **A powerful grease gun** for filling universal joints and steering gears is illustrated here. The barrel of the gun is a piece of 6-in. pipe about 16 in. long, and carries a metal piston having a single ring. This piston is forced downward through the action of a threaded rod, screwed into a cap at one end, and operated by a hand wheel. The other end of the barrel is likewise covered with a cap and carries a length of flexible tubing, through which the grease is forced to the part. The barrel is mounted on wooden uprights, and is large enough to permit one loading to supply several joints. The amount of grease used each time may be readily determined by weighing the gun before and after using.

Fig. 28. The oil drained from the crank case is usually a dead loss, as it is unfit for further motor use. It is, however, suitable for lubrication of farm machinery or such light implements as the lawnmower and the wheelbarrow, and may be reclaimed by the **settling tank** shown. The old oil is poured into the tank as fast as it collects, and the sediment is allowed to drop to the bottom, the clean oil rising to the top and being drawn off as required. The resale price should be made low to attract the trade, and is almost a clear profit.

The foregoing are suggestions taken from the *Motor World*.

Sponges, Chamois, and Waste

In selecting sponges, chamois, and waste, it is advisable to use only the best.

Waste usually comes in bales of 50 or 100 pounds. It is economy to buy waste by the bale. Nothing but the very best white waste is suitable for automobile work. When waste has been used and is ready to throw away, place it in a can (see Fig. 20).

Chamois skins are used for washing and cleaning the body and fine surfaces. It is a difficult matter to obtain a good, genuine chamois skin, but it is worth the difference in price to get the best. The French chamois skin seems to be the most durable and pliable. Chamois skins come in sizes 28″ x 32″ and 19″ x 21″. A package of chamois generally contains a dozen.

Sponges often contain sand and grit, especially the cheaper grade. Many cars have received scratches which cannot be removed, by using the cheap gritty sponge. The best sponges are the Rock Island Sheepswool sponges. They come in bales of 15, 25, 30, and 50 pounds. This class of material can be obtained of automobile supply houses.

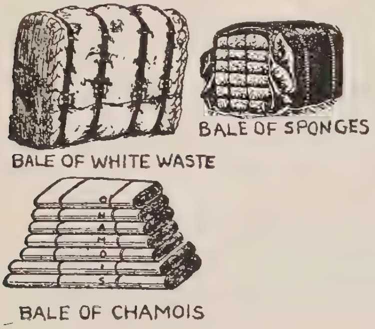

Fig. 29

Repair Pits and Methods for Working under a Car

An inspection pit, placed at a convenient place, or, still better, a floor level underworker, as shown in Fig. 30, is far better than working on your back under a car in a limited space. Several different methods are shown below.

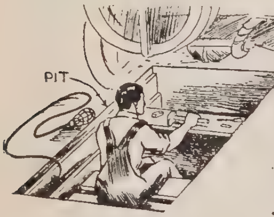

Fig. 30

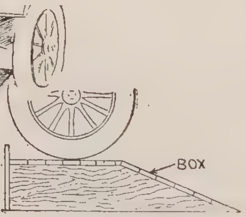

Fig. 31

Fig. 30. **A concrete repair pit,** the depth of which may be varied, is illustrated here. Ledges are provided at different heights, and boards may be placed across, giving the mechanic free access to the work. Much of the dampness of this type of pit is removed by the wooden floor and the space beneath. Several of the boards on one of the upper ledges may be left in place and used as shelves for the tools and for steps for getting into and out of the pit. Size of pit is usually 6′ long, 2′9″ wide, and 2′9″ deep.

Fig. 31. While not new, the **substitute for a pit** illustrated here is worth describing because of its merit. Two heavy wooden boxes, one for each wheel, with a slope of about 30°, and a flat space on top are used. The boxes are constructed of 1½″ or 2″ planks; the height is about 10″, and the length about 4 feet. Such boxes will support even a heavy car.

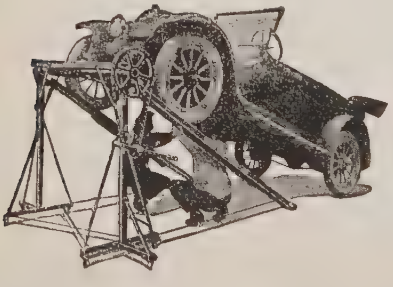

Fig. 32. **The Manley floor level underworker** elevates the car to any desired height, so that the mechanic can work to advantage while sitting in a perfectly natural position. Manufactured by The Manley Mfg. Co., York, Pa.

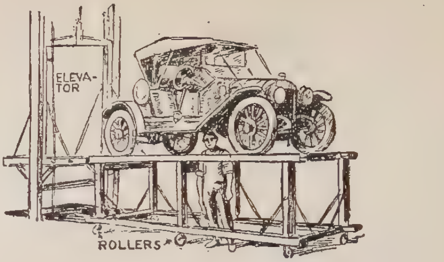

Fig. 33. Where there is an elevator and no pit. This structure serves the same purpose as a pit, with the additional advantages of being portable, more cleanly, and more accessible. It permits the workmen to perform most of their operations by daylight instead of subjecting them to the inefficient glare of an electric-light bulb. No skids are required with this structure in any garage where an elevator is provided; the elevator with the vehicle upon it is simply brought to a stop at the height of the truck, and the truck then adjusted so that the car can be rolled upon it. Being mounted on casters, the truck can be moved easily to the lightest portion of the shop.

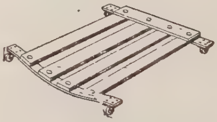

Fig. 34

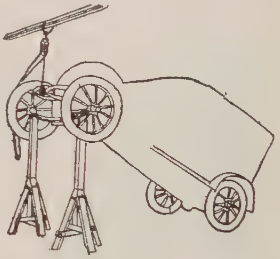

Fig. 35

Fig. 34. **A creeper** is easily made, and is strong enough to permit a car to run over it without injury. Cross strips are 2″ x ½″ steel and bent slightly to give clearance for the swivel casters and yet keep the body of the creeper low. Slats are 4″ x ¾″ hardwood. The Continental Auto Parts Co., Columbus, Ind., manufactures creepers, engine stands, hoists, etc., at very reasonable figures.

Fig. 35. **Another method for working under a car.** The front end of the car is hoisted by chain and specially made wood jacks are placed under the axle. The stands or jacks must be designed for the least space possible, in order to give working room between them. It is also advisable to have the car supported by the chain hoist securely, and then, in case the jacks give way, no injury will result; also block the rear wheels securely.

Gasoline Storage

This subject is one the garage man can learn more about by writing to the concerns mentioned below, and securing their catalogues.

A curb or road-side pump is shown in Fig. 36. An electric light fixture with globe is placed above. The storage tank is buried under ground, usually as close to the pump as possible. It is connected by a 1½″ suction pipe with a foot valve placed at the end of the suction pipe. Standard tanks range from 1 to 20 bbl. capacity. Parts are: foot valve, vented fill pipe with lock, suction pipe, and gauge stick. (The American Oil Pump & Tank Co., Cincinnati, Ohio.)

An air-pressure gasoline system is manufactured by the Allen Pressure System Co., 1926 Broadway, New York, N.Y.

The Bowser Co. manufactures a piston type of gasoline pump which separates the water from the gasoline.

The gasoline storage tank to supply gasoline inside of the garage to a pump placed away from the tank requires special installation on account of the insur-

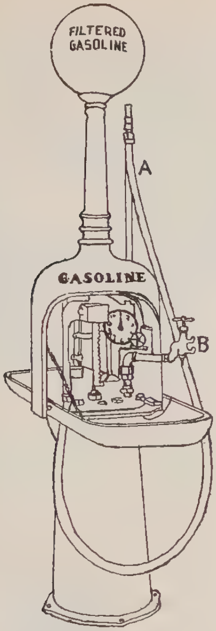

Fig. 36

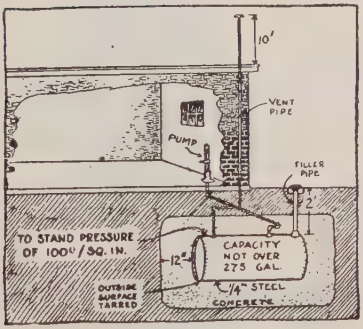

Fig. 37

ance. The tank can be placed in the ground 18″ below the surface. The insurance companies are very strict. The plan shown in Fig. 37 is one that passes inspection in New York. Give the tank 3 coats of asphaltum when placing it underground.

Addresses of some of the storage-tank manufacturers: Western Oil Pump & Tank Co., St. Louis, Mo.; O. K. Harry Steel Co., St. Louis, Mo.; Wayne Oil Tank Co., Ft. Wayne, Ind.; American Oil Pump Tank Co., Cincinnati, Ohio; S. F. Bowser Co., Ft. Wayne, Ind.; Tokheim Oil Tank and Pump Co., Ft. Wayne, Ind. By writing these concerns full information can be secured.

A Gasoline Filling Station Layout and Greasing Rack

A suggestion for the layout of a filling station is made by *Motor Age*, as shown in Fig. 38.

A good method of determining the probable trade in a certain location is to count the number of cars passing per day at the location selected. If there are about 3,000 cars or more per day, on an average, passing the filling station, this will no doubt insure a profitable investment. There is no surer method of getting gasoline business than going where the traffic is heavy. A corner where traffic passes both ways, especially around the corner, is the most valuable kind of a plot.

The biggest problem in making a layout is the finding of space where cars may take on air and water and where a greasing rack may be placed without interfering with or obstructing the passages to and from the gasoline pumps.

The driveways in the plan shown in the illustration are very liberal, but they should be so, as it is of the utmost importance to make it easy for customers to get in and out without interference. This building does not seem large, but will be found of ample size. The necessary tanks and pumps are provided, i.e., about four tanks, two 1,500-gallon tanks for commercial gasoline, one 550-gallon tank for high-test gasoline, and one 550-gallon tank for kerosene oil. Free air and water should be provided (see "Air compressors").

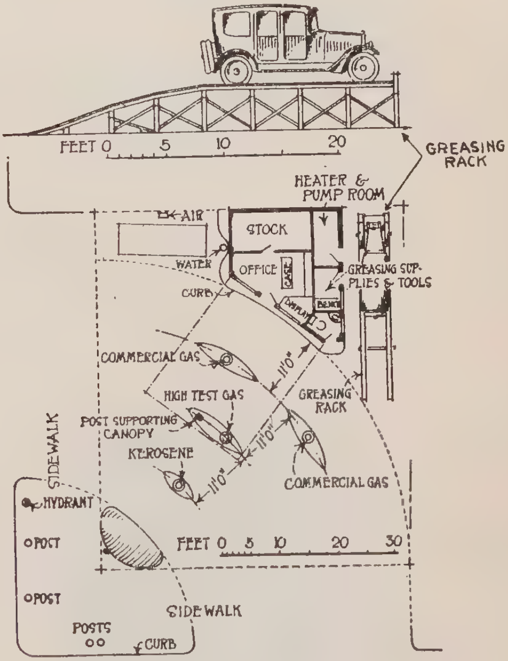

Fig. 38

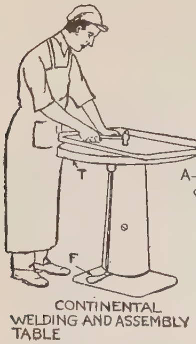
A mistake is often made in planning filling stations, even by experts of the big oil companies. Many times they place their free air hose so that a car taking on air will obstruct one of the passages. At ordinary times this does not matter, but during rush hours it matters considerably, since if there are several cars waiting, other prospective customers will go on to another station, rather than stand in line.

The greasing and oil-changing branch is getting to be quite an important factor in motor-car service, and, if handled intelligently, should be a good source of profit. **A greasing rack** is shown in the illustration (Fig. 38).

Engine Stands, Axle Stands, and Hoists

Engine stands for working on the engine at various angles, and hoists for lifting the engine or transmission from the frame are very necessary. There are several firms who manufacture such devices: Continental Auto Parts Co., Columbus, Ind.; Service Station Equipment Co., Chicago, Ill.; The Manley Mfg. Co., York, Pa.; and the automobile supply jobbers mentioned farther on.



T
F
CONTINENTAL WELDING AND ASSEMBLY TABLE

Fig. 39

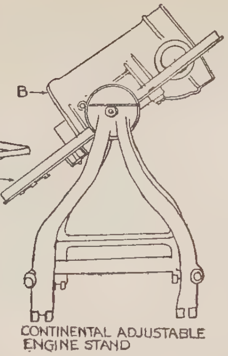


Fig. 40

Fig. 39. **The Continental assembly and welding table** greatly helps to speed up all kinds and types of assembly work. It is not necessary continually to change the position of the article being worked on, in respect to the table, as the table may be revolved and the work comes to the right position. The table is instantly locked (Continental Auto Parts Co., Columbus, Ind.).

Fig. 40. The Continental adjustable engine stand.

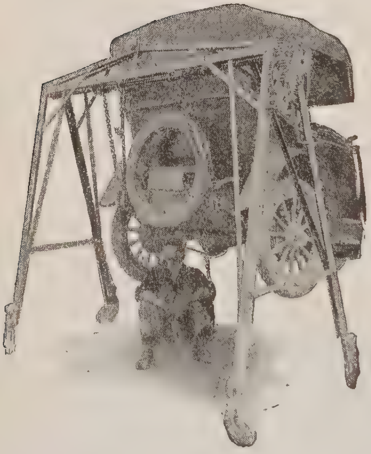

Fig. 41. **The Manley portable hoist.** This hoist is composed of steel angles thoroughly braced. The top frame is in the form of a standard bridge truss.

The hoist is wide enough to clear the fenders and allow the workman ample space to work efficiently between it and the car. The crank handle in the latest hoists has been brought down low enough for the most efficient operation.

The chains may be used single or double, giving in the first case twice the speed with one-half the leverage, and in the second case the reverse, thus proportioning the leverage to the power required to lift any load efficiently and quickly.

There is also provided a brake to lower the load—a feature of the greatest importance, as the lowering is done without effort and in one-tenth the time required by other hoists, which necessitate turning the handle both to raise and lower.

The gears have spur teeth with ample leverage ratio for the complete range of auto work.

The 4,000 lbs. capacity hoist is ample for all passenger cars and light trucks. The 8,000 lbs. capacity truck is intended for the heaviest truck service. (Manley Mfg. Co., York, Pa.)

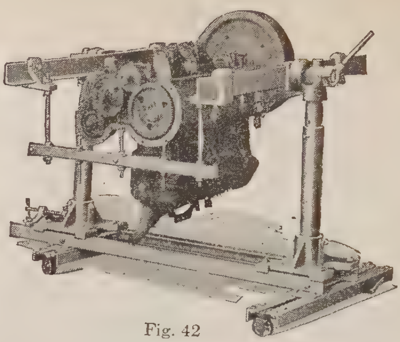

Fig. 42

Fig. 42. **The Manley Universal engine stand.** A cone locking clutch enables the operator to place and lock the engine in any position without the use of pins or other make-shift methods. The Cadillac, Dodge, and Overland 90 require special fittings, which can be furnished.

The unit construction enables this to be converted into an axle stand, thereby tripling the value to the garage. By removing the engine-stand parts, and putting on the axle-stand attachments, the machine is converted from one to the other in three to five minutes.

It will mount 85 to 90 per cent of all motors without special attachments, by means of the Universal suspension bar. Made in two types, geared and plain.

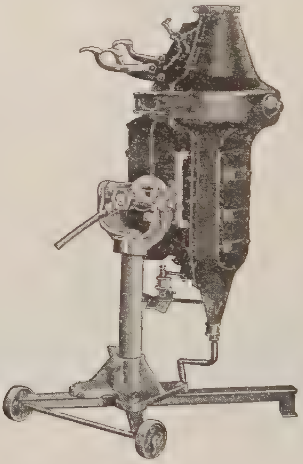

Fig. 43. **The Manley Ford-Chevrolet Universal engine stand.** The cone-clutch-locking method allows the mechanic to lock the motor in any position in a complete circle. The whole power plant, including the oil pans, can be assembled or disassembled while on the stand.

The axle stand parts shown in Fig. 44 may be attached in two to three minutes, converting it into an efficient axle stand.

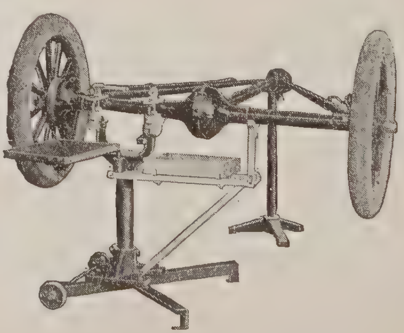

Fig. 44. **The Manley Ford-Chevrolet axle stand.** The engine stand (Fig. 42) is converted into an axle stand by removing two cap screws, releasing the clutch and fitting assembly, and applying to the yoke the two clamps. A collar is placed over the upright to support the grease pan and outboard support. Separate support is included for torque tubes. It is adapted to all types of split rear axles and to any front axle

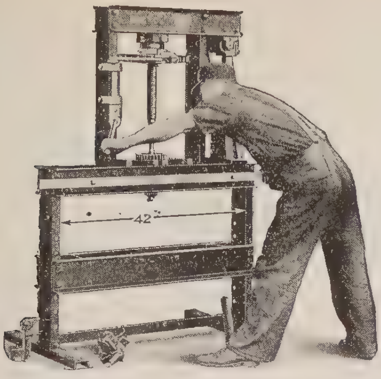

Fig. 45. **The Manley 22-ton press.** The illustration shows the Manley combination press, consisting of a powerful screw press, a high-speed rack and pinion sensitive press, and a straightening attachment all in one unit. This combination covers the range of auto service work completely. Its 42" clearance is necessary for wide work and straightening jobs; its 30-ton capacity is required to handle all auto work; the rack and pinion press is essential for light work, and the straightening attachment is used continuously in every garage. Combining the three in one unit is very much superior to three separate units, and the cost is much less.

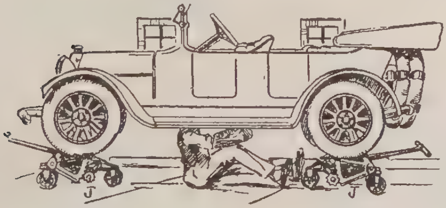

Fig. 46. Car raised by specially made jacks for the purpose of working underneath.

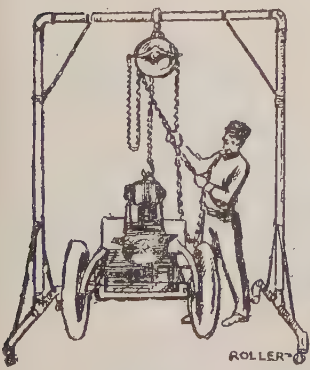

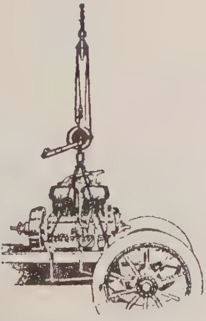

Fig. 47 Fig. 48

Fig. 47. A home-made chain hoist and frame for lifting engines from the chassis. The frame is made of heavy iron pipe with rollers.

Fig. 48. **The Pull-U-Out** is a combination device. It can be used as a hoist and also for pulling cars out of mud holes, etc. Can be carried in a car.

This device has advantages over the old-fashioned block and tackle, being lighter and more powerful. A pressure of 30 lbs. exerted on the handle will lift one ton, whereas a triplex chain block would require 82 lbs., and an ordinary block and tackle 176 lbs. See also Index.

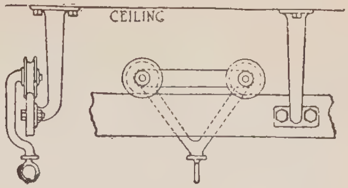

Fig. 49. **An overhead railway for repairshop use** may be patterned after those in use in large butcher shops. It consists of a track made out of stock about ½" x 2", and suspended from the ceiling by arms at frequent intervals. On this track is placed a cap, to which the block and tackle is attached.

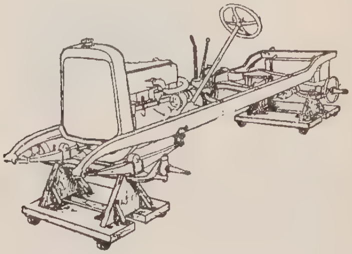

Fig. 50. **Axle stand.** Work is faciliated by the use of this special stand. The one illustrated is fitted with rollers and permits the chassis to be moved about, rendering the parts more accessible.

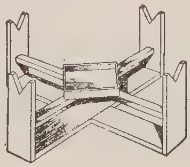

Fig. 51. Though designed for work on the Ford rear axle, this stand could readily be adapted to the requirements of many makes of axles. The ends of the axle are supported on notched uprights, about 30 in. from the floor, and the torque tube is placed on either of two uprights similarly notched.

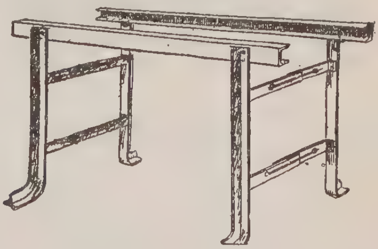

Fig. 52. **A home-made engine stand that is adjustable** as to width, and that is very light yet strong, can be made out of structural steel. The top members are 4" channels, the legs 2" x 3" T-iron, and the cross-members are made of flat stock ¼" x 1".

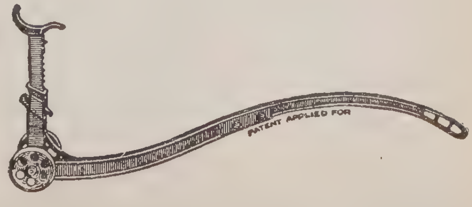

Fig. 52A. The Hovey garage jack for general garage use Can be secured of J. H. Whetstone Co., Lapeer, Mich.

TOWING TRUCKS, WRECKING CRANES, SERVICE CAR, ETC.

A towing truck with devices for towing in disabled cars is a necessity and a profitable investment for a garage.

With the proper equipment one man can accomplish in an hour's time what would ordinarily require two or three men several hours to perform under the former methods of towing. Towing trucks are suitable for towing in cars where either the front or rear axle is disabled. For instance, if the rear axle is out of commission and the car cannot be towed from the front end, then it is necessary to place a dolly under the rear axle and to tow the car backwards, or from the rear end. In this instance the steering wheel can be tied by passing a light rope around the windshield brace, and then tying it to the steering wheel and then to the other side of the windshield brace, which will keep the front wheels in line.

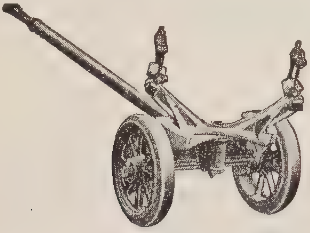

Fig. 53. **The Manley towing truck** is simple in construction. The load is carried on an off-set saddle directly over the center of the axle. It is equipped with roller bearings, located in the hubs, which are lubricated through large grease cavities; 14" wheels, 11 ft. massive two-inch telescoping towing pole, made from malleable iron and steel. It can be attached to the front or rear axle of any car.

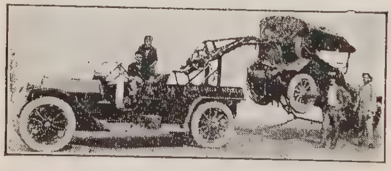

Fig. 54. **Manley wrecking crane:** This device is intended to be attached to the rear of a service car. The illustration shows how it is used. The crane can also be used as a portable floor crane for garage and shop use.

A Home-Made Towing Truck

It will probably be cheaper to purchase a towing truck, but for those who have the time and inclination to make it themselves a brief description is given. (See Fig. 55.)

The heavy metal wheels are 11" di., 6" hub, 1½" spindle. A tongue, preferably an I-beam steel member about 8' or 10' long with a coupling pin to couple to the tow link of the service car (see Fig. 62, page 677), is mounted on the heavy metal axle of the dolly (towing truck). A hook-shaped flat piece with a hook at each end is provided to set the axle or differential housing on and to hold the axle in place.

Then chains are passed around the axle housing and fastened to the axle of the dolly, in order to keep the axle from moving sidewise. The rear end of the service car is then coupled to the end of the dolly and the car is towed backwards. The axle of the dolly, in fact all parts, must be very substantial, as the vibration is very great.

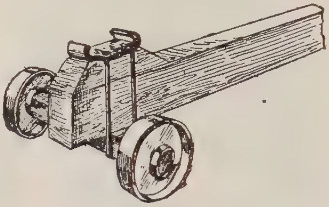

Fig. 55

Chains with catch hooks should be provided to pass over the axle to prevent side play.

Towing Pole

A towing pole is shown in Fig. 56 and a towing bar in Fig. 57. Methods of using a rope for towing are shown in Fig. 58.

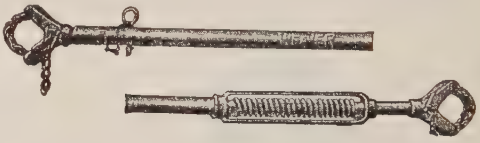

Fig. 56. **The Weaver towing pole.** With this device a car can be pushed or pulled.

Construction: The pole proper is made of double-strength steel tubing, and is constructed in two sections, one telescoping within the other. A convenient pin adjustment provides for varying the length from 5 feet 6 inches to 8 feet. The heads or sockets are well designed of malleable iron, and carry a convenient spring latch for securing the end of the heavy chain. The heavy coil spring is amply strong to meet the requirements of the heaviest passenger car service. The yoke which encases the spring is of malleable iron. Shipping weight, 30 pounds. (Manufactured by Weaver Mfg. Co., Springfield, Ill.)

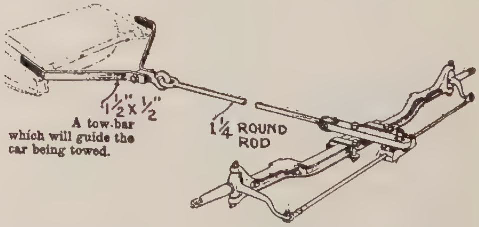

Fig. 57. **A tow-bar** whereby two cars may be brought in by one driver. A towing bar, attached to the rear of the driven car, pulls the towed car by a clamp in the front axle. The bar extends behind the axle, and a stud on a clamp on the tie rod goes in a hole in the bar. In this way, when the bar turns, it moves the tie rod, and the towed car follows its leader.

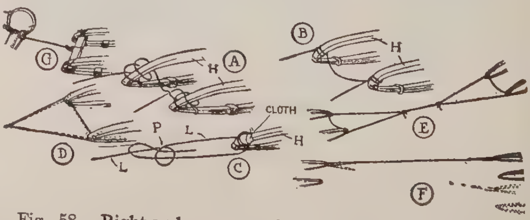

Fig. 58. **Right and wrong methods of securing the tow rope to the vehicle to be towed.** The best way is shown at (G), a piece of wood being tied under and across the frame horns as illustrated, and a single rope connecting it to the rear axle of the towing vehicle. The rope should be as long as convenient, and should be attached as near the outer end of the axle of the towing car as possible.

To loop the rope under the frame as at (D) is very bad, as a severe strain would bend the horns inward, as indicated by the dotted lines.

The bowline knot is the best to use at all times, as it is easy to make and just as easy to untie; it is illustrated at (C). Attention is called to the cloth wrapped (H).

When a bar of wood is not readily obtainable, and a heavy car is to be towed, the rope may be secured as illustrated at (E), two half-hitches being used, as shown at (A), to secure the rope to the horns of the frame, the rope between the two horns being left slack. When using this method, the bights also should be as long as possible. Two long bights are shown at (E); an undesirably short bight is depicted at (D). (A) shows how the two half-hitches are made, and (B) shows how they look when drawn taut, the slack being shown in the rope between the horns (H) to prevent their being drawn together at (D).

The knots at (A) and (C) are the most useful. Their advantage over other knots is that they will neither slip nor jam. (*Motor Age* and *Automobile.*)

How to Make a Service Car

A service car is necessary in all up-to-date garages. It bears the same relation to a service station as does an ambulance to a hospital. It is a traveling representative of the service station, and should impress the public that quick, clean, and efficient service is given.

Any old chassis can be utilized for the purpose, and by following the dimensions in the table below (Fig. 59), a very attractive and serviceable car can be constructed.

Table of Service Car Body Dimensions

As Taken From Representative Detroit Service Cars

Car	Model	A	D	E	F	G	H	I	J	L	M
Hudson	4–37	70	39½	20	14	12	15	12	70	43½	18
Cadillac	53	84	28	23	12	12	19	14	53	55	15
Studebaker	4–58	58	25½	25	8	10	18	12½	55	45	11
Ford	T	48-up	O-up	15¾	...	..	..	..	48	34	15¾
Chevrolet	4–90	55	29	16	8	9	..	13*	43	32	13½
Dodge	...	60	35	19	11	8	16	12	43	47	17
Chalmers	5–15	68	31	24½	10	11	12	10	48	45	20
Hupmobile	32	47	23	15	9	5	..	..	50	41	13
Paige	6–46	68	30	22	10	10	..	12	52	54	12

(*—seat on one side only.)

All dimensions in inches

Fig. 59. Dimensions referring to Fig. 61.

The figures given are intended to be for the average requirements of the average service car built on the various chassis which are listed in the table.

One very important point to bear in mind is that the service wagon must be attractive in appearance—clean, well-painted, and it must run smoothly and quietly. It will be one of the best investments you can make.

Painting: Cars giving Chalmers service are painted English vermillion, with black hood and running gear. Hudson service cars are white, with black trimmings. If the dealer is giving service on a particular make of car, he should find if a standard service car color is used; if not, the car may be painted any bright color that will give distinction.

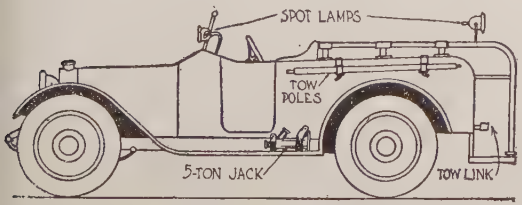

Fig. 60. After studying hundreds of service cars in dozens of the largest cities and many smaller ones, *Motor World* believes that a design of this general kind is best. Note particularly the method of carrying the towing pole, the jack mounting on the running board, and the location of the several spot lamps.

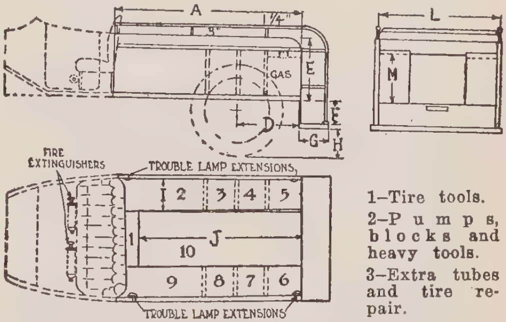

1–Tire tools.
2–Pumps, blocks and heavy tools.
3–Extra tubes and tire repair.
4–Bolts, nuts, and small repair parts.
5–Gas can.
6–Oil can.
7–Bolts, nuts, screws.
8–Small repair parts.
9–Tools.
10–Towing dolly, shovel, axe, pick, bars, battery, spare tires, etc.

Fig. 61. Here is a detail drawing of the body shown above. The lettered dimensions on the drawing are given in the table (Fig. 59). The figures refer to the location of the various tools and accessories.

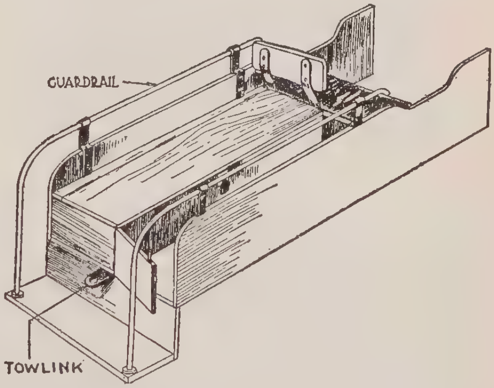

Fig. 62. An alternative type of body, built especially for very light chassis, is often desirable, in which case the arrangement can be made something like this. This is a body that is used quite successfully by the Chevrolet Co. in Detroit. There is an almost endless variety of arrangements, and in laying out a car a shop foreman should be guided by the particular class of work he expects to be called upon to do.

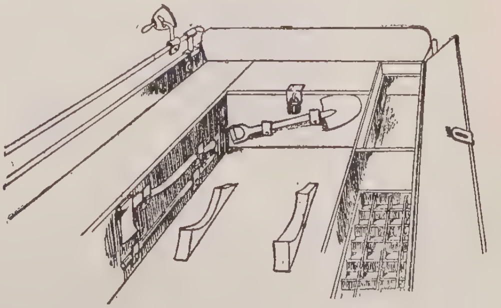

Fig. 63. This is a view of the interior of the service car shown in Fig. 60. Note the chocks and the neat arrangement of the tools, the seat at the right not being shown, so that the compartments are visible.

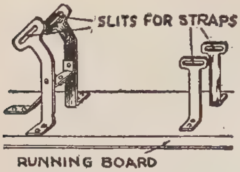

Fig. 64

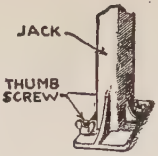

Fig. 65

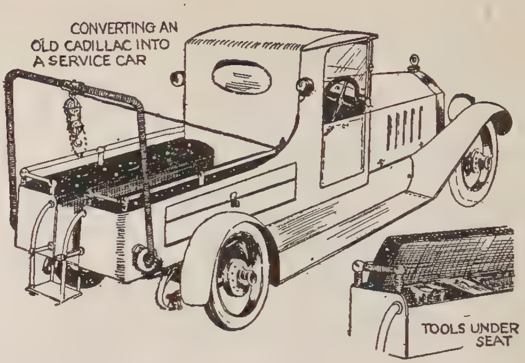
Fig. 64. This is a detail drawing of the jack mounting shown on the service car illustrated in Fig. 60. In this case 5-ton jacks are carried, though any size can be substituted. Get them big enough to care for the heaviest work to be done, and they will also serve for light work.

Fig. 65. The service jacks can be carried bolted to the running board, like this, thumb-screws being used for quick action.

Several of the foregoing illustrations are by Mr. S. Thornton Williams, the *Motor World.*



CONVERTING AN OLD CADILLAC INTO A SERVICE CAR
TOOLS UNDER SEAT

Fig. 66. Another example of a service car as suggested by *Motor Age.*

THE STOCK ROOM

More money is lost in the repair shop and garage than in any other part of the business by having supplies scattered over the shop promiscuously.

Every repair shop, no matter how small, should provide a stock room with a good lock and key, and everything in the way of supplies should be kept therein. (See Fig. 67.)

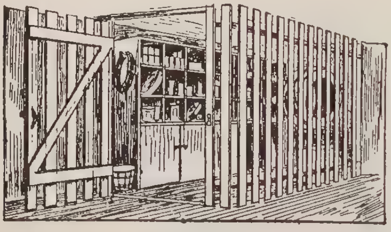


Fig. 67

Systematic arrangement and a place for everything and everything in its place will save time and money.

The **stock room** is generally placed in some convenient place in the garage or repair shop. It is usually constructed of lattice work with a good Yale lock on the door. In large shops the stock room is in charge of a responsible person, whose business it is to keep the stock replenished and deliver material to the workmen and customers.

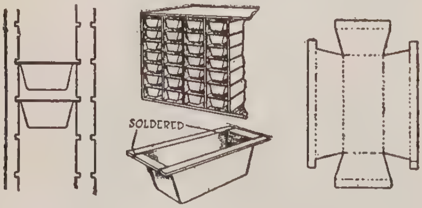

Fig. 68. Small parts, such as screws, bolts, washers, nuts, gaskets, and the like, are conveniently kept in tin drawers, as illustrated. The drawers are cut from a single piece of tin and are soldered, as shown by the heavy lines. The drawers slide in grooves cut in planks placed vertically. The grooves are made with a saw and chisel. The advantage of this method of storing parts is that the construction of the receptacles is very inexpensive, and maximum convenience is afforded. It is possible to see what is in the various drawers without pulling them out, which is a feature peculiar to this design, and saves considerable time when the exact drawer a certain part is in is not known.

Supplies in the rubber line: Repair shops can make extra money by carrying rubber supplies which are generally made by tire concerns. Some of these are as follows: Automobile rubber mats which come in rolls 3/32″ to ⅛″ thick and 35″ to 48″ wide; matting also comes corrugated and perforated; radiator hose; tire tape; rubber tubing; tire inflating tubing (comes in black, white, or red; sizes ⅛″, 5/32″, 3/16″, and ¼″ inside diameter).

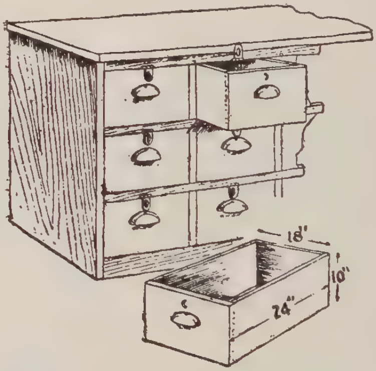

Fig. 69. Substantial drawers of large size provide convenient means **for storing parts removed from cars that are being repaired.** The usual method is to place the parts on the bench but this is objectionable because there is always danger of their being mislaid or used on other cars. A drawer 10″ x 18″ x 24″ is large enough to take all the ordinary parts, such as bolts, nuts, washers, carburetor, magneto, pistons, connecting-rods, bearings, etc. The drawer may be placed at the side of the car, and as soon as all the parts have been removed it may be put back in the cabinet. A padlock safeguards the parts until they are needed again. These drawers also aid in keeping the shop neat and protect the parts from dirt. The top of the cabinet may be used as a bench or table.

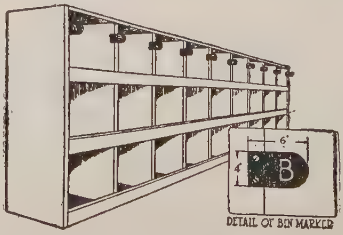

Fig. 70. **This stock-bin marker** permits ready location of any bin in the stock room. It is a sheet metal tag, bearing the number of the bin to which it is attached. As it projects out into the aisle, and is large enough to be easily read, the location of any desired bin may be seen at a glance.

Parts of Cars for the Stock Room

Parts for axles, engines, transmissions, steering gears, etc., should also be carried if there is very much work on any particular car in the vicinity. Otherwise secure a Parts Book of the manufacturer of the cars you are likely to be called to work upon, and order them as required.

Minor parts, such as windshields, radiators, ball cups, bearings, springs, fenders, wheels, rims, tires, bodies, ignition coils, distributors, generators, starting motors, batteries, axles, frames, gears, etc., can be secured from automobile parts supply houses, such parts not usually being made by the manufacturer of the car. Automobile parts supply houses also wreck cars of different makes and sell the parts, and very often a part can be secured at a very reasonable figure. Reliable concerns in this line issue circulars giving the description of such parts and their condition.

It is a good plan always to ask your customer if he wants genuine parts from the manufacturer, or parts from an automobile parts supply house.

Automobile Parts Supply Houses

Some of the automobile parts supply houses are given below:

Puritan Machine Co., Detroit, Mich.
Auto Parts Co., 4114 Olive St., St. Louis, Mo.
Auto Salvage & Exchange Co., 2823 Locust St., St. Louis, Mo.
American Automobile Parts Co., 125 W. 52d St., New York, N.Y.
Auto Parts Exchange Co., 621 Van Ness Ave., San Francisco, Cal.
Auto Wrecking Co., 1413 McGee St., Kansas City, Mo.
Machined Parts Corporation, 245 W. Larned St., Detroit, Mich.
See also "Orphan Car List" for other supply houses in this line.

See also page 687 for "Automobile Jobbers," and, if in the repair business, send for catalogue of nearest firm.

Manufacturers of Automobile Parts

Some of the manufacturers of parts for standard makes of cars are as follows:

Standard Metal Goods Co., 2080 E. 30th St., Cleveland, Ohio.
C. A. Cathart, 222 Massachusetts Ave., Boston, Mass.
Jos. Gorey & Co., 354 W. 50th St., New York, N.Y.

Gear Manufacturers

Concerns who specialize in the manufacture of transmission and rear axle gears and shafts, etc., are:

Automotive Gear Works, Atlanta, Ga.
Auto Gear Co., 844 Eighth Ave., New York, N.Y.
Auto Gear Co. of Boston, Boston, Mass.
Auto Gear Co. of Chicago, 1461 S. Michigan Ave., Chicago, Ill.
Auto Gear Co. of Los Angeles, 1213 S. Hope Ave., Los Angeles, Cal.

Some of the Small Supplies and Fittings for Stock Room

The assortment listed below, as well as all other supplies, can be secured of automobile supply houses.

Asbestos—sheet and wicking.
Babbit metal—for bearings.
Blue, Prussian, for "spotting in" bearings.
Body polish—brass and nickel.
Bolts—stove and carriage, assorted sizes.
Brake band rivets, Nos. 7, 8, 9, and 10 (copper).
Brake lining—see Index.
Brushes—for generator and motor.
Brushes—paint, scratch, file.
Bushings—for crank shafts.
Candle wicking—for pump packing.
Carbide—in cans.

CAP SCREWS
U. S. S. AND S. A. E. THREADS

An assortment of 12 in a box. Two each, ¼ inch bolt, 1 and 1¼-inch long. Two each, ⅜-inch bolt, 1 and 1¼-inch long. Two each, ⅝-inch bolt, 1¼ and 1½ inch long.

S. A. E. CASTELLATED
HEXAGON NUTS

An assortment of 15 in a box. Four each, ¼, ⅜-inch; three ⅞-inch; two each, ½, ⅝-inch. All perfect, well-finished nuts.

STANDARD HEXAGON NUTS

An assortment of 24 in a box. Standard threads. Eight each, ¼, 5/16, ⅜-inch. All perfect, well finished nuts.

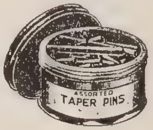
LOCK WASHERS

An assortment of 10 each in the following sizes: ¼, 5/16, ⅜-inch; three each, ⅞ ½ ⅝ inch.

CAMPBELL SPRING COTTERS

100 spring cotter pins assorted sizes; all sizes for automobile work put up in boxes.

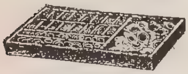
TAPER PINS



An assortment of 40 in a box. Six sizes, from 0x1 to 5x2¾ inches. High grade, turned pins.

Celluloid sheets—for top curtains.
Chalk line—for aligning wheels.
Chamois—for washing car.
Clamps—hose and screw.
Cloth—crocus and emery.
Cocks—compression and pet.
Cotter-pins—assorted sizes.
Cup and transmission grease.
Cylinder oil—light, medium, heavy.
Drill rods and drills.
Dry cells—testing not less than 25 amperes.
Electric lamp bulbs—see Index.
Ells—brass; for gasoline and oil lines.
Emery Cloth—No. 00 to No. 1.
Felt—sheet and washers.
Fibre—sheet and block.
Flux—for soldering aluminum and brass, etc.
Gaskets assorted—copper, asbestos lined for valve caps, carburetor, exhaust and inlet manifold, spark plugs, etc.
Gas tank keys—for Prest-O-Lite gas tanks.
Gas tips—½ ft. and 1 ft. sizes.
Graphite—powdered and flake.
Grease cups—⅛", ⅜".
Hand washing compound.
Hemp wicking—for packing.
Hose—for radiator and gas.
Hose clamps—for radiator hose.
Inner shoes—for blow outs.
Inner valve parts—for tire valves.
Iron—bars and rods.
Iron—sheet.
Kerosene—for general cleaning.
Key stock—in bars.
Keys—Woodruff, Whitney and straight.
Lard oil—for thread cuttings, tapping and drilling.
Leather—(heavy) for under radiator and bodies and refacing cone clutches.
Lock washers—¼" to ⅝".
Moboline, Raybestos, multibestos, etc.—for packing.
Nails—assorted.
Neatsfoot oil—for clutch.
Outer shoes—for cuts in casing.
Paper—heavy brown, sand, emery.
Pipe plugs—iron and brass ⅛" to ¾".
Platinum points—for interrupters, and magneto.
Priming cups.
Rivets—iron and copper, assorted.
Rubber—matting.

Rubber—sheet packing 1/32″ to 3/16″.
Rubber—tubing for gas, air, tire hose, etc.
Screws—machine, cap, lag, wood and set.
Sheet—iron, brass, copper, tin and lead.
Shellac—for gaskets, etc.
Shims—laminated.
Solder—half and half, string and aluminum.
Soldering compound and acid.
Spark plugs—½″, S. A. E., metric.
Spring—steel and assorted springs.
Steel bars: a few feet of ¼″, ⅜″, ½″, ⅝″, ¾″, ⅞″, and 1″ iron bars; also steel, brass, and wire rods.



Gasket, Assortment

License Bracket Bolt and Nut

Copper Wire Terminals

Spring Assortment

Machine Screws and Nuts, Assorted

Steel rods—bar, tool.
Switches—push, snap
Tacks—assorted sizes.
Tape—adhesive; for electric wiring.
Taper pins—¼″ to ⅜″.
Tees—⅛″, ¼″ brass for gas lines.
Tubing—copper, brass, for gas and oil lines ⅛″, ¼″. This tubing generally comes hard, but can be annealed (softened) by heating it.
Unions—brass, ⅛″, and soldering connections for gasoline lines.
Valve caps—for leading engines, valve caps for tire valves.
Valve grinding compound.
Valves—for gasoline and oil lines, tire valves and oversize valves for engine.
Washers—punched, split, and brass.
Wire—copper, brass, spring, piano, and insulated.
Wire—for wiring cars, such as: primary flexible cable and secondary cable.

Copper Gaskets for Spark Plugs

S. A. E: ⅞″ (inside diameter ⅞″; outside diameter, 1⅛″).
Half inch: (inside diameter, 27/32″; outside diameter, 1 3/32″).
Metric: (inside diameter, 23/32″; outside diameter, 63/64″).

Assorted Piston Rings

For new and older model cars. Can be secured of piston ring manufacturer. See Index under "Piston ring sizes."

S. A. E. Flared Tubing Fittings and Couplings[1]

These are made of cast brass for use on carburetors, oil and gasoline pipe lines, etc.

FIG. 19

FIG. 20

Fig. 17. **Grease cups** ought to be carried in every stock room. The sizes of grease cups run as follows: 000—⅛″ pipe thread; 00—⅛″ pipe thread; 0—⅛″ or ¼″ pipe thread. The diameter of 000 is ¾″; 00 is 1″; and 0 is 1¼″.

Fig. 18. **Oil cups** run as follows: No. 1—¼ x 32 thread, ⅜″ diameter. No. 2—5/16 x 32 thread, 7/16″ diameter. No. 3—⅜ x 24 thread, ½″ diameter. No. 4—7/16 x 24 thread, 9/16″ diameter.

Fig. 19. **Oil cans** which are in demand.

Fig. 20. **Cotter pins:** An assortment of cotter pins, ¾″, 1″, 1¼″, 1¾″, and 2″ lengths.

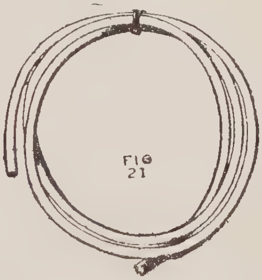

FIG 21

Fig. 21. **Brass tubing:** Annealed seamless brass, size ¼″, 5/16″, and ⅜″.

Fig. 22. **Armored cable:** This type of cable is used in all high-grade wiring installations. Conductor is standard copper No. 16 gauge insulated with rubber and varnished fabric. Sherardized protecting cover on outside. Diameter, 3/16″.

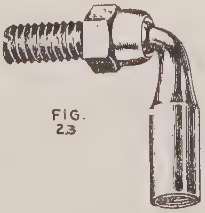

FIG. 23

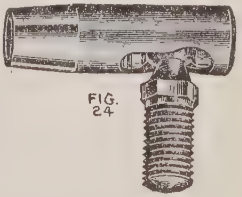

FIG. 24

Figs. 23, 24. **Spark and throttle ball-joints,** used for connecting magneto timer levers and carburetor throttle lever, with levers on steering wheel. They eliminate all lost motion and give more perfect control. The screw end fits the timer and carburetor lever; the tapped hole fits the connecting rod. They come 25 in a box, assorted (Stevens & Co.).

MONEY-MAKING ADDITIONS TO THE GARAGE

There are several departments which can be added to the garage, all necessary and well worth the investment.

Tire department: A small or large vulcanizer for repairing tires. See the discussion of the subject of "Tires."

A battery charging and repair department: For recharging, starting, lighting, and ignition batteries. See "Storage Battery" Instruction.

During the winter months, there is much more of such battery recharging work brought to the garages because the cold weather reduces the charge-holding capacity of the storage batteries, while at the same time the cold engines require more current from the batteries to start them.

Electric testing and repair department. See Index under "Electric testing and repairs."

Oxy-acetylene outfit: For welding and carbon cleaning, see index. Of course, with all this, more room will be necessary, but it is surprising in how small a space all these departments can be carried on, if properly planned.

Carbon cleaning outfits for removing carbon. See Index.

Radiator repairs. See Index.

There is quite a profit in handling lubricating oils, grease, and gasoline. If possible, an equipment for handling these should be added.

The car rental and towing service is something worth considering, and can be added in time.

Sell Supplies

A supply department is very remunerative, providing the proper supplies are carried.

It is necessary, however, to display your goods so that customers can see them and ask for them. Sales follow as a natural sequence. A very serviceable and attractive display bin is shown in Fig. 25. Fireproof metal bins are of course preferable to wood construction.

Ask for an illustrated booklet of the Walker Bin Co., Penn Yan, N.Y.

When the motorist drives up to your garage for gas or oil, or for air for his tires, give his car the quick once-over and see if you can't sell him some accessories.

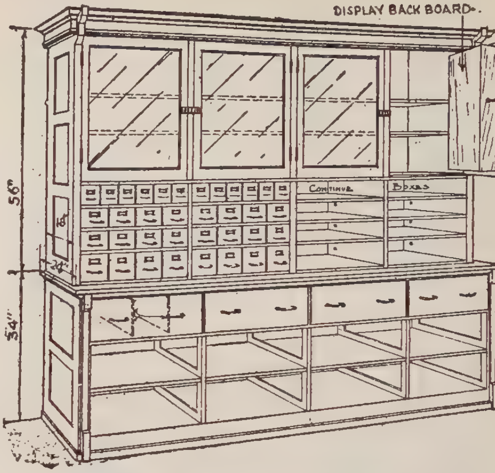

Fig. 25. Display bin for supplies.

When a motorist asks for an accessory, this should suggest something else that you can sell him. But it is not enough to ask him if he wants it. You have got to tell him why he ought to have it. That's what these selling arguments are for. Use them!

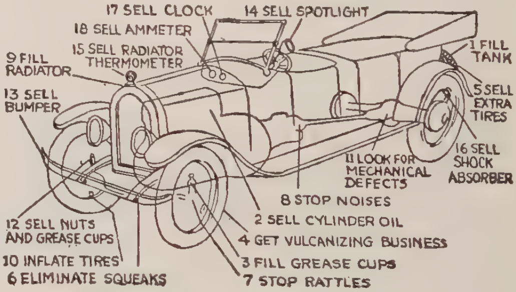

Fig. 26. Sales and service chart.

Fig. 26 shows a brief list of merchandise or auto supplies, etc., which the garage dealer ought to sell to his customers. The illustration is taken from *Motor World*, and is intended to be kept in front of the dealer that he may memorize the list.

ORPHAN CARS;[1] WHERE TO OBTAIN PARTS

A list of cars no longer manufactured and where the parts can be obtained follows:

Abbott: The Boneyard, Washington, Iowa; Auto Salvage Co., 1701–03 Main St., Kansas City, Mo.; Auto Salvage & Exchange Co., 1317–19 Locust St., Des Moines; Iowa; Auto Parts Co., 4116–18 Olive St., St. Louis, Mo.; Puritan Machine Co., 422 Lafayette Blvd., Detroit, Mich.; Standard Motor Parts Co., Detroit, Mich.

Adams: Longaker Co., V. A., 448–50 N. Capitol Ave., Indianapolis, Ind.

Aerocar: Auto Gear & Parts Co., 291–93 Marietta St., Atlanta, Ga.; Auto Salvage & Exchange Co., 1317–19 Locust St., Des Moines, Iowa.

Alco: Alco Service Co., 158–62 N. Twenty-Second St., Philadelphia, Pa.; Auto Salvage Co., 1701–03 Main St., Kansas City, Mo.; American Locomotive Co., Providence, R.I.; International Motor Co., West End Ave. and 64th St., New York, N.Y.; Levene Motor Co., 2200–18 Diamond St., Philadelphia, Pa.; Puritan Machine Co., 422 Lafayette Blvd., Detroit, Mich.

Alden-Sampson: Puritan Machine Co., 422 Lafayette Blvd., Detroit, Mich.; Standard Motor Parts Co., New Castle, Ind.

Allis-Chalmers: Puritan Machine Co., 422 Lafayette Blvd., Detroit, Mich.

Alma: Dayton Auto Parts Co., 1777 Broadway, New York, N.Y.

Alpena: Auto Gear & Parts Co., 291–93 Marietta St., Atlanta, Ga.; Auto Salvage & Exchange Co., 1317–19 Locust St., Des Moines, Iowa; Puritan Machine Co., 422 Lafayette Blvd., Detroit, Mich.

Alter: American Motors Parts Co., 430 N. Capitol Ave., Indianapolis, Ind.; Auto Gear & Parts Co., 291–93 Marietta St., Atlanta, Ga.; Puritan Machine Co., 422 Lafayette Blvd., Detroit, Mich.

American: American Motors Parts Co., 430 N. Capitol Ave., Indianapolis, Ind.; Purt Motor Car Co., W. J., Pico & Hope Sts., Los Angeles, Cal.; Longaker Co., V., 448–50 N. Capitol Ave., Indianapolis, Ind.

American Mors: St. Louis Car Co., 8000 N. Broadway, St. Louis, Mo.; Wichita Auto Wrecking Co., 805–809 W. Douglas Ave., Wichita, Kan.

American Underslung: American Motor Parts Co., 430 N. Capitol Ave., Indianapolis, Ind.; Auto Gear & Parts Co., 291–93 Marietta St., Atlanta, Ga.; Auto Salvage Co., 1701–03 Main St., Kansas City, Mo.; Longauer Co., V. A., 448 N. Capitol Ave., Indianapolis, Ind.; Puritan Machine Co., 422 Lafayette Blvd., Detroit, Mich.

Ames: Auto Gear & Parts Co., 291–93 Marietta St., Atlanta, Ga.; Auto Salvage & Exchange Co., 1317–19 Locust St., Des Moines, Iowa.

Amplex: Gillette Motors Co., Mishawaka, Ind.; Gorey & Co., Jos. C., 354 W. Fiftieth St., New York, N.Y.

---

A HOME GARAGE FOR ONE MACHINE

The home garage shown in Fig. 27 is designed for housing one machine, and to give a little space about it so that a person can clean the exterior of the automobile and do small repairs.

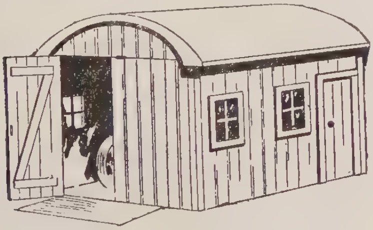

Fig. 27

The first thing to be considered is the foundation, or base, which is made of concrete (Fig. 28). The earth should be excavated for a depth of 6 inches, and to the exact dimensions given for the floor plan. The hole is then filled with cinders, well tamped in and leveled on top. A frame, about 4 inches high, is built up of cheap lumber, so that the space within measures 12 ft. wide and 16 ft. long, except at the double-door opening where a sloping runway is formed for the easy entrance of the automobile. A 2-inch layer of concrete—a mixture of 1 part cement, 2 parts sand, and 4 parts gravel, or crushed stone—is placed on top of the cinders, and a neat mixture of cement and sand, ½ inch thick, is placed on the concrete and made perfectly level. When putting in the concrete, ½-inch bolts, about 5 inches long, are set in the edge with the threaded end extended about 3 inches above the upper surface of the cement, and in line with the center of the 2 by 4 inch timber used as a sill. The detail of this construction is shown in the sketch. About four of these bolts should be set on each side, three on the end, and one on each side of the double doors.

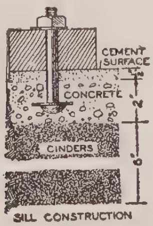

Fig. 28

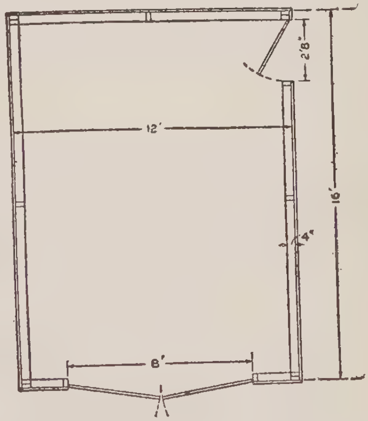

Fig. 29. Floor plan, showing the location of the sills, studs, and corner posts on the concrete floor.

The corner posts and studs are cut so that their length, together with the thickness of the sill and the two pieces for the plate, will measure 8 feet. This is the proper length to cut the boards without waste from standard lengths of lumber. After raising the corner posts and studs, and nailing the plate pieces on top, the siding boards are nailed on vertically to the plate and sill, and the battens are nailed over the joints.

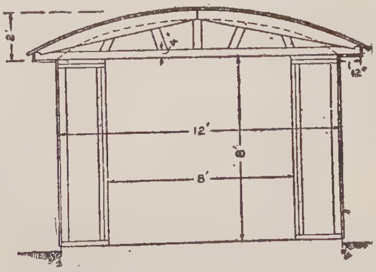

Fig. 30. End elevation, showing the rafter construction and the finishing facia boards on the eaves.

The rafters are built up in a manner similar to that used on large garages now so popular. Each one, or each pair, consists of a cross-piece that rests on top of the plates at the sides and is notched at the ends, to receive the ends of the convex rafter pieces. The pattern for one of these pieces, with dimensions, is shown in the drawing (Fig. 31). After the three main parts are fitted to form one rafter across the building, they are fastened together with short pieces of boards, which can be cut from scrap. The rafters are set on the plates 16 inches apart from center to center.

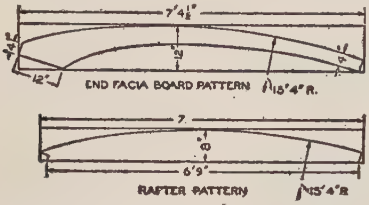

Fig. 31. Pattern layout for the rafter pieces and the finishing facia boards for the eaves at the ends.

The sheathing boards are nailed to the curved edges of the rafters lengthwise, and as the material list calls for boards 12 feet long, one and one-half lengths will cover the rafters and allow 1 foot projection at each end for the eave. The facia boards are cut on a curve in the same manner as the rafter pieces, and the under side is cut as shown in the detail, so as to make a neat-appearing connection to the end of the frieze boards. Straight facia boards are fastened on the eaves, at the sides, in the same manner, and a frieze board is nailed to the under side, the ends being finished, as shown in the detail drawing (Fig. 31).

Prepared roofing is fastened to the sheathing in the usual manner, beginning the layers at the eave and finishing in the center, allowing the center piece to overlap on both sides.

The windows consist of four single casements, two being placed on each side. These can be of any size to suit the builder, and can be bought from a mill ready to be set into the openings cut for them.

The doors can be made up of the same material as that used for the siding and battened together, or, if a more elaborate door is desired, they can be purchased at a reasonable price, paneled and with a glass in the upper part. If paneled doors are used, 18 boards can be deducted from the siding-material list. The double doors will require fastenings at the center, and, in placing the concrete floor, a keeper should be set in the surface cement for the foot latch. The upper keeper can be attached to the end rafter cross-piece. The usual hardware is necessary for the small door at the opposite end.

Material List

CONCRETE FLOORS

2 bbls. cement.
4.5. cu. yd. cinders.
2.2. cu. yd. sand.
4.3. cu. yd. gravel.

SILLS, PLATES, AND STUDS

6 pieces, 16 ft. long, 2 by 4 in.
4 pieces, 12 ft. long, 2 by 4 in.
20 pieces, 8 ft. long, 2 by 4 in.

SIDING

90 boards, 8 ft. long, ⅞ by 8 in.
90 battens, 8 ft. long.

RAFTERS

10 boards, 14 ft. long, ⅞ by 8 in.
10 boards, 14 ft. long, ⅞ by 4 in.

ROOFING

Enough sheathing boards, 12 ft. long to cover 260 sq. ft.
Enough prepared roofing to cover 260 sq. ft.

WINDOWS

4 single casements.

FINISHING PIECES

2 frieze boards, 18 ft. long, ⅞″ by 1 ft.
2 facia boards, 18 ft. long, ⅞″ by 4 in.
4 facia boards, 8 ft. long, ⅞″ by 1 ft.
8 corner boards, 8 ft. long, ⅞″ by 4 in.
6 door-facing boards, 8 ft. long, ⅞″ by 4 in.

HARDWARE

1 pair of door hinges.
1 door lock.
3 pairs of heavy door hinges.
1 foot latch.
1 upper latch.
1 large door lock.
10 lb. 20-penny nails.
20 lb. 8-penny nails.
10 bolts, with double washers, ½″ by 5 in.

A garage built up in this manner and well painted will last for years, and if it becomes necessary to move it, nothing will be lost except the concrete floor, as the building can be lifted from the bolts and taken away bodily. (*Popular Mechanics.*)

INSTRUCTION No. 62

THE REPAIR SHOP OR SERVICE STATION, and Its Equipment

EQUIPMENT FOR A SERVICE STATION

The repair shop can be incorporated as a part of the garage business, or as a separate enterprise. Where only repairing is done and supplies are sold with no storage, it is termed **a service station.**

The service station is divided into departments as shown in Fig. 1.

The 10 h.p. electric motor shown in the layout (Fig. 2) is designed to run at 1,800 r.p.m. This will give the line shafting a speed of 400 r.p.m. With a 20″ pulley on the shaft to drive the grinder, the latter will run at 2,000 r.p.m., which is about 4,000 ft. per minute surface speed for an emery wheel 7″ in diameter.

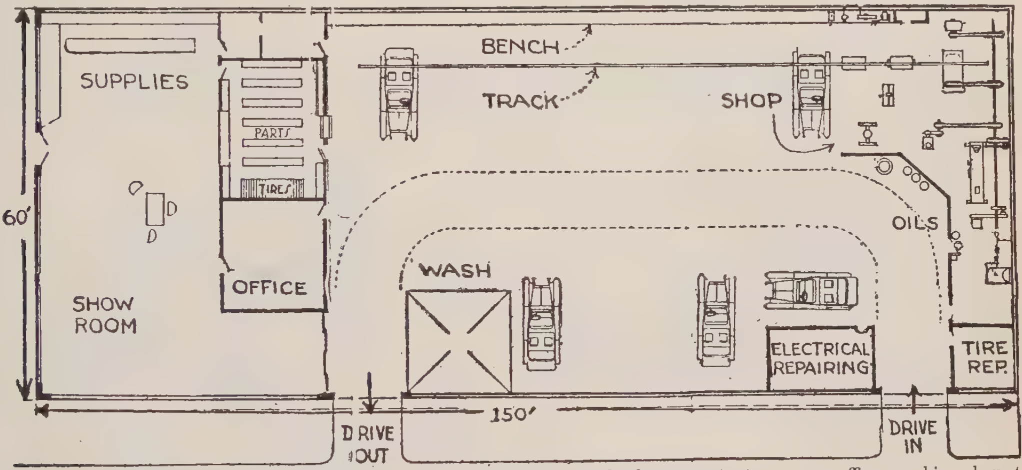

Fig. 1. Illustrates the layout for arranging a one-floor salesroom, supply department, store room, office, machine shop, tire repair, and electrical repair department as suggested in *Motor Age.*

Measurements are 60 ft. wide and 150 ft. long. Note the "drive in" and "drive out," also the track for the chain hoist to lift the engine from the frame to the work bench. Note further the space partitioned off for electrical repairing, tire repairing, and battery charging.

The air compressor driven by an individual electric motor instead of from the line shaft is shown in Fig. 2. The first cost of a 2 h.p. electric motor required to drive the compressor will be a little more, but we believe this will be absorbed in the saving of current. Furthermore, there is the advantage of

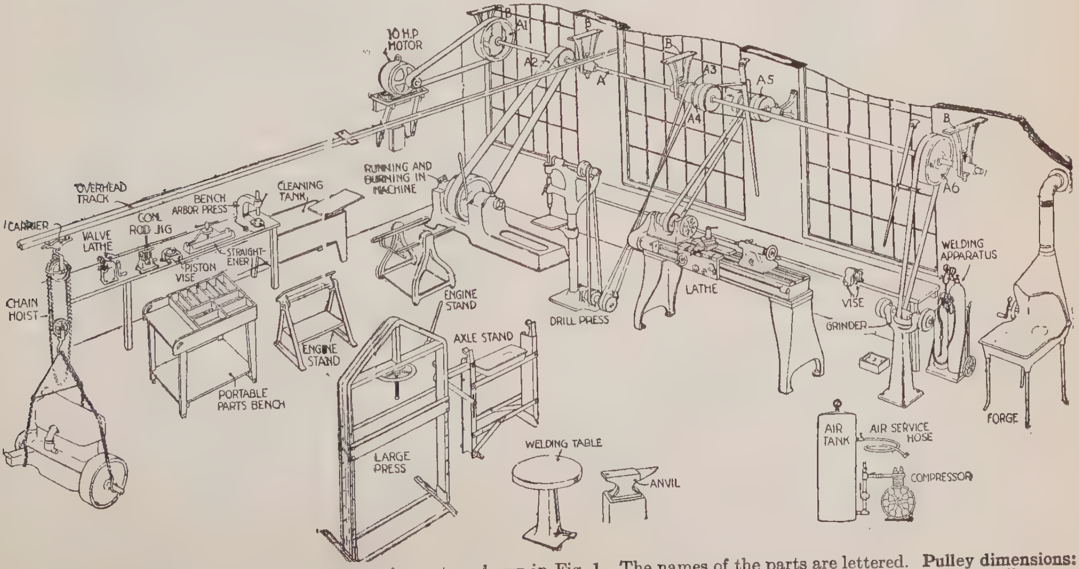

Fig. 2. Layout of the machine shop equipment as shown in Fig. 1. The names of the parts are lettered. **Pulley dimensions:** **(A)** line shaft 1½″; **(A1)** 32″; **(A2)** 20″; **(A3)** 7″; **(A4)** 10″; **(A5)** 14″; **(A6)** 20″; electric motor, 8″; grinder pulley 4″.

automatic starting and stopping, which cannot be done when the outfit is driven from the line shaft. A service station needs compressed air all the time, but it is not economy to keep a 10 or 15 h.p. motor going just for the air line.

Machine Tools and Equipment of Shop Shown in Figs. 1 and 2

Line shaft, 30 ft. long, 1½″ dia.	$ 11.00
Adjustable hangers	20.40
Electric motor, 10 h.p. Lathe countershaft, included in lathe price	335.00
Burning and running-in machine with fittings	490.00
Drill press, 14″	85.00
Lathe, 11¼″ swing over carriage	818.00
Grinder	33.00
Welding table	70.00
Forge	27.00
Welding apparatus	90.00
Anvil	15.00
Air compressor outfit	247.00
Axle stand	36.00
Engine stand	50.00
Engine stand	49.00
Overhead track, 100 ft. with brackets	48.00
Overhead carrier and hoist	34.00
Valve lathe	3.75
Connecting-rod jig	30.00
Piston vise	10.00
Crank-shaft straightener	34.00
Bench arbor press	35.00
Cleaning tank	40.00
Large press	76.50
Total	$2,687.65

These prices are approximate only. Write the Service Station Equipment Co., Chicago, Ill., or the Continental Auto Parts Co., Columbus, Ind., or to any of the auto supply jobbers for catalogs, if interested.

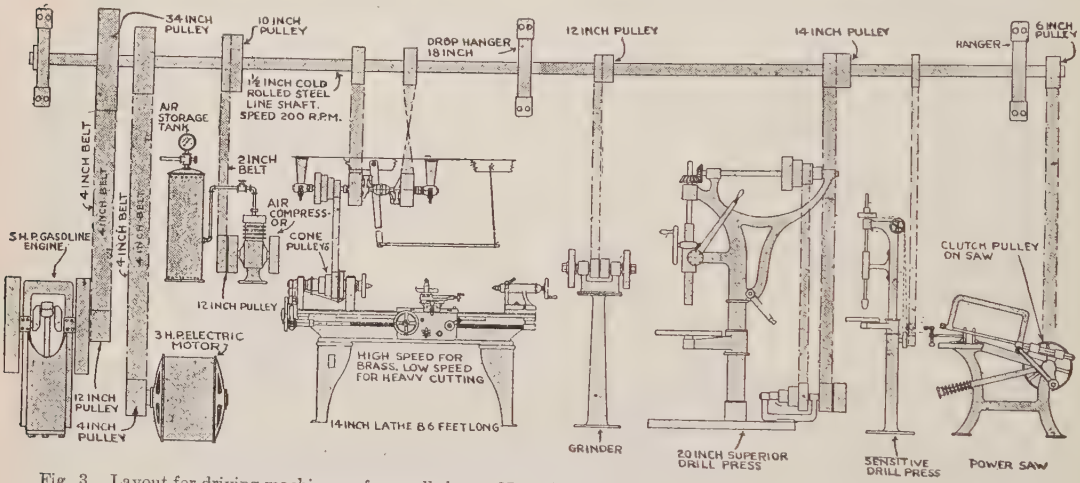

Fig. 3. Layout for driving machinery of a small shop. Note that either an electric motor or gasoline engine can be used.

ANOTHER MACHINERY EQUIPMENT FOR A SMALL SHOP

In Fig. 3 we have laid out a standard line of machinery suitable for a machine shop. The line shaft is arranged in a straight line, whereas in close quarters it may be necessary to place two line shafts.

Although a gasoline engine and an electric motor for power are both illustrated, only one is necessary; both are shown in order to explain the method for belting if one or the other is used. The electric motor is usually placed on the ceiling, or on a post or wall.

The gasoline engine ought to be equipped with a clutch in the drive pulley or in the pulley on the line shaft.

Approximate Prices

1—20″ superior drill press	$ 60.00
1—14 in. x 6 ft. lathe	234.00
1—emery stand with two 6 x 1 wheels	5.30
1—sensitive drill press for small work	60.00
1—Marvel No. 1, power-shop saw	15.00
25 ft. line shafting and 4 drop hangers and belting	50.00
Compressed-air outfit, belt driven from line shaft	43.75

We will assume that the electric motor is rented from the electric company. If not, add about $100 for the electric motor or gasoline engine.

For a large shop an 18″ swing, by 12 ft. lathe, is best..$400.00

To Find Diameter of Pulleys

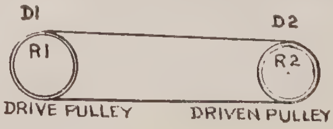
To find the diameter of the driver, the diameter of the driven and its revolutions, and also the revolutions of the driver being given: Multiply the diameter of the driven by its revolutions, and divide the product by the revolutions of the driver; the quotient will give the diameter of the driver.

To find the diameter of the driven, the revolutions of the driven, also diameter and revolutions of the driver being given: Multiply the diameter of the driver by its revolutions, and divide the product by the revolutions of the driven; the quotient will give the diameter of the driven.

To find the revolutions of the driver, the diameter and revolutions of the driven, also the diameter of the driver being given: Multiply the diameter of the driven by its revolutions and divide the product by the diameter of the driver; the quotient will give the revolutions of the driver.

To find the revolutions of the driven, the diameter and revolutions of the driver, also the diameter of the driven being given: Multiply the diameter of the driver by its revolutions and divide the product by the diameter of the driven; the quotient will give the revolutions of the driven.

The same rules may be applied to gearing by using the number of teeth instead of the diameter. See also page 624.



D1 × R1 ÷ D2 = R2.
D1 × R1 ÷ R2 = D2.
D2 × R2 ÷ R1 = D1.
D2 × R2 ÷ D1 = R1.
D1 represents diameter of driver.
D2 represents diameter of driven.
R1 represents revolutions of driver.
R2 represents revolutions of driven.

Fig. 4

MISCELLANEOUS MACHINERY, TOOLS, ETC.

The machinery equipment, together with a list of machinery necessary for a large or small shop, is given in the matter preceding.

Equipment for a fairly large shop in which almost any work can be done is shown on page 691.

Equipment for a smaller shop in which all average work can be done is shown on page 692.

An air compressor outfit is important. The air pump could be operated from the line shaft, but if in active use it would be best to run it from a separate electric motor. See Index under "Air compressors."

The battery charging outfit could consist of a motor-generator set. See Index.

For a still smaller shop, a Tungar or other type rectifier could be used instead of a motor-generator set, together with testing outfits for storage-battery work. Electrical testing instruments of smaller size costing less money, will suffice where there is not very much work to be done.

The cost of the tire repair outfit could also be reduced by obtaining a smaller outfit, as suggested in the discussion on the tire repair subject.

Power to run the machinery may be a gasoline engine or an electric motor. The electric motor is more convenient, and can, in many cities, be rented from the electric company.

Work benches should always be placed next to windows where there is light. Such a bench should measure at least 8 or 10 feet long, height about 3 feet, and width 2 ft. 6 in. and be made of 2-in. thick, well-seasoned pine, or, better, birch.

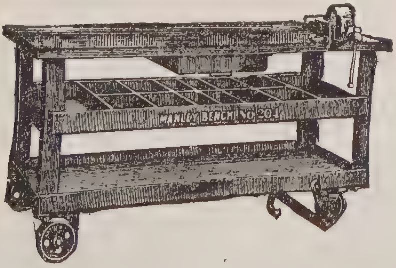


Fig. 5. **The Manley portable work bench,** or floating repair shop. In repair shops the stationary benches are built along the wall, and are located at considerable distance from the car upon which work is being done. This necessitates many steps, consuming time and the energy of the workman, all of which is saved by placing the bench at the car. Manley portable work benches are of a substantial construction, with hardwood top, steel drawer, shelf partitions of seasoned wood, roller-bearing casters, and provision is made for locking wheels. Made in two sizes. (Manley Mfg. Co., York, Pa.)

Lathes

The choice of a lathe depends upon the amount of work and kind of work one proposes doing. If equipment is desired capable of making repairs on axles, axle housings, and fly wheels, then a 16-in. swing 8 ft. bed lathe would be recommended.[1]

A smaller lathe for work on bearing bushings, pins, grinding piston pins and bolts, a lathe with a 4 ft. bed and 6 in. swing is required.

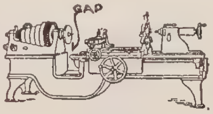

Fig. 6

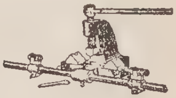

Fig. 7

Fig. 6. **Gap-bed lathe.** The distinguishing feature of this lathe is that the guides near the lathe head are cut away, thereby increasing considerably the size of the swing, without increasing the other dimensions. It is possible to handle much larger work with this style than could be handled on the regular type of the same dimensions.

Fig. 7. **A shaft-straightening press.** While this press is made mainly for straightening shafts, it is applicable for axle straightening as well. A tremendous power can be brought to bear by the action of the long lever and heavy screw. A section of perfectly true shafting is centered bewteen the adjustable tail stocks and is used as a guide or measuring point as the shaft is being straightened.

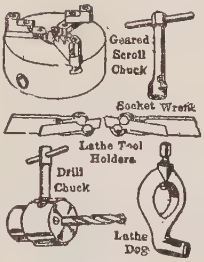

Fig. 8

Fig. 8. **Lathe tools:** 5″, 3-jaw geared scroll chuck; socket wrench ⅜″, ½″, and ⅝″; lathe tool holders 4″, to be used with 14″ lathe; drill chuck with Nos. 1 and 2 arbor to hold drills up to ½″; lathe dogs, ½″, 1″, 1½″ each.

Drill Press

A large drill press, of back-geared type, with a 16″ table, for work such as reaming cylinders, drilling holes in frames, etc. will be required.

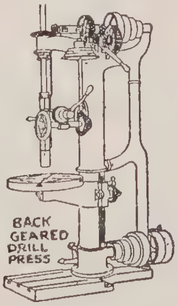

Fig. 9. **A back-geared drill press.** The advantage of the back-gear feature is obvious, as it is often very desirable to reverse the direction of rotation of a drill.

A sensitive drill press for light work, such as drilling cotter-pin holes, small shafts and rods, such as those on the steering device, timer, etc., is very necessary.

Some of the manufacturers of drill presses are: Barnes Drill Co., Rockford, Ill.; W. P. Davis Co., Rochester, N.Y.; Champion Blower and Forge Co., Lancaster, Pa.; Canedy-Otto Mfg. Co., Chicago Heights, Ill.

Portable electric drills are very handy for drilling holes in frames for attaching shock absorbers, horns, mufflers, etc. See page 700.

---

[1] "How to Run a Lathe" and "First-Year Lathe Work" are two 64-page pamphlets, fully illustrated, which will be supplied to readers of this book for 10c. each. Address South Bend Lathe Works, South Bend, Ind., and mention the fact that you have this book. See advertisements of various lathes in the back of this book.

Power Hack-Saw

Power hack-saws are used for cutting all kinds of metal. They are made self-feeding with an automatic stop.

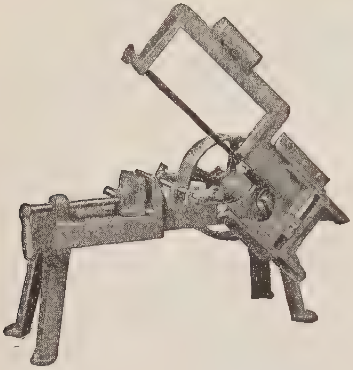

Fig. 10. This **power hack-saw** is especially designed and built for garage service. It is small enough to mount on a bench, if desired. It has a cutting capacity up to 4″ x 4″. It is well built, is equipped with an automatic stop, using a 9″ blade, and has all the features of the highest priced power hack-saw. (Manley Mfg. Co., York, Pa.)

Manufacturers are: The Manley Mfg. Co., York, Pa.; West Haven Mfg. Co., New Haven, Conn.; Millers Falls Co., Millers Falls, Mass.; Goodell Pratt Co., Greenfield, Mass.

Chain Hoist

The chain hoist can be secured in capacities of from ¼ to 1 ton, suitable for general automobile work. The lift varies from 6 ft. for the ¼-ton, 7 ft. for the ½-ton, and 8 ft. for the 1-ton capacity.

Manufacturers are: Edwin Harrington Sons & Co., Philadelphia, Pa.; Wright Mfg. Co., Lisboro, Ohio.

Emery Wheels and Stand

The emery wheel is used principally for finishing up tool work, taking off metal, and also for buffing and polishing brass parts. Two emery wheels, No. 40 and No. 60 grade at least, should be secured, and also cloth buffers for polishing.

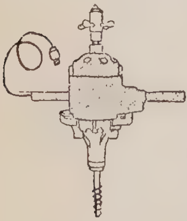

Fig. 11

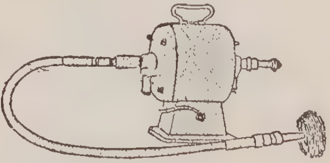

Fig. 12

Fig. 11. **A portable electric drill.** One of the handiest devices in the shop. See also page 700.

Fig. 12. A portable electric buffing machine.

A very compact electric emery wheel and buffer is made by the LeBron Electric Works, Omaha, Neb.

Machines for Cylinder Work

For cylinder enlarging work, a grinder, boring machine, or reamer is used. See Index for "Cylinder grinding."

Concerns manufacturing cylinder reboring machines and tools are: Storm Mfg. Co., Minneapolis, Minn.; Barnes Drill Co., Rockford, Ill.; South Bend Lathe Works, South Bend, Ind.; Sunderland Machine Shops, Omaha, Neb.

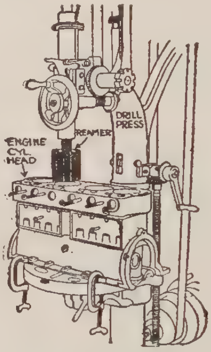

Fig. 13

Fig. 13. **A cylinder reaming machine for enlarging cylinders.** The reamer is built up with inserted blades and fitted with a No. 4 Morse taper shank. It can be used in any ordinary drill press which is geared down to run about 30 r.p.m.

The use of **cylinder grinders** for grinding cylinders to enlarge them instead of boring or reaming, is considered the best practice. See Index. The Heald Machine Co., Worcester, Mass., manufactures grinding machines, and also issues a very instructive catalog on the subject.

Blacksmith Equipment

Almost every shop needs some sort of a blacksmith equipment, even though it is only a small outfit, as shown below.

If a forge which burns coke or coal is used, it should be under a separate roof or piped, so that the smoke will pass outside. Gas is used quite extensively for heating purposes. Supplies of this nature can be secured of automobile supply houses.

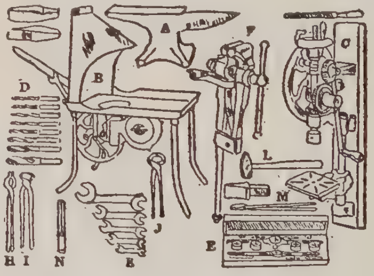

Fig. 14. **Blacksmith equipment:** (**A**) anvil, 100 lb.; (**B**) forge with 12″ fan, 25″ x 36″ hearth; (**C**) post drill; (**D**) drills ⅛″ to ¾″; (**E**) screw plate set; (**F**) blacksmith vise; (**H**) flat-lip tongs; (**K**) flat wrenches; (**L**) 3-lb. hammer.

INSTRUCTION No. 63

SMALL TOOLS FOR THE SHOP: Wrenches, Flat and Socket Type; S.A.E. Cap Screw and Bolt Sizes; U.S. Standard Bolt Sizes; Tap and Die Sets; Portable Electric Drills; Electric Bench Grinder

Some of the necessary small tools are shown on this and the pages following.[1] Farther on, explanations are given as to the use of small tools. These can be secured of automobile supply houses.

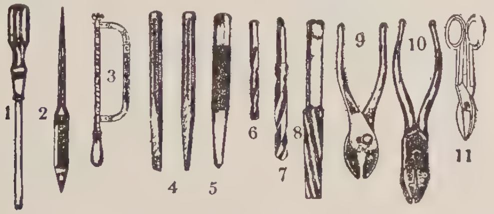

Fig. 1. (1) screwdriver; (2) soldering iron; (3) hack-saw; (4) chisels; (5) center punch; (6) straight shank drill (for hand and breast drill); (7) taper shank drill (for drill press); (8) reamer; (9) gas pliers; (10) cutting pliers; (11) tinners shears.

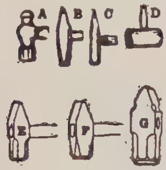

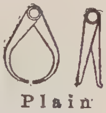

Plain calipers.

Fig. 3

Fig. 4

Fig. 5

Fig. 2. **Hammers:** (A) machinist's ball pein; (B) riveting; (C) tinner's riveting; (D) rawhide mallet; (E) engineer's hand hammer; (F) blacksmith's hand hammer; (G) blacksmith's sledge.

Fig. 3. Stillson pipe wrench.

Fig. 4. Monkey wrench.

Fig. 5. Adjustable flat wrench.

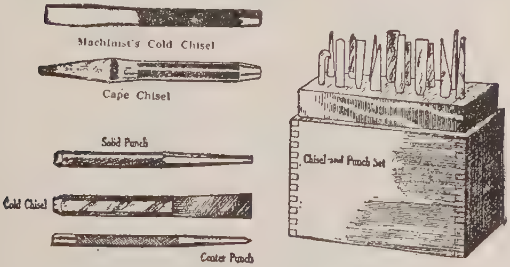

Fig. 6. **A center punch** is used to punch center marks in metal parts to be drilled, giving the drill a center to start in, and for reference marking, etc.

Chisels are made in many forms. The most popular is the cold chisel which is used for cutting metals. A cape chisel is the next most popular, and is used for cutting key ways and working in narrow grooves, channels, etc.

The diamond point chisel is used mostly for grooving in close places where a cape chisel could not be used.

Other popular chisels are round nose or gouge, used for cutting oil grooves in bearings and chipping out broken bolts or pipe threads from fittings. An assortment of small chisels and punches is shown in the illustration.

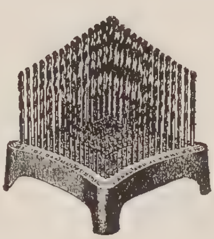

Fig. 7

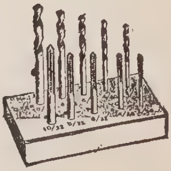

Fig. 8

Fig. 7. Set of straight shank drills for hand, breast, or bench drill—from No. 1 to 60. See Index under "How to read drill sizes."

Fig. 8. Tap and drill set for average small work, such as on lamps, speedometers, horns, etc. Tap sizes are 2/56"; 4/40"; 6/32", and 10/32", with drills to match. See Index under "How to read marks on drills."

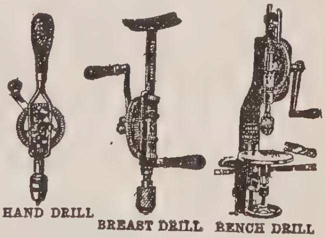

Fig. 9. Three types of hand-drilling machines are shown above, intended for light work.

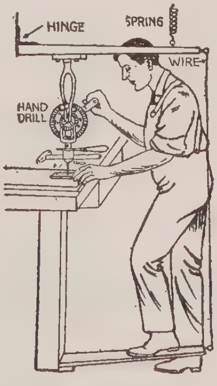

Fig. 10. Showing a method of applying pressure to an ordinary hand drill. The hand drill is attached to a bar, as shown. The bar is hinged to the wall.

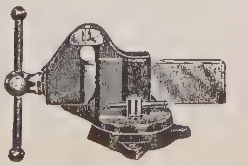

Fig. 11. Vise. Note that the swivel-base 4" or 6" jaw is generally used for average small work. A larger vise is also necessary.

---

[1] **The Webster Magnet Light** is indispensable when night repair work around a car is necessary. It consists of a 4 c.p. light with reflector and 12 feet of cord which permits reaching any part of the car. The plug is inserted in the dash light socket. The main feature of this light is that it will "stick where stuck." It will hold tenaciously to any iron or steel surface, curved or flat, on fenders, axle housing, or engine. It exerts a pull of 3 lbs. and operates from the battery. Manufactured by the Webster Electric Co., Racine, Wis.; price $2.50.

List of Small Tools and Approximate Prices as Suggested by "Motor Age."

Wrenches	Price
18″ pipe wrench	$ 2.10
12″ pipe wrench	1.60
6″ pipe wrench	1.15
18″ monkey wrench	2.55
12″ monkey wrench	1.45
6″ monkey wrench	.95
Set double-end S-wrenches	2.30
Set 15° double end	2.45
Spark-plug socket	.60
Ratchet-handle socket set	24.00
Adjustable 6″ end wrench	1.00
Adjustable 8″ end wrench	1.20
Narrow-jaw monkey wrench	.85
Set speedwrenches	7.00

Files	
12″ bastard cut, flat	$ 0.56
12″ bastard cut, half round	.75
10″ bastard cut, round	.45
10″ bastard cut, square	.52
10″ bastard cut, three cornered	.50
8″ second cut, flat	.40
8″ second cut, half round	.50
8″ finishing cut, flat	.40
8″ finishing cut, half round	.52
8″ finishing cut, three cornered	.38
8″ finishing cut, rat tail	.70
6″ finishing, flat	.36
File for contact points	.20
File brush and handles	1.30

Measuring Tools	
24″ carpenters' square	$ 2.30
6″ machinists' square	3.80
Carpenter's 2 ft. rule	.45
Machinist's 12 in. scale	1.95
Machinist's 6 in. scale	.95
Machinist's 2 in. scale	.40
Combination protractor and square, 18 in.	6.85
Spirit level	.85
Thread gage	2.90
Thickness gage	2.65
Small and large external calipers	3.40
Small and large internal calipers	3.40
Small and medium spring dividers	2.75
Friction joint dividers, large	.90
Internal micrometer and extensions	10.60
Micrometer, 3″	16.90
Micrometer, 2″	15.25
Micrometer, 1″	10.40

Shears	
Tinner's snips	$ 1.40
Heavy shears	2.10
Bolt cutters	2.00

Hammers	Price
Rawhide mallet	$ 1.65
Lead hammer mold	2.10
Straight pein, 4 oz.	.65
Ball pein, ½ lb.	.80
Ball pein, 1 lb.	1.00
Ball pein, 2 lb.	$ 1.40
Blacksmith's sledge, 12 lb.	3.60
Blacksmith's, 4 lb.	1.20

Screwdrivers	
Small jeweler's	$ 0.40
6″ blade	.85
10″ blade	1.20
12″ blade	1.75
Offset	.80
T-handle, large	2.30

Bench Equipment	
Small bench anvil	$ 3.60
Swivel vise	17.00
Medium pipe vise	3.70
Surface plate	5.40
Machinist's clamps	7.00
C-clamps	8.00
Surface gage	2.50
Straightedge	4.20
Scriber	3.65

Chisels	
Cape, large	$ 0.35
Cape, medium	.25
Cape, small	.20
Chipping, large	.40
Chipping, medium	.35
Chipping, small	.20
Round nose, large	.40
Round nose, medium	.35
Round nose, small	.25
Cotter pin puller	.15
Diamond point, large	.40
Diamond point, medium	.30
Diamond point, small	.20
Center punch, large	.45
Center punch, medium	.30
Center punch, small	.20
Drift pins, 1/16″ to ¾″ by 16ths	2.40

Pliers	
Combination 8″	$ 1.50
Combination 6″	1.30
Piston ring expanding	1.15
Side-cutting, parallel jaws	1.40
Cotter pin	1.10

Miscellaneous Tools	
Wheel and gear pullers	$18.00
Valve spring lifter	2.00
Breast drill, two-speed	11.50
Valve seat reamer set	70.00
Soldering copper, large	2.75
Soldering copper, small	1.00
Gasoline blow torch	6.00
Hand drill, small	2.50
Belt punch	.60
Hacksaw frame and blades	2.50
Small hand vise	3.50
Oil stone	2.50
Three bearing scrapers	1.85
Three carbon scrapers	1.10
Pickup pliers	.85
Gasket cutter	13.50
Portable electric drill and valve grinding attachment	110.00
Piston ring compressor	.45
Total	$487.89

Open-End Flat Wrenches

Probably the most abused, the least considered, and yet the most indispensable tool in the kit of the mechanic is the wrench, the solid open-ended wrench, known to the British mechanician as the "fixed spanner," and known in the United States as the "machinist's" wrench.

Of the many kinds of wrenches, the cheapest, strongest, most efficient, and most durable is the open-end wrench. This style of wrench varies in quality and price in the following order: gray iron castings, malleable iron castings, sheet steel stamped, and steel drop forgings. The drop-forged wrench is superior. See illustrations for proper name of the popular type of open-end wrenches.

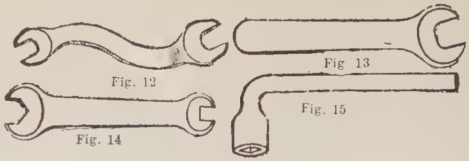

Fig. 12. The popular "S"-wrench.
Fig. 13. Engineer's single-end wrench.
Fig. 14. Double-head engineer's wrench, machinist's type.
Fig. 15. Socket-type wrench, with bent handle.

Open-end wrenches are used on cap screws, bolt heads, and nuts.

They may be divided into two general classes: **the U. S. S., and S. A. E.** The only difference between them is the width of opening between the jaws.

A standard wrench for a ½″ U. S. S. bolt will not fit a ½″ S. A. E. cap screw, and vice versa.

The S. A. E. wrenches are usually of the **"cap-screw size"** and the U. S. S. wrenches are of the **"U. S. S. bolt and nut size."** The Tables 1 and 2 explain this, and also give the various sizes for automobile work. The head is always larger on a U. S. S. bolt than on a cap screw.

Markings: Wrenches are usually marked with the size on each end. They are also marked with the manufacturer's number; this number is an indication of its size (see Tables 1 and 2).

Explanation of Tables 1 and 2

The first columns in each table give the trade number of Williams wrenches, and those sizes marked (*) are those most used for auto work. See Tables 1 and 2.

The second columns in each table give the actual diameters of the body of the bolts and cap screws.

The third columns in each table give the milled (or actual) opening size of the wrench at each end, and are the sizes suitable for the heads and nuts, with allowance for an easy fit.

Table 1

Number	For U. S. Standard Nuts Size Bolts	Openings Milled
21	1/8 & 3/16	5/16 & 13/32
22	1/8 & 1/4	5/16 & 1/2
•23	3/16 & 1/4	13/32 & 1/2
24	3/16 & 5/16	13/32 & 19/32
25	1/4 & 5/16	1/2 & 19/32
26	1/4 & 3/8	1/2 & 11/16
•27	5/16 & 3/8	19/32 & 11/16
28	5/16 & 7/16	19/32 & 25/32
•29	3/8 & 7/16	11/16 & 25/32
30	3/8 & 1/2	11/16 & 7/8
31	7/16 & 1/2	25/32 & 7/8
•32	7/16 & 9/16	25/32 & 31/32
•33	1/2 & 9/16	7/8 & 31/32
34	1/2 & 5/8	7/8 & 1 1/16
35	9/16 & 5/8	31/32 & 1 1/16
36	9/16 & 3/4	31/32 & 1 1/4
37	5/8 & 3/4	1 1/16 & 1 1/4
•38	5/8 & 7/8	1 1/16 & 1 7/16
39	3/4 & 7/8	1 1/4 & 1 7/16
40	3/4 & 1	1 1/4 & 1 5/8
41	7/8 & 1	1 7/16 & 1 5/8
42	7/8 & 1 1/8	1 7/16 & 1 13/16
43	1 & 1 1/8	1 5/8 & 1 13/16
44	1 & 1 1/4	1 5/8 & 2
45	1 1/8 & 1 1/4	1 13/16 & 2

Probably the most universally used wrench is the Williams wrench. See notes at foot of Table 2.

To find the size of wrench to fit an S. A. E. cap-screw head, consult Tables 3 and 2.

To find the size of wrench to fit a standard bolt and nut, see Table 4, and refer to Tables 1 and 2 for additional information.

Table 2

	Number	For Hexagon Head Cap Screws; Diameter Screws	Openings, Milled
*	721	1/8 & 3/16	5/16 & 3/8
	722	1/8 & 1/4	5/16 & 7/16
	723	3/16 & 1/4	3/8 & 7/16
	723A	3/16 & 5/16	3/8 & 1/2

	730	7/16 & 9/16	5/8 & 13/16
	731	1/2 & 9/16	3/4 & 13/16
	731A	1/2 & 5/8	3/4 & 7/8
*	731B	9/16 & 5/8	13/16 & 7/8
	732	9/16 & 3/4	13/16 & 1
	733	5/8 & 3/4	7/8 & 1
	734	5/8 & 7/8	7/8 & 1 1/8
	735	3/4 & 7/8	1 & 1 1/8
	736	3/4 & 1	1 & 1 1/4
*	737	7/8 & 1	1 1/8 & 1 1/4
	738	7/8 & 1 1/8	1 1/8 & 1 3/8
	739	1 & 1 1/8	1 1/4 & 1 3/8
	739A	1 & 1 1/4	1 1/4 & 1 1/2
	739B	1 1/8 & 1 1/4	1 3/8 & 1 1/2

The foregoing list is Williams double-head open-end wrench.

Nos. 21 to 45 will fit U. S. standard nuts and bolt heads.

Nos. 721 to 739B will fit cap-screw heads (U. S. or S. A. E.).

S. A. E. Cap-Screw and Bolt Sizes

Table 3 gives the diameter of cap screw (D); threads per inch (P); thickness of head (A1); diameter across flats of nut or head—where wrench fits (B); size of drilled hole for cotter pin for castellated nut (E); depth of slot in head (I); width of slot (K); diameter of cotter pin (d). The diameter of bolts and cap screws is one one-thousandth of an inch less than the nominal diameter.

Fig. 16. Walden's No. 100 thin wrench set for close places, check nuts, etc. Sizes are: 1"; ⅞"; ¾"; ⅝"; 9/16"; ½"; 7/16"; ⅜"; 3/16"; and ⅛" (actual width of opening; Walden Co., Worcester, Mass., or automobile supply jobbers).

Fig. 17

Fig. 17. Williams spark-plug wrench: No. 993, socket end fits ⅞" and ½" spark plug with ⅞" hex. and ½" U. S. standard nut. The open end fits a ⅜" S. A. E. nut or screw and a ⅜" U. S. S. cap screw (9/16" actual opening). No. 994 size, socket end, fits spark plugs with 1" hex. Open end is ⅞" actual opening. (J. H. Williams Co., Brooklyn, N.Y.

S. A. E. spark-plug shell dimensions are given elsewhere; see Index.

S. A. E. spark plugs are all ⅞-18, meaning that the outside diameter is ⅞", and there are 18 threads to the inch. See page 235 for difference in spark-plug threads and explanation of spark-plug sizes. **Gaskets must be used with the S. A. E. spark plugs.**

A ⅞" **S. A. E. spark plug requires a special tap** cutting 18 threads, whereas the standard S. A. E. ⅞" thread is 14 threads to the inch.

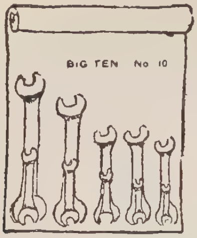

Fig. 18. Williams "Big 10" wrench assortment for general automobile work. Note the sizes in the table (Table 5). This is a recommended assortment taken from the list in Tables 1 and 2. The St. Louis Machinist's Supply Co., St. Louis, Mo., carries a full line of these wrenches, as do other supply houses.

Table 5

Socket Wrenches

Probably the handiest wrench to use for all nut and bolt work about a car is the socket wrench.

Socket wrenches are made with handles attached (Fig. 19), and in sets or singly, to which a ratchet lever is fitted (Fig. 20).

Socket Wrenches with Handles Attached

There are a number of different makes of wrenches of this type. The Walden Co., Worcester, Mass., manufactures a very extensive line. The wrenches can be purchased in sets or singly.

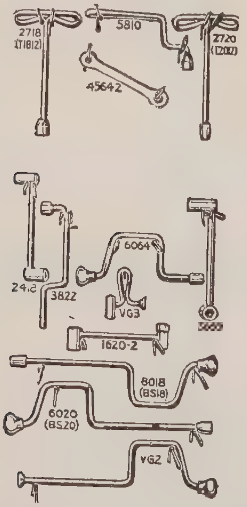

Fig. 19. **The Walden socket-wrench set showing some of** the different shaped handles which are designed for reaching nuts on certain parts of an engine or car. For example, the **set shown is for a Ford.** No. 2178 wrench is designed to reach the clutch release; No. 5810 is for the connecting rod; No. 2720 is for the brake shoe; No. 2418 is for the clutch lever, and so on. Sets such as the one shown are made for all parts of Ford, Chevrolet, Overland 4, Maxwell, and other cars. Can be secured of automobile supply houses, or the manufacturers, the Walden Co., Worcester, Mass.

Ford Socket Wrenches with Handles

The list below gives the Walden number of the socket wrench designed for each different part of a Ford, as itemized. The wrenches are designed to fit the nuts on the parts mentioned.

Front Axle

Ball socket	6018–2418
Front radius rod	5660
Front spring clip	2418
Front spring hanger	5660
Front spring perch	5660
Spindle bolt	5660
Spindle bolt nut	2418
Spindle connecting rod	5660
Steering yoke clamp	2418

Rear Axle

Axle housing	6064–1620
Brake-shoe support	1620–2418
Differential case	2418
Differential drive gear	1620–6064
Drive-shaft roller bearing	2720–1620
Hub nut	5660
Radius rod	5660
Rear-spring clip	5660
Rear-spring hanger	5660
Rear wheel to brake drum	5660

Engine

Carburetor flange (on cars without self-starter)	1018
Commutator-case support	6018–2718
Commutator-case support (on cars with self-starter)	6020–2720
Connecting rod	1020–5810
Crank case	6018–2718
Crank-case arm	2418
Crank-case lower cover	1620–6064
Crank-shaft bearing	1881–2418
Cylinder cover	6018–2718
Cylinder cover (on cars with self-starter)	6020–2720
Cylinder head	6020–1020–1620
Cylinder-valve cover	1018
Fan adjustment	6018–2718
Fan bracket	2418
Fly wheel	3822
Inlet and exhaust clamp	1018–2418
Magnet	6018–2718
Motor support, front	6020–1621
Piston-pin locking screw	1880
Radiator support	2718–2418
Valves	VG–2 VG–3
Water cyl. inlet conn.	1020–1620
Water cyl. outlet conn.	1620

Steering Assembly

Steering-post bracket	2418
Steering-tube flange	6064

Transmission

Brake adjustment	4564
Brake and reverse support	2418
Clutch-pedal support	2418
Controller shaft, bracket	2418
Hub brake-rod support	1620
Reverse adjustment	4564
Transmission cover	6018
Universal ball cap	1018–2718–2418

Miscellaneous

Body bracket	5660
Dash bracket to dash	1620–6064
Front fender iron	2418
Muffler	1620–6064
Running board	1881
Running board to fender	1881

Walden No. 23 Garage Service Set

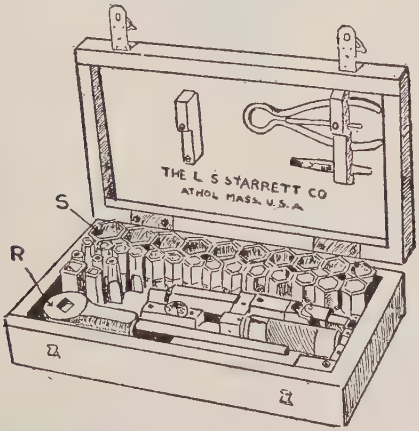
The No. 23 garage service set is especially adapted for general use on different cars. It will take care of the parts on the front axle, rear axle, and motor unit of the following cars: Dodge, Buick, Chevrolet Model "490," Cadillac, Nash, Hudson, Oakland Model "34-C," Essex, Marmon, Dort, Chevrolet Model "BH."

This set makes thirty-eight combinations and sells for $22.00. The manufacturers are the Walden Co., Worcester, Mass., or it can be secured of the supply houses.

Socket Wrenches and Ratchet Levers

Socket wrenches are often purchased in sets, that is, the sockets (S) (Fig. 20) which fit the nuts or cap screws are made in a variety of sizes, thus giving a very large assortment in a small case.

The socket is operated on the nut by the ratchet lever (R) and if the nut or cap screw is in an inaccessible place, such as a cylinder stud nut, an extension bar, which is included in the set, can be placed between the socket and ratchet lever.



THE L S STARRETT CO
ATHOL MASS. U.S.A
S
R

Fig. 20. **Starrett socket ratchet wrench set.** With this set one can reach nuts in inaccessible places and at an angle; has 28 hexagon steel sockets from 1/16" to 1", also 1 1/32", 1 5/32" and 1 9/32". Drill attachment for drills ⅛" and ½" included, $15.

How to Find Socket-Wrench Sizes

When selecting a socket wrench for a certain size cap screw or nut, the first point to determine is if the size wanted is an S. A. E. nut or cap screw, or a U. S. S. cap screw or a U. S. S. nut. **For an example,** refer to the table of sizes below (Table 6) and find a ⅜" S. A. E. or U. S. S. cap screw; note that this size nut will take a 9/16" socket (which is the wrench size); a ⅜" U. S. S. nut takes a 11/16" socket.

SOCKET STOCK NUMBERS		SOCKET SIZES	SIZES SCREW-BOLT-NUTS			
SQUARE	HEXAGONAL		S.A.E. NUTS CAP SCREWS	U.S. STAN. NUTS	U.S. STAN. CAP SCREWS	U.S. STAN. BOLT HEADS UNFINISHED
112		3/8				
114	214	7/16	1/4		1/4	
116	216	1/2	5/16	1/4	5/16	1/4

140	240	1 1/4	7/8	3/4	1	3/4

Table 6. From the Walden catalogue.

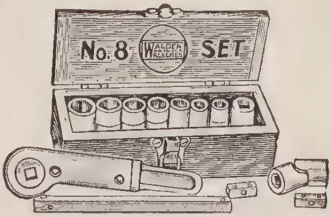

Fig. 21. Walden No. 8 socket wrenches and ratchet lever set. Assortment particularly selected to fit Ford cars: No. 516, 9" ratchet wrench; No. 1139, 9" extension bar; No. 1102, universal joint; No. 1109, plug connections (two); 7 sockets, hexagonal ½", 9/16", ⅝", 11/16", ¾", ⅞", 15/16"; 1 socket, square 9/16". Price complete, $9.90.

For socket wrenches for spark plugs, and also for spark-plug wrench sizes, see page 236.

Auto Machinists' Tap and Die Sets for Automobile Work

Among the essential and necessary tools for the repair shop is a set of taps and dies for cutting threads (see Index under "Threads"; "How to use taps and dies," etc.).

If the work is chiefly on Ford cars, the set shown below (Fig. 23) is designed for this purpose.

For all general automobile work the set shown in Fig. 22 is an excellent assortment.

Reamers (see Index) are also necessary. Tools of this description can be secured of the automobile supply houses.

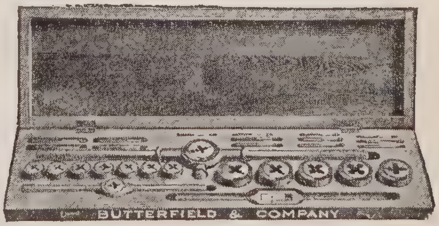

Fig. 22. **Butterfield screw plate set** No. 202, consisting of 7 sizes (14 different threads) 1-4 x 20—28, 5-16 x 18—24, 3-8 x 16—24, 7-16 x 14—20, 1-2 x 13—20, 5-8 x 11—18, 3-4 x 10—16, 14" and 26" Derby stocks, and adjustable tap wrench No. 10, as shown. Dies and taps to cut S. A. E. and U. S. S. threads as enumerated on the lid of box. (Butterfield Co., Derby Line, Vt.)

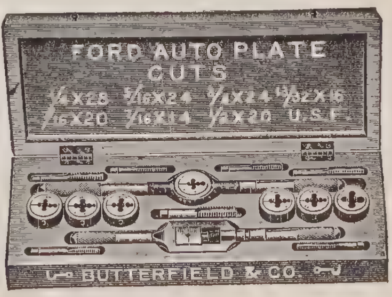

Fig. 23. The Butterfield screw plate is designed for Ford work, and contains taps and dies, cutting all the threads for bolts and screws on the Ford. (Butterfield Co., Derby Line, Vt.)

Pipe Dies and Taps

Taps and dies for cutting threads on small pipes, such as ⅛″, ¼″, ⅜″ and ½″, are shown in Fig. 24. See also page 709 for the "Briggs Standard" pipe-thread table. These can be secured of automobile supply houses.

Fig. 24. The Greenfield "Little Giant" set of taps and dies for cutting threads on pipes. (Greenfield Tap and Die Corpn., Greenfield, Mass.)

Pipe Specifications

Size	Outside Diameter	Inside Diameter	Length of Thread	Distance Pipe Screws into Fitting

Table 7

Electric Portable Drills

One of the handiest tools the automobile mechanic could possess is an electric portable drill. The electric drills shown below are the Black & Decker make, which can be secured of auto supply houses or direct from the manufacturers.

The drills are complete with interchangeable spade handle and breast plate and Almond chuck for straight shank drills and 15 feet of duplex electric cable and separable attachment plug.

This is the drill "with the pistol grip and trigger switch." Without removing or changing position of hands, current is switched on by pulling the trigger. The next pull on the trigger switches the current off.

This patented control prevents breakage of drill bits when operating the switch. It increases speed and accuracy of work.

The spindle on these drills is offset for close corner drilling.

The motors are built specially, and operate on direct current or 25, 40, or 60-cycle alternating current. They are cooled by forced circulation of air, and will not overheat under the most severe conditions of operation.

Reduction gears are packed in grease in grease-tight housing; extremely light and easily handled.

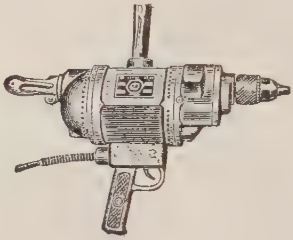

Fig. 25. Electric portable drill.

The Black & Decker portable electric drill is made in the following sizes:

Size 0 to ⅜″ for drilling steel; in hardwood, 0 to 9/16″; speed, no load, r.p.m. 900; weight 26 lbs.; volts, 110, 220, or 32; fuse ampere, 6, 3, 15.

Size 0 to ½″ for drilling steel; in hardwood, 0 to ¾″; speed, no load, r. p. m. 600; weight 34 lbs.; volts, 110, 220, or 32; fuse ampere, 6, 3, 20.

Size 0 to ⅝″ for drilling steel; in hardwood, 0 to ⅞″; speed, no load, r.p.m. 600; weight 34 lbs.; volts, 110, 220 or 32; fuse ampere, 6, 3, 20.

Electric Bench Grinders

For grinding tools or general grinding work.

These grinders should be connected to the electric power line, not the lamp socket. They are designed for alternating current of 110 or 220 volts, 3-phase current of 60 cycles.

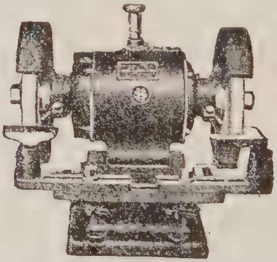

Fig. 26. U.S. ball-bearing bench grinder.

They are made in three sizes of ½, 1, and 2 h.p., and the speed is 3,000, 2,400 and 2,050 r.p.m. Wheels used are 8″ x 1″, 10″ x 1″ and 12″ x 1¼″ respectively. Can be secured of auto supply houses.

INSTRUCTION No. 64

PRECISION TOOLS FOR THE AUTOMOBILE MECHANIC: How to Use Them; How to Read Micrometer Calipers; How to "Mike" up Cylinders, Pistons, etc.; Miscellaneous Small Tools and Gauges; Types of Bolts, Screws, and Nuts; Standards of Threads; Sizes of Taps and Drills to Use for Cutting Threads; How to Select Dies and Taps and How to Use Them; How Drill Sizes Are Designated; How to Sharpen Drills; How to Select Reamers and How to Use Them; Types of Keys; Tightening and Removing Studs and Nuts; How to Select Files and How to Use Them.

Precision tools are those designed for accurate **measurements,** such as calipers, micrometer calipers, thickness gauges, etc. They measure in fractions of an inch, such as one one-hundredth and one one-thousandth part of an inch.

One feature of automobile repairing which has been sadly neglected by the average repairman is the use of electrical testing instruments for testing generators, starting motors, the wiring system, the ignition system, and storage batteries; as well as **the use of the micrometer caliper** for measuring and testing piston clearances, to see if the cylinders are out of round, etc.

The reason for this neglect is possibly the fact that the repairman has not realized the importance of making adjustments to a thousandth part of an inch, or else he thinks the subjects are too complicated for him to understand.

The writer would, however, advise every repairman who wishes to be skilled in making small measurements and in doing accurate work, not only to study the use of the instruments which will now be mentioned, but to become the proud possessor of the instruments. You will not only place yourself in a position where you can diagnose and remedy troubles, test cylinders, pistons, valve clearances, etc., with a degree of accuracy you have not been accustomed to, but you will be in a position to do work "over the head "of your competitor, and your work will be accurate, which of course will build a profitable business for you.

List of Precision Tools and Instruments Suitable for the Automobile Mechanic

1—**Model 280 Weston volt-ammeter,** for making tests as shown under electric tests and storage-battery tests. Price	$ 42.50
1—**Cadmium voltmeter** with cadmium stick, for testing storage-battery plates. Price	$ 26.50
1—**Hydrometer,** for testing electrolyte of storage batteries. Price	$ 1.50
1—**Wiring manual** to aid one in tracing electrical wiring circuits. Price	$ 15.00
1—**No. 203 micrometer caliper,** for measuring spaces from .001″ to 1″. This instrument can be used for measuring ball bearings, drills, screws, rods, sheet metal, etc. Price	$ 8.50
1—**No. 226 3-inch micrometer caliper,** for measuring the diameter of pistons, etc. Will measure from 2 to 3 inches in thousandths part of an inch. Price	$ 10.00
1—**No. 226 4-inch micrometer caliper,** for measuring the diameter of pistons, etc. Will measure from 3 to 4 inches in thousandths part of an inch. Price	$ 10.75
1—**No. 226 5-inch micrometer caliper,** for measuring the diameter of pistons, etc. Will measure from 4 to 5 inches in thousandths part of an inch. Price	$ 12.00
1—**No. 124A inside micrometer caliper,** for measuring the inside diameter of cylinders. Will measure spaces from 2 to 8 inches. Price	$ 7.25
1—**No. 72 thickness gauge,** for measuring spark-plug gap clearance; interrupter-gap clearance; piston-ring gap clearance, etc. Has 22 leaves varying in thickness from .004″ to .025″. Price	$ 2.50
1—**No. 172A thickness gauge;** has 9 leaves and measures smaller clearance than No. 72, as follows: .001½″ or .0015″; .002″; .003″ also .004″; .006″; .008″; .010″; .012″; .015″. These smaller measurements are necessary for measuring ring-groove clearance and valve clearances where under .004″. Price	$ 1.50
1—**Machinist's steel rule or scale,** 6″. Price	$ 1.00
1—**Inside caliper,** 5″, as shown in Fig. 7, page 704. Price	$ 1.00
1—**Outside caliper,** 5″, as shown in Fig. 8, page 704. Price	$ 1.00
1—**Compression tester,** for testing the comparative pressure of cylinders. Price	$ 6.50
Total	$147.50

You will note that all of the foregoing list is required, in order that one may make all tests. One micrometer caliper cannot be obtained that will measure all sizes of pistons, as, for instance, from 2 to 5 inches in diameter. Instead, a set is required as listed above.

Other suggested tools are: 4″ machinist's vise, $12.75; blow pipe torch for soldering, $8.50; set of drills 1/16″ to ½″ in thirty-seconds, $7.00; Townsend grease gun, $5.50. All material listed on this page can be secured of A. L. Dyke, Elect. Dept., St. Louis, Mo.

THOUSANDTH PART OF AN INCH

A thousandth part of an inch is infinitesimally small, but must be used to measure correctly the clearance of a spark-plug gap, the interrupter-point gap in ignition systems, and also for valve clearances, piston clearances, and for many other purposes.

What Is a Thousandth Part of an Inch

If 1″ is divided in 2 parts, each part is $\frac{1}{2}$″
If 1″ is divided in 32 parts, each part is $\frac{1}{32}$″
If 1″ is divided in 64 parts, each part is $\frac{1}{64}$″
If 1″ is divided in 100 parts, each part is $\frac{1}{100}$″
If 1″ is divided in 1,000 parts, each part is $\frac{1}{1000}$″

A hundredth part of an inch could be expressed in fractions as $\frac{1}{100}$ part of an inch, but is usually expressed in decimals as .01″.

A thousandth part of an inch could be expressed in fractions as $\frac{1}{1000}$ part of an inch, but is usually expressed in decimals as .001″.

To read decimals, start with the decimal point (the period); call it decimal or point; the next figure to the right of it, call tenths; the next figure, hundredths; the next figure, thousandths; the next figure, ten-thousandths; the next, hundred-thousandths, and so on.

Thus, the figure 3, standing alone, would represent three units, but if it had a decimal point in front of it, as .3, this would represent three-tenths; if expressed thus, .03, it would represent three-hundredths; if expressed thus, .003, it would represent three-thousandths; if expressed thus, .0003 it would represent three-ten-thousandths, and so on.

If an inch was measured off into one thousand equal parts, each part would represent one one-thousandth part of an inch or .001″.

Twenty-five of these parts would represent twenty-five one-thousandths of an inch (.025″), which is equal to 1/40 of an inch.

One hundred of these parts would represent one hundred one-thousandths of an inch (.100″), which is exactly equal to 1/10 of an inch.

Five hundred of these parts would represent five hundred one-thousandths of an inch (.500″), which is exactly equal to ½ an inch.

One thousand, or all of these parts would represent one thousand one-thousandths of an inch (1.000″), which is exactly 1 inch.

In order to gain an idea as to the thickness of a one-thousandth part of an inch, we will compare the thickness of this paper, which is only approximate.

.001 (one one-thousandth) = 1/3 thickness of this sheet of paper, or about the thickness of fine tissue paper.

.003 (three one-thousandths) = the thickness of this page you are reading (approximately). If it were 3½ one-thousandths, it would be expressed as .0035″ (thirty-five ten-thousandths of an inch).

.006 (six one-thousandths) = the thickness of two sheets of this paper.

.015 (fifteen one-thousandths) = the thickness of five sheets of this paper.

.020 (twenty one-thousandths) = the thickness of seven sheets of this paper.

.025 (twenty-five one-thousandths) = the thickness of eight and one-third sheets.

.030 (thirty one-thousandths = the thickness of ten sheets.

Decimal Equivalent of Fractional Parts of an Inch

In using Table 1, it is not necessary to carry out all of the fraction. As a rule, three figures to the right of the decimal point is close enough for all practical purposes—which would be, of course, read in thousandths, as .015 (fifteen one-thousandths). Note that ⅛ of an inch is equal to .125 (one hundred and twenty-five one-thousandths of an inch).

MICROMETER CALIPERS

It would be a difficult matter to divide an inch into one thousand divisions or graduations on a rule or scale, therefore an instrument known as **a micrometer caliper with a double scale is employed** for measuring spaces as small as .001″. In fact, by adding a third scale (called a Vernier, Fig. 4, page 703), and computing the ratio of one figure to another, a space as small as one ten-thousandth (.0001″) of an inch can be measured.

The automobile repairman seldom finds it necessary to measure spaces less than .001″; therefore this subject will be devoted to micrometer calipers reading .001″ and more.

The three kinds of micrometer calipers the automobile repairman will need most are shown in Figs. 1, 2, and 3.

The "outside micrometer caliper" (Fig. 2) is used for measuring the outside of pistons, etc. The "inside micrometer caliper" (Fig. 3) is used for measuring the inside of cylinders, etc.

The outside micrometer caliper shown in Fig. 1, this page, is a smaller one, it measures spaces only from .001″ to 1″. The one shown in Fig. 2 will take larger measurements, but also reads .001″ to 1″.

Micrometer Caliper Reading One-Thousandth Part of an Inch

How to read: Frame A (Fig. 1) and sleeve D are stationary. The thimble E and spindle C are connected together. On the inside of A and D there are threads (40 to the inch).

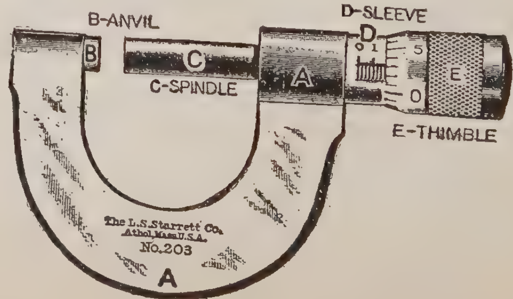

Fig. 1. Micrometer caliper which reads spaces as small as .001″, up to 1″. Lines on (D), .025″; lines on (E), .001″.

When the micrometer caliper is closed, the end of (C) is against (B) and the bevel edge of thimble (E) is on the vertical line (O) on (D), and the (O) line on the bevel edge of (E) is in line with the horizontal line on (D).

When caliper is opened (we will assume that it is closed), turn thimble (E) to the left. If it is turned one complete revolution, then the (O) line on (E) would have revolved from the horizontal line on (D) back again, and one vertical line will then be visible on (D) which represents a space of twenty-five one-thousandths (.025″) of an inch from (B) to the end of (C) (where all measurements are made).

The reason for this is the fact that the spindle (C) and thimble (E) are revolved on threads which are cut 40 to the inch, and a complete turn represents a movement of (C), of 1/40 of an inch, which, expressed in decimals, equals .025″ (twenty-five one-thousandths) 25/1000 = 1/40.

Each line, therefore, on (D) which is exposed by the bevel edge of thimble (E) as the caliper is opened, represents .025″ or 1/40 of an inch. Every fourth line is longer, and is numbered, 1, 2, 3, 4, etc. Therefore, if the fourth line with the number 1 on (D) is visible at the edge of (E), then we should have an opening at (B) to (C) of 4 x .025″, or .100″, or 4/40, or 1/10 inch. If eight lines on (D) were visible, the **eighth line** would be numbered 2, and we should have an opening of 8 x .025″, or .200″, or 8/40 of an inch, which is also equal to 1/5″.

Any fractional part of a complete revolution of (E) will be read on the edge of thimble (E). For instance, suppose thimble (E) is not revolved a complete revolution, but only a portion of a revolution. We know that a complete revolution of (E) represents .025″; therefore there are 25 divisions or lines on the bevel edge of (E), an equal distance apart, and every fifth line is numbered, from 0 to 25. Rotating the thimble (E) from one of these marks to the next, moves spindle (C) longitudinally 1/25 of twenty-five one-thousandths, or one one-thousandth (.001) of an inch, and this is where we get the reading in one-thousandths (.001).

For example, see Fig. 1: There are seven vertical lines (do not count the O line) visible on (D). Multiply this by .025 (7 x .025 = .175), then add the number of divisions or lines from (O) (do not count the O line) on thimble (E) to the horizontal line on (D), and we have 3 divisions or lines (each line represents .001). Therefore, we have a space from (B) to the end of (C) of (.178″) one-hundred and seventy-eight one-thousandths of an inch (7 x .025 = .175 + .003 = .178″).

The outside micrometer caliper (Fig. 2) is used for measuring the outside diameter of pistons, etc. Note that the frame is much deeper, which is necessary, so that there may be room to place the caliper over the piston.

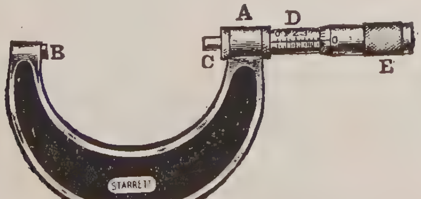

Fig. 2. Outside micrometer caliper.

The usual diameter of pistons for automobile engines varies from 2″ to 5″ diameter. In order to measure pistons from 2″ to 5″ diameter, it is necessary to have three micrometer calipers (see list, page 701), as each caliper reads only for 1″ measurement. In other words, the movement of (C) (Fig. 2) is only 1 inch. This 1″ movement can be read in thousandths of an inch, as explained in connection with Fig. 1.

For instance, on a caliper designed **for 2″ to 3″**, the permanent open space between end of (C) and (B) would be 2″ when the caliper was closed. Thus the micrometer reading in thousandths of an inch would be between 2 to 3 inches. This also applies to the 3″ to 4″ and 4″ to 5″ micrometer caliper. See reference to No. 226, 3″, 4″, and 5″ calipers, page 701.

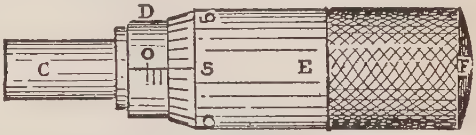

Fig. 3. Inside micrometer caliper.

To read the inside micrometer caliper (Fig. 3), the same method is used. However, bear in mind that in order to read the measurement of a cylinder, which, say, is 4.080″ (four and eighty one-thousandths of an inch in diameter), we should place an extension bar in the end of (C) (bars of different lengths are supplied with inside micrometer calipers). Then open the caliper slightly more than the required amount. Then close the caliper gradually until it will go into the cylinder freely. Then gradually open it until the edge of (F) touches the cylinder wall on one side and the end of the bar on the other side. Remove and note the reading (note that (F) is pointed, as is also the end of the extension rod which fits into (C), in order that they conform with the curvature of the cylinder).

The reading on **Fig. 3** shows three lines exposed on (D). The third line is hardly visible, but the bevel edge of (E) is just exposing the third line on (D). In fact, the spaces between lines is more often counted than the lines themselves. Do not count line (O). Therefore as each line on (D) represents .025″, we have 3 x .025 = .075 on (D). Then count the number of lines from the (O) line on (E) (at bottom), to the horizontal line on (D), counting each line as .001″, and we have 5 lines, or .005; therefore we have a reading of .080″ (3 x .025 = .075 + .005 = .080″).

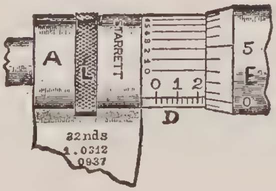

Fig. 4

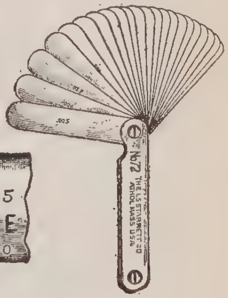

Fig. 5

Fig. 4. **The Vernier micrometer caliper** has a third scale and reads one ten-thousandth. To read, note the thousandths as in the ordinary caliper (Fig. 1); then observe the numbered line on (D) which coincides with the line on (E). If it is the line marked (1), add one ten-thousandth; if it is the line marked (2), add two ten-thousandths, etc.

Fig. 5. **A thickness gauge:** This tool is used for measuring the clearance of valve stems, spark-plug and interrupter points, etc. as mentioned on page 701 (No. 72 and 172A thickness gauge). This is the No. 72, and has 22 leaves which vary in thickness from .004″ (four one-thousandths) to .025″ (twenty-five one-thousandths) of an inch. See page 701 for description of the No. 172A gauge.

SYMBOLS OF DEGREES, MINUTES, SECONDS, INCHES, AND FEET

It will be observed that the same designations which stand for inches are also used for seconds, and those for feet are also used for minutes.

Degrees

A degree is a unit employed in measuring angles, and is the ninetieth part of a right angle or one three-hundred and sixtieth part of a circle.

The explanation of degrees is given on page 60. See also pages 68 and 69 for "Converting degrees into inches."

A circle is 360° around its circumference. If divided into 360 equal parts, each part would represent 1 degree, designated as 1°.

We can divide each degree into 60 parts called **"minutes,"** and each minute can be divided into 60 parts called **"seconds."** One minute would be designated thus (1′) and one second thus (1″).

Signs or Symbols of Inches, Feet, Minutes, and Seconds

The sign for inches or seconds is (″) as 6″.

The sign for feet or minutes is (′) as 6′.

MISCELLANEOUS SMALL MEASURING TOOLS AND GAUGES

Dividers Calipers.

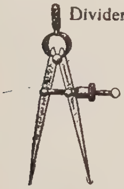

Fig. 6

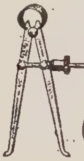

Fig. 7

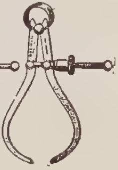

Fig. 8

Fig. 6. **Dividers** are used to lay off circles and distances on metal, for drilling, etc.

Fig. 7. **Inside calipers** are used for measuring inside diameters, such as cylinders, bearings, etc. The points of a caliper are then placed on a machinist's rule and the measurement is noted.

Fig. 8. **Outside calipers** are used for measuring exterior diameters, such as drill taps, etc. The caliper is adjustable, and after the measurement is taken the points of the caliper are placed on a rule or scale to find the measurement in inches or the fraction thereof.

Caliper dividers are made with and without springs. The spring is an advantage, however, inasmuch as when once set, they retain their setting.

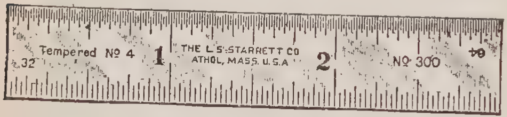

Fig. 9. **A machinist's steel rule or scale** is of thin tempered steel and comes in lengths from 2″ to 24″. The popular size is 6″, with graduations reading sixty-fourths and thirty-seconds of an inch on one side and sixteenths and eighths of an inch on the other side. They can also be obtained graduated in tenths and hundredths of an inch, as well as in millimeters.

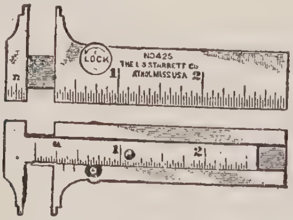

Fig. 10

Fig. 11

Fig. 10. **A pocket sliding rule,** also called a caliper rule, usually made in 3″ lengths; graduated in thirty-seconds on one side, and in sixty-fourths on the other. Handy for measuring sheet or bar stock, wire, tubing, etc.

Fig. 11. **A hook rule** for measuring the diameter of flanges or circular pieces, through the hubs of pulleys, setting calipers or dividers, etc.

Fig. 12. **A scriber,** used for scribing fine lines on planed surfaces of iron or steel, such as timing marks on fly wheels, etc. The points are of tempered tool steel.

Fig. 13. **Double-point scribers,** threaded to screw into the holders and knurled for finger grip.

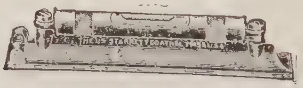

Fig. 14. **Spirit level,** used for lining up pistons, connecting rods, etc., when used in conjunction with a steel square. Also used for finding grades.

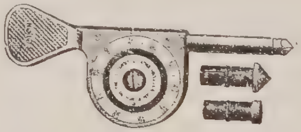

Fig. 15. **A speed indicator,** or revolution counter, as it is sometimes called, is a necessity in high-speed work. The dial can be set at the 0 mark, and when timed with a watch for a minute or fraction thereof, will indicate the total number of revolutions made by the crank shaft, line shaft, motor, or generator.

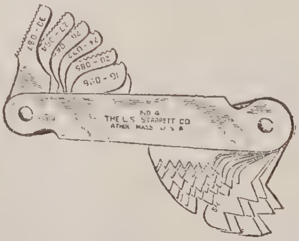

Fig. 16. **Screw pitch gauge** for determining the number of threads to the inch on bolts, taps, etc. The shape of the blades makes it applicable also for inserting in nuts and bolt holes. Sizes and decimal equivalents are stamped on each blade. This particular tool is made in pocket-knife form.

Wire and Sheet-Metal Gauges

Standard gauges for wire and sheet metal: The standards were originated by the various plate and wire manufacturers, thus causing several standards to be recognized.

To avoid confusion it would be well, when ordering wire or sheet metal, to specify the diameter or thickness in dimensions of an inch. If this is not possible, and a wire or sheet-metal gauge can be used, gauge the stock, and when ordering, specify the gauge number and the name of the gauge.

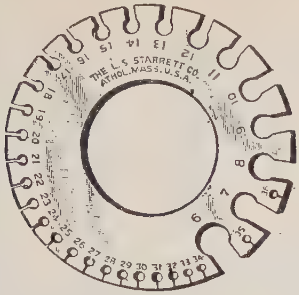

Fig. 17

There are three standards in general use, and they all look very much like that shown in Fig. 17.

The "United States Standard Gauge" for sheet and plate iron and steel was legalized by Act of Congress, March 3, 1893, as a standard gauge to be used by the custom-house department for sheet iron and steel. This gauge is now the adopted standard of the tin-plate manufacturers, there being about forty-five manufacturers using it for their steel. The number of this gauge is No. 283.

The steel-wire gauge is known as the "American Steel and Wire Gauge," as well as the "W and M Standard" (Washburn and Moen Standard). This gauge is applied to all steel wire upon the recommendation of the Bureau of Standards at Washington (No. 287).

The American Standard Wire Gauge is the gauge usually recognized in the United States as the standard for copper wires and wires of metals other than steel (No. 281).

No confusion should be encountered between these two gauges; that is, the "Steel Wire Gauge" is used only to gauge steel wire, and the "American Wire Gauge" is used on copper wire and wires of metals other than steel.

Before using these gauges the material to be gauged should be cleaned thoroughly of all rust and grit. A gauge is then applied, and tests of the different gauge slots are made until one is found that fits the material snugly. Never force the gauge on the material. By doing this the gauge may be sprung, which will cause it to be inaccurate. When gauging a sheet or plate, file off the edges smooth to eliminate danger of error in engaging.

Tap and Drill Gauge

By the use of this gauge one is enabled to select at once the right-sized drill, to suit the machine screw taps most commonly used, leaving just stock enough for the tap to cut as near a full thread as is practical without breaking it, thus saving much time and uncertainty of result attending the former crude ways of selection.

Explanation of illustration (Fig. 18): The first row of figures, for instance, reads thus, 14 x 20 10 ¼. The number 14 (in the first row of figures) means the number or size of the tap; 20, the pitch or number of threads per inch; 10, the size of drill to use which will leave the right stock for proper thread; and ¼, the size of drill to use to let this tap or screw through outside of the thread.

The figures—1, etc., up to 60—designate the number of drill (the size agreeing with the holes). Other figures, 228, 221, etc., designate the size of the hole in thousandths of an inch.

Example: Suppose you had a cap screw of a certain size and you found that it required a 10 x 32 tap. First find the tap size 10 x 32 in the first column to the left (on the drill gauge). Referring to the second column (tap-drill size), you will find that a drill is required of such size as will be a snug fit in the No. 20 hole. Referring to the No. 20 hole you will note that it has the decimal .161 under it. This is the diameter in thousandths of an inch of the drill to use, and is the proper size for tapping, to insure a full thread.

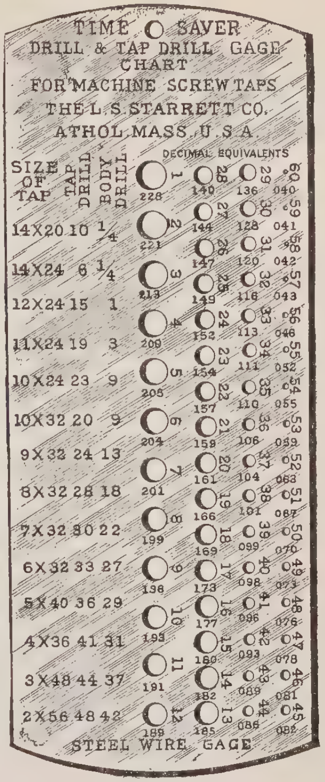

Fig. 18

Suppose, however, that in this particular job you were fastening a bracket or brace to the frame of the chassis. It would then be necessary to drill a hole large enough through the bracket so that the screw would pass through it (as there would be no threads required in this piece). Referring to the third column (body size of cap screw), you will find after the figures 10 x 32 20, the figure 9, thus the proper size drill to use is the one that is a snug fit in the No. 9 hole, and under hole 9, the decimal size is .196 (196 one-thousandths). By referring to the table on page 702 of Decimal Equivalents, the nearest size of the drill to use can be found.

In selecting a drill to drill a hole (whose diameter is expressed in thousandths), always select the nearest size to it, preferably a size or two larger. As an example, take the decimals above: the first one was 161 thousandths. Referring to the table on page 702, you will find that the nearest decimal to this is 171 thousandths. Thus this is equivalent to a 11/64 drill.

The second decimal was 196 thousandths, and we find that the nearest size to this is 203 thousandths, equivalent to a 13/64 drill.

If you select a size smaller instead of larger, you run chances of breaking the tap when trying to cut the threads, especially in hard or very thick metals. As long as there is 75 per cent of the thread available, the thread will be stronger than the bolt itself, and so there is no harm done by having the hole a trifle larger.

BOLTS, SCREWS, AND NUTS

Nuts are not usually used on capscrews, as the capscrew is generally screwed right into the metal part. However, nuts can be put on to them, and they can be used in place of bolts.

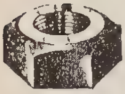

Fig. 19

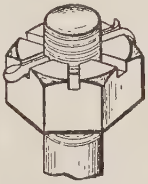

Fig. 20

Fig. 21

Fig. 22

Fig. 19. A hexagon nut.

Fig. 20. A "castellated" nut. The castellated nut is slotted to take a cotter pin to prevent it coming loose.

Fig. 21. U. S. S. (United States Standard) capscrew and bolt thread.

Fig. 22. S. A. E. Standard cap screw and bolt thread. These exaggerated illustrations are intended to show the only difference between a U. S. S. capscrew and an S. A. E. capscrew —which is in the thread. Note that in this illustration (S.A.E.) the thread is much finer. Therefore there are more threads per inch.

By referring to Table 4 (page 697) it will be seen that a ¼″ U. S. S. capscrew has 20 threads per inch; whereas a S. A. E. capscrew (Table 3, page 697) has 28 threads per inch.

Bolts always have nuts on them, either square or hexagon, and in most cases the nuts are larger than the head and consequently take a different size wrench. For instance, a ⅜ machine bolt has a 11/16″ head and a ⅝ nut; whereas an S. A. E. ⅜ capscrew has a 9/16″ head (see page 697, Table 3).

The measurement for the diameter of a bolt or screw is taken just below the head, where the metal is full diameter. If measured across the threaded part, they will be found to be of slightly less diameter, owing to the "flat" (see Fig. 27, page 707).

U. S. S. and S. A. E. Bolt and Cap Screws

The U. S. S. and S. A. E. capscrews are alike in all respects, with the exception of the pitch diameter and the number of threads per inch. By referring to table No. 5, page 709, you will notice the number of threads to the inch on the S. A. E. is more than on the U. S. S. (table 4).

On the automobile we find bolts are used on the springs and various parts. In fact there is hardly a part of the entire mechanism that does not have its quota of bolts, capscrews, machine screws, or carriage bolts (the latter used for holding the body to the frame). Stove bolts are used frequently for fender and drip pans.

Difference between Bolts and Cap Screws

The difference between a capscrew and a machine bolt lies mostly in the method of manufacture.

In making **a capscrew,** the usual method is to cut off a piece of the required length, from a piece of steel of hexagon shape and of the size required for the head. The piece is then turned down to the size required for the body, and a thread is cut on it (or it is milled).

In making **a machine bolt,** the stock is cut from a bar of round steel of the required diameter of the body, and the head is then formed by a process called "upsetting." The machine bolt has a slightly larger diameter head than the capscrew, but the threads are identical in both.

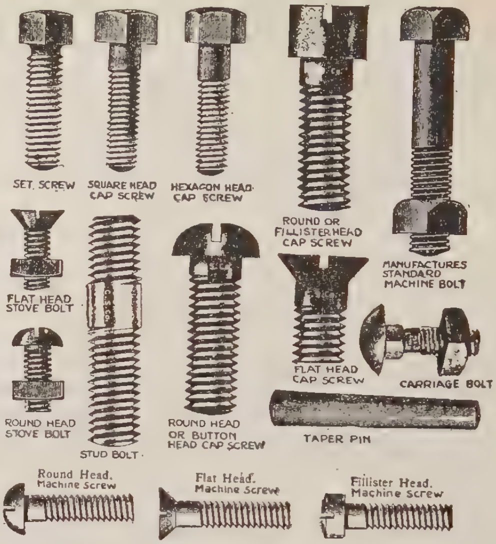

Fig. 23. Illustrations showing the different kinds of bolts and screws. The square-head capscrew is seldom used for automobile work.

The only difference between an S. A. E. bolt and an S. A. E. capscrew is in the amount of thread cut on it. The size and shape of the head are the same and the number of threads per inch is the same.

The difference between a U. S. S. bolt and a U. S. S. capscrew is also in the length of thread and the size of head. The thread on a capscrew is run down nearly to the head, while on a bolt it is run down only about one-third of its length. The heads differ in that the bolt head is larger than the capscrew head, and in the former is usually square instead of hexagon.

The difference between a machine screw and a machine bolt is mostly in the shape of the head. The screw has either a round or a flat head, but never a hexagon head, and differs in the further respect that the head is slotted for the reception of a screwdriver.

A wrench that fits a U. S. S. capscrew will fit an S. A. E. capscrew, because the heads are of the same size.

A wrench that fits a U. S. S. machine bolt will not fit an S. A. E. capscrew, because the U. S. S. bolt head is larger.

A wrench that fits a U. S. S. capscrew will fit an S. A. E. machine bolt, because the S. A. E. bolts have the same heads as capscrews.

A wrench suitable to fit any and all of those mentioned above is the adjustable S-wrench, and open wrenches in sets.

Studs, Taper Pins, and Set Screws

Studs are usually placed in the top of cylinders with detachable heads. The cylinder head is slipped over the studs and fastened down with hexagon nuts. They are also used on top of the crank case.

Taper pins require taper pin reamers—a reamer must always match the pin (see Index for a taper pin reamer). Taper pins are used for locking collars to shafts (where keys cannot be conveniently used), and for various other purposes.

Set screws are usually cut full, so as to fit tight in the part to be held. They are either pointed or cupped at their lower ends, and are either square headed or slotted. In using, set up tight and tap them directly on top with a light hammer, then tighten again. This will set the point or cup in the shaft. The threads are always U. S. Standard.

When driving out bolts that are to be used again, strike the hardest blow you can, and use a heavy hammer. Light blows and the use of a small hammer will upset or rivet the bolt.

THREADS

The two principal threads with which the repairman or mechanic should familiarize himself are the **bolt thread** and the **pipe thread.** A little study and use of the various sizes will enable him to know the particular kind and size by merely looking at it. A comparative difference in size between a bolt tap and a pipe tap is shown in Figs. 38 and 39, page 710.

Note how much larger a ⅜″ pipe tap is than a ⅜ bolt tap. This is due to the fact that a ⅜″ pipe is measured on the inside and twice the thickness of the metal (of which the pipe is made) must be added to the ⅜″ to get the diameter required. In the bolt tap the measurement is taken on the outside, consequently the tap is of practically the same diameter as the bolt. See also, Fig. 24, page 700, for pipe dies and outside and inside dimensions of pipes.

Explanation of the Meaning of Threads

Note the original size of stock on which the thread was cut in Fig. 24. Then note the meaning of "angle," "pitch," and "V-thread." The "root diameter" is measured from the base of threads and the **"basic diameter"** is measured from the top of flats (used in this illustration merely to explain its meaning).

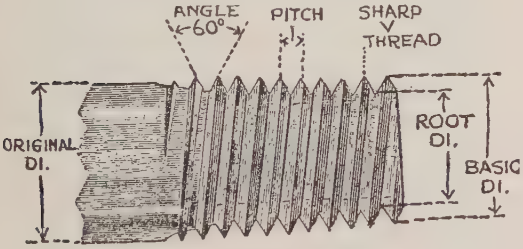

Fig. 24

Root Diameter Determines Drill Size

Root diameter means the diameter of the bolt measured from the **bottom** of one thread to the bottom of the thread diametrically across from it, and is the measurement that must be taken into account when figuring the working strength of the bolt, and is the diameter that gives you the drill size.

In practice the drill size is a little larger, so that after a thread is cut, it will be found that it is not really a full thread, but is full enough for all practical purposes if the drill is not unnecessarily large.

The sharp V-thread (Fig. 25) with its razor-like edge, is a thread the manufacturers do not favor. The flat thread (Fig. 27) is the one favored.

The length of a thread on a capscrew is more than on a bolt.

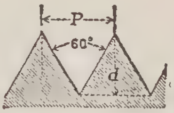

Fig. 25

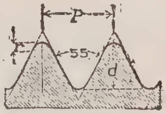

Fig. 26

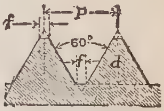

Fig. 27

Fig. 25. The sharp V-thread (U. S. S.).

Fig. 26. Whitworth's standard (oval). Note that the thread does not come to a point at either top or bottom.

Fig. 27. The U. S. S. (United States Standard) and S. A. E. thread. Note the flat at top of thread. This is also called the A. S. M. E. thread.

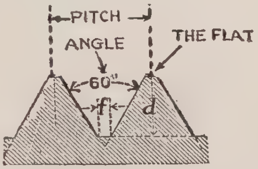

Fig. 28

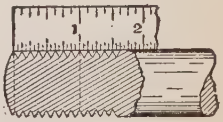

Fig. 29

Fig. 28. Explains the meaning of "pitch," "angle," and "flat." The "pitch" is the distance from one thread to another. The "angle" is the degree of slope, and is usually 60°, except Whitworth, which is 55°. The "flat" is the top of the thread coming to a flat instead of to a point.

Brigg's standard thread which is only for pipe, is oval like the Whitworth.

Fig. 29. The number of threads to an inch can be measured as here shown, or with a screw-pitch gauge as in Fig. 16, page 704. The pitch is the number of threads per inch. A screw-pitch gauge is a quicker and more accurate method for finding the number of threads per inch.

U. S. S. and S. A. E. Threads Used Most

The threads most commonly used in this country are the United States Standard and the S. A. E., formerly A. L. A. M. This latter is the standard adopted by the Society of Automotive Engineers for automobile work.

The diameter and angle of the S. A. E. thread is the same as the U. S. Standard, the only difference being that the S. A. E. thread is of finer pitch (see Fig. 22, page 706), or more threads to the inch.

Take, for instance, a U. S. Standard ¼″ screw. It has 20 threads per inch, while a ¼″ S. A. E. screw has 28 threads per inch (see Tables 4 and 5, page 709).

This **finer thread** has been found by experience and tests to have several **advantages over the coarse** U. S. S. **thread** in auto construction, one of which is in meeting the incessant vibration to which a fast-moving automobile is subjected. A nut with fine threads takes more revolutions or turns to remove it than one with coarse threads, and the chances are that were the threads coarse, the nut would be far more likely to be lost, whereas the fine-thread nut with the same number of turns would be only loose. There are various other reasons, of as much or more importance, which led the manufacturers to adopt this finer thread.

The fine thread is nearly always used where hardened material is employed (such as case hardened), and the coarser thread where soft material is used, such as aluminum, brass, bronze, etc.

Other thread standards used somewhat in this country (although they are made principally for foreign business) are the Whitworth Standard (Fig. 26) and the metric or French standard (not illustrated).

Pipe Threads

The Briggs Standard (Table 6) **is for pipe work** only, and has no connection with capscrews or bolts.

Pitch of thread: By this is meant the number of threads per inch, or the distance from the top of one thread to the top of the next. This pitch is always the same for the same size bolt, nut, tap, or die of the same standard.

To Find the Pitch or Threads per Inch

To find the pitch of a screw when a thread gauge is not convenient, place a scale on the screw (Fig. 29), so that the end of the scale is opposite the top point of any thread; count the number of spaces under the scale between the threads, for a distance of one inch, viz.: there are eight spaces underneath the scale in one inch, therefore the screw is ⅛″ pitch or eight threads per inch.

Another method is to place the scale as shown in Fig. 29, and count the top of the threads for a distance of one inch, omitting one thread. The reason for omitting one thread may be seen by following the two dotted lines drawn from the top point of the first and ninth threads; count the number of complete threads between the dotted lines at the bottom of the screw, and you will find it to be eight.

Pitch angle: By this is meant the angle or degree of slope that the sides of the individual threads have, and is always 60° in the various standards, with the exception of the Whitworth which has 55°. This angle is clearly shown in Fig. 26.

Flats: See Fig. 27; note that U. S. S. and S. A. E. use this thread, but while the angle and flat are the same, the S. A. E. is of finer pitch, or more threads per inch.

In Tables 4 and 5, page 709, a tabulation is given **of sizes and threads per inch,** from ¼″ to 1″ for U. S. and the S. A. E. standards, and **also the drill size** to use for drilling a hole preparatory to tapping or cutting the threads.

Size of Tap and Drill to Use for U. S. S. Threads Expressed in Decimals

The sizes of tap and drill to use for U. S. S. (United States Standard) **or A. S. M. E.** (American Society of Mechanical Engineers) screw thread, are given in Table 3 this page.

The first and sixth columns give the size of tap designated in numbers; the second and seventh columns, the outside diameter of tap; the third and eighth columns, the number of threads per inch; the fourth and ninth columns, the size of drill expressed in decimal parts of an inch; the fifth and tenth columns, the number, or size, of drill which is necessary to drill the hole for the tap. Those sizes marked (+) are most commonly used.

Example: Suppose that on the tap the numbers 14–20 appeared. This would mean that the tap number was 14, and 20 is the number of threads per inch. Therefore by referring to the sixth and tenth columns, the size of tap to use would be No. 14 and the size of drill to use for this tap would be No. 10 drill which is .1932″ in diameter. See page 712, explaining drill numbers and page 711, explaining tap numbers.

Note. A ¼″ S. A. E. tap is larger in diameter than a U.S.S. ¼″ tap, due to the difference in the root diameter of the bolt or screw. See page 707, explaining root and basic diameter.

How drills are designated: Refer to Table 7 page 712, which explains how certain sizes of drills are lettered instead of numbered, etc.

Table 3

Size of Tap	Outside Diam	Threads per Inch	Nearest Commercial Size Drill producing 75% depth of thread		Size of Tap	Outside Diam	Threads per Inch	Nearest Commercial Size Drill producing 75% depth of thread

9	.177	30	.1445	27	30	.450	14	.3804	V

Note. A common nut, drilled out so that it contains only 50 per cent of a full-depth thread will break the bolt before it will strip.

A 75 per cent depth of thread yields an ample margin of safety (2 to 1), and is economical in tapping.

A full depth of thread in a common nut is only about 5 per cent stronger than a 75 per cent depth of thread; yet it requires three times the power to tap.

Size of Tap and Drill to Use for U. S. S. Threads Expressed in Fractions of an Inch

Tap and drill sizes for U. S. S. threads: Table 4 gives the diameter of the tap, the threads per inch, and the size drill to use (expressed in common fractions) for the tap. The diameter of the tap expresses the screw size. For instance, a ¼″ tap is for a ¼″ screw with 20 threads; therefore the size of drill to use would be 3/16″, etc.

To find what size and number tap to use for a ¼″ U. S. S. bolt with 20 threads to the inch: First find the decimal equivalent of ¼ inch (see page 702); ¼ inch is equal to 2/8 inch, so by looking in the column under heading of "8ths" Table 1 (page 702), you will find that ¼ (or 2/8) is equal to 250 one-thousandths, or decimal point 250. Referring back to Table 3, this page, find the nearest decimal. This will be found in column No. 7, and can be either .242 or .268; so you could use either a No. 14 or a No. 16 tap.

To find what would be the number of the drill for a ¼″ U. S. S. tap, 20 threads to the inch: Proceed as in the previous instance. First find the decimal equivalent of ¼ inch. This you have found to be

U.S.S. Threads

Diam. Tap in Ins.	Thds. per inch	Size of Drill Ins.	Diam. Tap in Ins.	Thds. per inch	Size of Drill Ins.	Diam. Tap in Ins.	Thds. per Inch	Size of Drill Ins.
¼	20	3/16 in.	9/16	12	29/64	1¼	7	1 5/64
5/16	18	¼ in.	⅝	11	33/64	1⅜	6	1 11/64
⅜	16	5/16 in.	11/16	11	37/64	1½	6	1 19/64
7/16	14	⅜ in.	¾	10	⅝			
½	13	11/32 in.	13/16	10	11/16			
½	12	13/32 in.	⅞	9	47/64			
			15/16	9	51/64			
			1	8	27/32			
			1⅛	7	61/64			

Table 4

250 one-thousandths. The nearest decimal to this is in column No. 7, Table 3 (page 708), and can be, as before, either .242 or .268; and the proper drill corresponding thereto is found in column No. 10 and can be either a No. 10 drill or a 7/32 inch drill. You will notice by referring to Table 4 that a 3/16-inch drill will also answer.

Note. The only difference in using one or the other of the various drills would be in the fullness of the thread. The larger the drill, the less depth of thread. You can readily see that by using a drill **too large**, you would cut away the metal that should go to make the thread, and, on the other hand, if you use a drill **too small**, you would not be able to enter the tap. See note at bottom of Table 3.

Tap and Drill Size for S. A. E. Threads

Tap and drill size for S. A. E.: Table 5 gives practically the same information as Table 4—but for S. A. E. capscrews. The first column gives the size of tap to use; the second column, the number of threads to the inch (pitch); the third column, the size of drill to use.

To find what number of **tap** would be required, or the number **of drill**, the procedure would be the same as in the case of Table 4. The diameter of drill and tap would be the same as for the U. S. S., but the number of threads per inch would be greater, as would also be the root diameter. A comparison of the two drills for the 5/16″ taps, for instance, will make this clear.

Stove Bolt Threads

Diameter	Threads per Inch
3/16″	24
¼″	18
5/16″	18
⅜″	16

Tap and Drill Size for Pipe Threads

Tap and drill size for pipe threads: Table 6 gives the size of drill to use for a certain size of pipe tap. The Briggs standard is the one used in this country.

Note that the threads on a ¼″ pipe tap are 18 to the inch, whereas on the S. A. E. (Table 5) there are 28 threads to the inch, and on the U. S. S. (Table 4) there are 20 threads per inch. See also, page 700 for "Pipe specifications."

The diameter of a pipe tap is larger than a stated size of any other tap (see page 710).

S. A. E. Threads

Diam. in.	Pitch	Tap Drill
¼	28	No. 4
5/16	24	17/64 in.
⅜	24	21/64
7/16	20	⅜
½	20	7/16 in.
9/16	18	½
⅝	18	9/16
11/16	16	39/64
¾	16	43/64
⅞	14,18	51/64, 13/16
1	14	59/64

Table 5

Pipe Threads

Size Tap Inches	BRIGGS STANDARD	
	Thread	Drill
⅓	27	21/64
¼	18	27/64
⅜	18	9/16
½	14	11/16
⅝		
¾	14	29/32
⅞		
1	11½	1⅛

Table 6

The size of a No. 4 drill, as shown in the third column of S. A. E. threads above (Table 5) can be found by referring to Table 8 (page 712). It is .207. The nearest decimal to this on page 702 is .203, or 13/64″.

Note that the ⅞″ S.A.E. thread with 18 threads per inch is for the S.A.E. spark plug.

DIES AND TAPS

Tap and die sets are shown on page 699, under Figs. 22, 23, and 24. An explanation as to how to select and use dies and taps is given below.

Dies

The subject of dies is really a part of the tap subject, inasmuch as where the one is used, the other must be used also. The tap cuts a thread on the **inside** and the die cuts the companion thread on the outside. Thus you would **"tap a hole"** or nut, and **"run a die over"** a bolt or pipe.

Dies, as in the case of taps, are divided into two classes: **pipe dies** and **bolt dies.**

The better grade of dies are adjustable as to size, that is, you can make them cut a little larger or a little smaller than "standard." This will be found to be of special value in repair work.

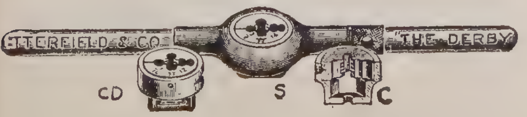

Fig. 30. **Cutting male threads** is accomplished with a die and stock, or on a lathe. When a die and stock is used, it is placed in a collet (C), and the collet and die (CD) are then placed in a stock (S). This is worked over the part to be threaded. The illustration shows a die and stock for cutting threads on machine screws.

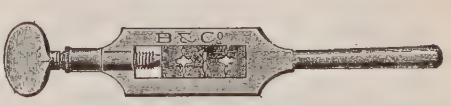

Fig. 31. **A screw plate or gunsmith's die.** It cuts threads in the same manner as the one shown in Fig. 30, but there is no collet. Bicycle dies are often made in this form.

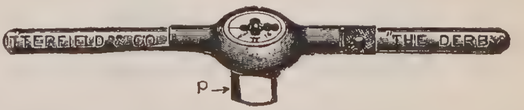

Fig. 32. **A stock and die for cutting threads on pipe.** The pipe is held stationary and the tool revolved. Note projection (P) at bottom, to hold the die to the pipe.

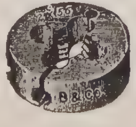

Fig. 33

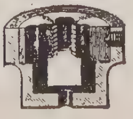

Fig. 34

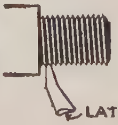

Fig. 35

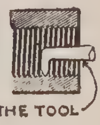

Fig. 36

Fig. 33. Die without collet. Fig. 34. Sectional view collet and die. Fig. 35. Threads may also be cut on a lathe. Note the lathe tool cutting an outside, or **male thread.** Fig. 36. Note the lathe tool cutting an inside or **female thread.** The tool is held stationary—just the reverse of hand-cutting.

The solid die is non-adjustable, and, when worn, will not cut deep enough. As a consequence, the nut or fitting is nearly ruined by forcing it on. It sometimes happens that a cutting lip is broken off; this necessitates the purchase of an entire new die, whereas in the adjustable die one can renew—just the broken lip—at slight expense.

How marked: Dies are marked as to **size, number of threads per inch,** and whether **right or left hand** thread, designated by the letter R or L. In a great many instances it is both necessary and convenient to cut a left-hand thread, and it is advisable to have a few of the most used sizes on hand. (A brake rod, for instance, where it screws into the turnbuckle, has a left-hand thread.)

Dies and their corresponding taps are so made relative to the diameters at the top and bottom of thread, that when the nut is screwed on the bolt, the extreme tops do not touch one another. In other words, there is a small space allowed, called the **"clearance"** (about .002″). The real bearing surfaces are the angular sides of the thread. This clearance space is accountable for the rust that is found in the threads of old bolts and nuts, and it is in this space that the kerosene soaks, when applied to loosen up a rusty nut.

See page 699 for illustration of a set of dies of various sizes and also the stocks in which they are used, as well as tap wrenches.

The stock is the holder for the die while cutting, and usually has removable handles.

"Screw plate set" is a term used to express the entire outfit, as shown on page 699. Although we have shown Fig. 30 as a die and Fig. 31 as a screw plate, the term is used as stated above.

Screw Taps

Taps may be divided into two distinct groups: bolt and pipe taps.

Machinists' hand taps are used for cutting internal threads in metal, and are usually bought in sets of three, viz., taper, following, and bottoming, as shown in Fig. 37.

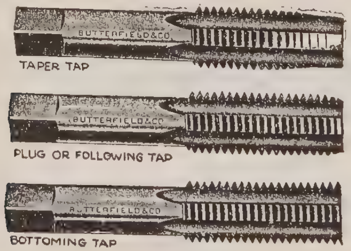

Fig. 37

Pipe taps are used for cutting threads in pipe fittings and cutting threads for the insertion of pipes, pet cocks, drain plugs, etc. (see Fig. 39, also Table 6, Briggs standard, page 709).

The taper tap (Fig. 37), so called owing to its sides being tapered, is the one first used after the hole is drilled. This is in reality a roughing tool, and does not give a full thread unless run all the way through. It is used for open work, such as the truing up of the threads in a nut, and also for tapping various parts of the chassis.

The "following" tap (Fig. 37) is next used, and, in the majority of cases, is all that will be required to finish the tapping process. Where tapping is done in solid metal, this is the one generally used. If threads are desired clear to the bottom of the solid work, then the "bottoming" tap is used.

The "bottoming" tap (Fig. 37): In many instances, the thickness of the metal is such that a tap cannot be run in far enough to cut a complete thread all the way to the bottom of the hole. It is therefore necessary to use the bottoming tap. There is no taper to this tool, consequently it cuts full size from start to finish, and the thread must be started with one of the other taps first.

Flutes: This term applies to the grooves cut in the sides of taps for the reception of iron cuttings or chips and any foreign matter that might be present while cutting. It is the almost universal practice to make taps with four flutes, as shown in the end view of Fig. 45 (page 711). This makes it convenient to caliper the diameter, which otherwise could not be so easily done if there were five or any other odd number of flutes.

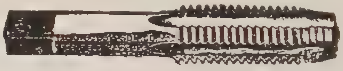

Fig. 38. A ⅜″ machinist's tap.

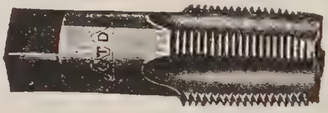

Fig. 39. A ⅜″ pipe tap.

Figs. 38 and 39 are intended to show the comparative difference in size between a ⅜″ machinist's hand tap and a ⅜″ pipe tap, as explained in the text.

U. S. S. and S. A. E. Taps

Sizes of tap: After the proper size of hole is drilled, it will then be in order to get the proper size and standard of tap necessary to cut the thread.

Suppose, for example, you wished to tap a hole to fit a ⅜″ S. A. E. screw. If you drilled the hole of such a size as called for in Table 5, page 709, you would have used a 21/64″ drill. Therefore you would call for a ⅜″ S. A. E. tap.

If the bolt or stud was the U. S. Standard ⅜″ size, use a 5/16″ drill, as in Table 4. Note that the S. A. E. tap is 1/64″ larger than the U. S. S. (page 709) and use a ⅜″ Standard tap.

If, on the other hand, you are working on a ⅜″ pipe job instead of a bolt job, you would have used a 9/16″ drill (see Table 6, page 709). Therefore use a ⅜″ pipe tap. Notice that the drill used for a ⅜″ pipe tap is nearly twice as large as that used for a standard bolt of the same size (see Figs. 38 and 39, above, for relative size).

How Taps are Marked

You will find on all taps at least two marks: They refer to the diameter and to the threads per inch. Thus, a tap marked ¼-20 or ¼-28 will denote that the tap is for ¼″ size nut or hole, and has 20 or 28 threads per inch. The ¼-20 is a U. S. S. tap, and the ¼-28 is an S. A. E. tap.

A great many taps are marked with a number instead of a fraction, thus: 14-20, means that the number of the tap is 14 and the threads are 20 to the inch.

In Table 3 (page 708) is shown a complete list of tap numbers from 0 to 30. Those marked with a + mark are the sizes most used for ordinary work. The table also gives the proper size of drill to use with the various taps. The dimensions are given in thousandths of an inch. By referring to Table 1 of "Decimal Equivalents" (page 702), you can get the proper size in fractions of an inch.

Tap Sizes

Sizes of numbered taps: Taps from No. 1 to No. 30 run from 1/16″ to 7/16″ outside diameter, varying approximately by thirty-seconds.

Numbers above 30 are marked according to the size and thread; for instance, a ½″ tap (U. S. S.) would be marked ½-13, meaning ½″ size and 13 threads to the inch. When taps are marked in this manner, they run from ½″ to 1″, varying in 1/16″ sizes, or fractional parts of an inch.

Size of taps most used: A set for small work would be from No. 1 to No. 30 (page 708, Table 3), which runs from 1/16″ to 7/16″ with variations by sixteenths, then from ½″ to 1″, varying in eighths of an inch. Taps are seldom used over 1″ for general auto work.

Special Taps for Spark Plugs

For regular ½″ size (Fig. 13, page 235), with 14 threads per inch, use the regular standard ½″ pipe tap and a drill 11/16″ (see Table 6, page 709).

For S. A. E. ⅞″ size, with 18 threads per inch, use the S. A. E. ⅞″ "special spark-plug tap." Note, by referring to Table 5, page 709, that the standard ⅞″ S. A. E. screw tap has 14 threads, and the S. A. E. spark plug has 18 threads. It is for this reason that a special tap is required. A 13/16″ drill is the proper size to use.

The metric 18 m.m. size uses the metric 18 m.m. spark-plug tap (French standard).

See page 235 for S. A. E. spark-plug dimensions, and page 236 for spark-plug gaskets.

How to Use Taps[1]

Before using a tap, the hole must be drilled to the proper size. Never use a monkey wrench or an S-wrench unless in a tight corner, as there is a liability of breaking the tap.

Get the work perfectly level and rigid before starting the tapping, and start the tap true.

When the tap is caught, sight or use a square (Fig. 40) to see if it is true; if not, turn the tap backward, and then forward, pressing in the direction required to straighten on the forward stroke only.

Start the taping with a No. 1 tap, or "taper tap," followed by the No. 2 or "following" tap, and if threads are desired a little large, or particularly clean, and to the bottom of a hole, then use the "bottoming," or No. 3 tap. (See page 710 for the meaning of "taper," "following," and "bottoming" taps.) Fig. 41 above also shows the three taps.

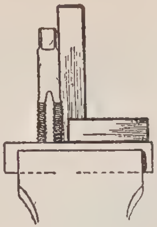

Fig. 40

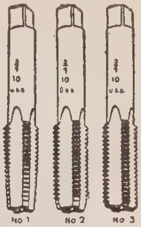

Fig. 41

Lard oil should always be used on taps, or dies, never a mineral oil.

Brass or cast iron requires little oil; **steel,** a continued application, and the tap should not be forced during the cutting. If the tap sticks, backing off and starting over will usually permit the tapping to be done with little exertion.

Several methods are employed to make a tap cut oversize. One is to pack the groove with cotton waste; another, to place a thin strip of copper or brass over one cutting lip, and another, to place the tap in boiling water, and cut the thread while the tap is still hot. Of the three, the first is perhaps the best method.

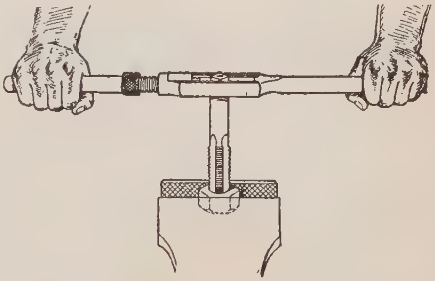

Fig. 42. The tap should be started square, and with even pressure on each arm of the "tap wrench."

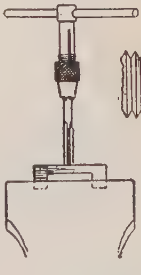

Fig. 43

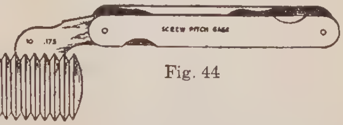

Fig. 44

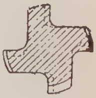

Fig. 45

Fig. 43. A large tap and reamer wrench (Fig. 42) should never be used for small taps. Use the small "hand-tap-wrench" illustrated in Fig. 43.

Fig. 44. Illustrates a screw-pitch gauge, similar to that shown in Fig. 16, page 704.

Fig. 45. End view of a regular type (4-flute) tap. See page 710 for meaning of "flute."

DRILLS

Twist drills are the kind always used for boring in metals. They are generally made with two flutes or spiral grooves, for the reception of the cuttings or chips of the metal being drilled.

Flute drills are those having flutes or grooves arranged longitudinally along their length. They are mostly used for soft metal, and are the kind which usually come with hand drills in small sizes.

Shanks: The part that goes into the chuck is called the shank. The shanks most generally used for a power-drill press are either straight or taper.

Straight shank drills are used in lathes or in drill chucks. For instance, where a straight shank drill is desired to be used in a power drill press which takes a taper shank only, then a taper arbor (B), Fig. 46, can be fitted in the end of **drill chuck**[1] (C), and the tapered end of the taper arbor (A) can be inserted in the drill press. This method is usually employed where the drills are ½″ or less.

---

Drill Chuck.

Taper Arbor

Fig. 46

Taper Shanks on Drills

Taper shanks on drills vary. For this reason, drill presses are usually fitted with four sizes of taper shanks as follows:

For drills 1/16″ to 9/16″ with No. 1 taper shank
For drills 37/64″ to 29/32″ with No. 2 taper shank
For drills 59/64″ to 1¼″ with No. 3 taper shank
For drills 1 17/64″ to 2″ with No· 4 taper shank

How Drills Are Designated in Sizes[2]

You will observe in Tables 7 and 8 that in the sizes from 1½″ to No. 80 (0.013″ or 13/1,000 of an inch) the drills are numbered and lettered. The No. 80 is the smallest size. In other words, the larger the number, the smaller the drill (see also "Drill Gauge," on page 705).

Drills from No. 80 to No. 1 (1/64″ to 7/32″) do not bear size numbers or letters on them, but are measured on drill gauges (see page 705).

Drills from No. A to Z (15/64″ to 13/32″) have their size designated by letters stamped on their shank.

Drills from Z to 1½″ have the actual size stamped on them (as 27/64″ to 1½″).

Comparison of Tables 7 and 8 with Table 3: The exact size of a No. 30 drill, for instance, as given in Table 8, is 127 one-thousandths of an inch. In Table 3 (4th column) it is given as 131 one-thousandths. This difference is only slight, and does not affect the strength of the thread. This difference is due to using a table of actual drill size (Table 3), and a table of drill rods (Tables 7 and 8).

Table 7

Size drill	D. E.	Size drill	D. E.	Size drill	D. E.
1½	1.500	15/32	0.4687	O	0.316

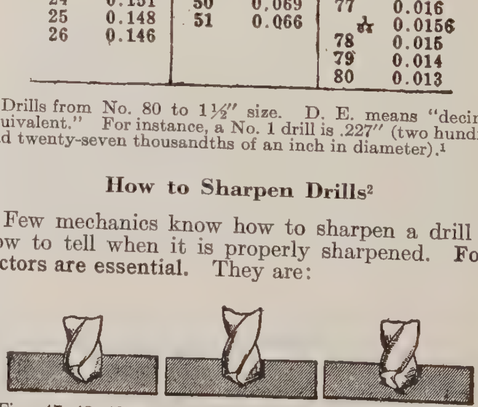
Drills from No. 80 to 1½″ size. D. E. means "decimal equivalent." For instance, a No. 1 drill is .227″ (two hundred and twenty-seven thousandths of an inch in diameter).[1]

How to Sharpen Drills[2]

Few mechanics know how to sharpen a drill or how to tell when it is properly sharpened. Four factors are essential. They are:



Figs. 47, 48, 49. Results of improperly ground drills: Fig. 47 has an unequal lip angle; Fig. 48 shows an unequal lip length; in Fig. 49, both lip angle and length are unequal.

---

[1] See page 693 for a drill and lathe chuck.

[2] See page 709 for the size of drills to use for U. S. S. and S. A. E. taps.

[1] From Shield's "Mechanic's Guide Hand Book."

[2] From *Motor World*. Figs. 47, 48, and 49 are from *Electrical Experimenter*.

1. Both cutting lips should have the same angle to the axis; otherwise the cutting will all be done by one lip, and the drill will drill oversize (see (Fig. 47).
2. Both cutting lips should be exactly the same length; otherwise it will throw the point of the drill off-center, causing the drill to cut oversize (see Fig. 48).
3. Proper clearance back of the cutting edge is necessary. Insufficient clearance causes the drill to drag, cut hard, and get dull quickly.
4. The angle of the lips should be about 60° each, as shown in Fig. 51.

To Sharpen

5. Hold the drill lightly against the wheel, as shown in Fig. 54, with the cutting lip on the wheel.

   Wheels for drill grinding should be fairly soft and open so that they will not clog or burn. The drill should be pressed lightly against the the wheel and carefully watched to see that it is not burned and the temper drawn. Watch the surface from which the grinding wheel leaves, as the heat is concentrated there (see Index for "Tempering drills and small tools").

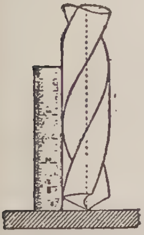


Fig. 50

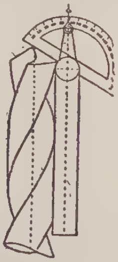

Fig. 51

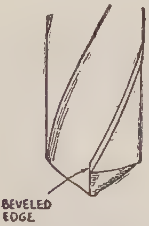

Fig. 52

Fig. 50. Method of measuring cutting-lip length.

Fig. 51. Measuring the angle.

Fig. 52. Method of beveling cutting lip to cut thin or hard material.

6. Twist the drill and at the same time throw the right hand down in order to grind the proper clearance.

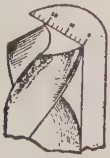

Fig. 53

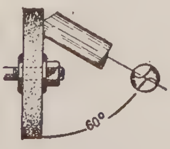

Fig. 54

7. Check the length of the cutting lip, as shown in Fig. 50.
8. Check the angles of the cutting lips, as shown in Figs. 51 and 53, when sharpening it. The best cutting angle is 60°.

Drilling

9. Brass or thin sheet metal may be more readily drilled if the cutting lips are beveled, as shown in Fig. 52. This prevents the drill from digging in and catching.
10. Always clamp or hold the work being drilled to prevent the drill catching and breaking, and place a block of wood under the work.
11. In starting to drill use moderate speed, gradually increasing until the best cutting speed is obtained.
12. When drilling small holes, speed the drill up and go carefully when the drill is breaking through the work. This is the point where the drill usually catches and breaks.
13. When drilling large holes, say 3/8" to 3/4" in diameter, it is better to drill a small hole first.
14. It is advisable to always make a center punch mark in metal to be drilled.
15. Case-hardened steel must first be softened until an even red heat is reached, and re-hardened again.
16. The following are the cutting compounds for the various metals:

    Hard steel—turpentine, kerosene; **soft steel**—lard oil, machine oil; **brass**—soda water, if anything; **aluminum**—kerosene; **cast iron**—none. An air blast is a very good cooling medium for cast-iron drilling.
17. If the drill chips out at the cutting edge there is too much feed, or the drill has been ground with too much clearance. A split up the web is caused by the same improper grinding.

Laying Out Work for Drilling

The easiest way to lay off work for drilling, etc., on iron or steel is to cover it with a coating of chalk, which permits the lines to be scribed on the surface with a steel-pointed instrument so as to be readily seen.

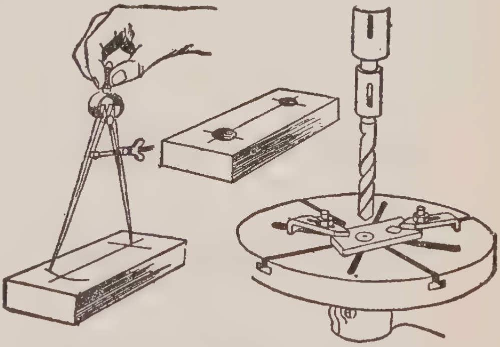

Fig. 55 Fig. 56 Fig. 57

Fig. 55. Accurately mark off the center distances with a pair of steel dividers, after first lightly prickpunching one center.

Fig. 56. Shows the part to be drilled after having scribed it and prick-punched the centers.

Fig. 57. The piece must be clamped to the drill table by steel clamps; otherwise the drill will wander, destroying the accuracy of the hole.

All lines showing the size, location of holes, etc., are scribed out on the metal, previously chalked over, as mentioned, or, if on wood, simply by a hard pencil, and all centers of holes to be drilled should then be center punched by a hard-steel punch.

The finished piece, with the center lines scribed, is shown in Fig. 56.

When drilling a piece of thick metal, if the drill has a tendency to bore crooked or off the center, it can be re-centered again by cutting a groove with a diamond-point chisel on the side towards which you wish to draw drill, as shown in Fig. 58, next page.

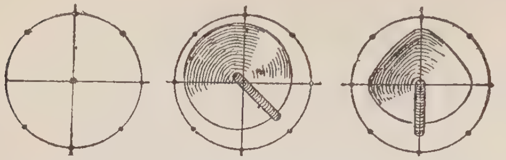

Fig. 58. Left—The piece prepared and ready for drilling; the prick punch marks should be made carefully and lightly. Center—The groove should be made the depth to which it is desired to draw the drill, and on the side that the drill is to be drawn. Right—A triangular hole may be corrected in the manner illustrated.

A diamond-point chisel, shown in Fig. 58A, should be used in "drawing" the drill.

One method for finding the size drill to use for tapping is to select one that will be a sliding fit in the die which goes with the tap. If the drill is to large to go into the die (a nut will do just as well the threads will not be full, and if it is smaller tha the die or nut, the tap will turn so hard that it wi probably break (see Fig. 58B).

Fig. 58A. A diamond-point chisel.

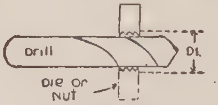

Fig. 58B

REAMERS

Reamers are used a great deal in automobile work, as they enable one **to enlarge a hole** to any desired size without having to resort to any particular size of drill. Simply drill a small hole and ream it out to size.

Reamers are also used for reaming crank-shaft bearings, connecting-rod bushings, piston-pin bushings, etc.

Each flute has a cutting edge which actually cuts the metal with a shearing action.

Reamers are of two general types: straight flute (Fig. 60) and spiral flute (Fig. 59). The object in cutting the **flutes spiral** on a reamer is to prevent chattering, which is very likely to happen if the work is carelessly done. **Straight-flute** reamers always have an odd number of flutes, so that no two flutes can ever be exactly opposite each other, and this also helps to stop chattering.

Fig. 59. Spiral flute reamer.

Fig. 60. Straight flute reamer.

Fig. 61. Taper reamer for finishing.

Fig. 62. Taper reamer designed with a head or stock to use in an ordinary brace.

Fig. 63. An expanding type of reamer.

Reamers are made in stock sizes from 1/8" to 1 3/8" by thirty-seconds and by sixty-fourths, and also in metric sizes. Most **taper** reamers are special, although there are a few stock sizes.

Expanding reamers are ground .005" undersize, and can be brought up to .005" oversize.

Use of Reamers

Reamers are used for reaming out such parts a piston-pin bushings, steering-spindle bushings transmission-gear bushings, cam-shaft front and rea bushings, crank-shaft bearings, etc. In fact, they are indispensable to the repairman.

A reamer for piston-pin bushing is shown in Fig. 73. It is used for reaming through both the piston-pin bushings for perfect alignment of the piston pins.

Fig. 76. Main bearing reamers. (*Motor World.*)

Aligning Reamer

A reamer, as shown in Figs. 76 and 76A, is designed **to ream all three main bearings simultaneously,** and saves much time in scraping and refitting bearings.

The unequal distribution of weight and of driving strain on the crank shaft of an engine naturally causes unequal wear in the main bearing. It can be seen that tightening up on the bearing caps only will spring the shaft out of line and throw additional strain on the bearings, causing them to wear loose again very rapidly. This reamer will bring all bearings to proper size and perfect alignment. An allowance of .0025" is made for wear of the crank shaft.

This reamer can also be used for **reaming the connecting-rod lower bearings,** as they are of the same diameter as the main bearings. (Can be secured of K. R. Wilson, 16 Lock St., Buffalo, N.Y., and also of automobile supply houses.

CUTTING A KEY-WAY; TYPES OF KEYS

Key-way cutting with a chisel is an art that requires skill. There are many men who can cut a key-way nearly as well as can be done by a machine; not so the amateur. The first thing to do is to mark out on the shaft the key-way required, with a line to show the center. It is best to drill a series of holes in the shaft to the depth of the bottom of the proposed key-way with a flat-bottom drill. The holes should not be in actual contact; if they were so, the drill would not bore straight. Then, with a narrow cape chisel, chip away the intervening spaces and file with a small, blunt, square file. Allow the file to work up to the ends of the key-way. The key must be of steel, fitted to the bed on the bottom of the key-way and tight at the sides. Keys of different sizes (in the rough) can be bought at tool shops. The key and key-way must be slightly tapered. The key-way will be found shallowest in the middle; this must be worked down, using the edge of a flat file.

Note. **Key-ways on automobile work are seldom cut by hand, but are milled on a milling machine,** or by a special key-way cutting machine. This explanation is given as a matter of information.

Keys

There are three kinds of keys used on shafts: the square key, the round, and the half-disk type, called the Woodruff.

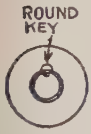

Fig. 77

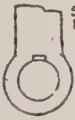

Fig. 78

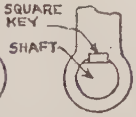

Fig. 79

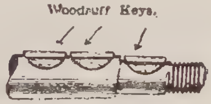

Fig. 80

The Woodruff key is used more on automobile work. It is the easiest to remove and to apply, but when fitted, the shaft must be milled on a milling machine to take this key (see Figs. 80, 81).

The round key (Fig. 77) is seldom used because it is difficult to remove. If, however, a quick job is desired, the round key is the most speedy, as a hole can be drilled and the round key hammered in (not advised except on temporary work).

The square key (Figs. 78, 79), if applied properly, can easily be removed.

Woodruff Key-Ways

The key-way for a Woodruff key must be **milled.**

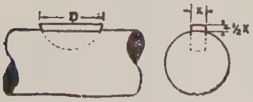

Fig. 81

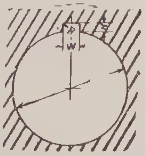

Fig. 82

A shaft that has been milled for a Woodruff key is shown in Figs. 80 and 81, with keys inserted. (X) (Fig. 81) equals the thickness of the key. The key should project above the shaft one-half its thickness.

Standard key-ways for pulleys and shafts: Table 9 shows the recognized standard for the depth and width of a key-way in pulleys. The same formula of course may be used for the depth and width of a key-way in a shaft. A list of the standard sizes of key-ways, both for pulleys and shaft, is given. The radius (**R**) refers to the round corners on the key.

Diameter (D) of Hole	Width (W) of Keyway	Depth (H) of Keyway	Radius (R)
3/8″ to 9/16″	3/32″	3/64″	
5/8 to 7/8	1/8	1/16	030
15/16 to 1 1/8	5/32	5/64	035
1 3/16 to 1 3/8	3/16	3/32	040
1 7/16 to 1 3/4	1/4	1/8	050
1 13/16 to 2	5/16	5/32	060
2 1/16 to 2 1/2	3/8	3/16	060
2 9/16 to 3	7/16	3/16	060

Table 9

A Drift

A drift (Fig. 83) is used for many purposes. In this instance it is used with square keys.

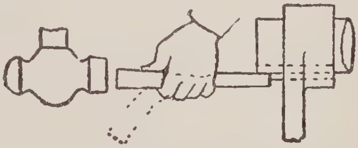

Fig. 83

If the shaft projects from the boss, a drift should be used to prevent damaging the key-way by the blows of the hammer. The drift (Fig. 83) is a steel tool with a hardened nose. They are sometimes curved (note the dotted lines), as in many cases it is impossible to get a straight blow at a key. Care should be taken not to burr up the end of the key. A piece of heavy copper held over the end of the key by an assistant will prevent this.

Tightening Nuts on Cylinder Heads

Attention is called to the method of tightening the nuts on a detachable cylinder head, as well as to the importance of locking nuts to prevent them from coming loose.

Detachable cylinder heads are now quite generally used, and it is very important that they be kept tight against leakage at the joint with the main cylinder casting. A striking loss of power in a certain engine was puzzling until a thorough inspection revealed that some of the head bolts were loose, allowing some of the compression pressure to escape.

There also are many instances of careless tightening of heads and cylinder blocks which has resulted in cracking the casting. This is due to drawing down one bolt or series of bolts too tightly before equalizing the strain by tightening others in another part of the casting. The object is to pull the casting down uniformly without any tendency to bend or distort the piece.

In the diagram (Fig. 84A) (the Dort cylinder head), the cylinder head has fifteen bolts, and the numbers on the diagram indicate the order in which they should be tightened. It will be seen that the center bolts are adjusted first; then the rest are tightened alternately.

REMOVING TIGHT NUTS AND STUDS; LOCKING NUTS, ETC.

To Remove a Tight Stud

A method of removing a tight stud is to use two nuts and lock them, keeping the wrench on the lower nut (Fig. 84).

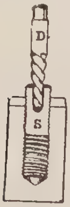

Fig. 85

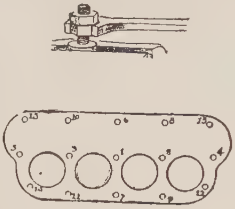

Fig. 84 (upper)
Fig. 84A (lower)

Removing a Broken Stud

A broken stud or screw (S) (Fig. 85) can best be removed by a special left-hand drill (D), called the "Ezy-out," manufactured by Cleveland Twist Drill Co., Cleveland, Ohio.

Other methods are: Pour kerosene around the stud to soak into the threads. If a piece of the broken stud stands above, the broken part may be removed with a chisel and hammer—not a sharp chisel, however. A diamond-point chisel is best. If it will not move, then drill it out, using a drill well under the size of the thread. The hole should then be cleaned out with a tap, the same size as the thread. In the case of a hardened set screw which is broken, use a blow torch and heat. **Another method:** If the broken part projects, saw a slot and use a screwdriver.

Over-Size Stud in Worn Bolt Hole

Use an over-size stud which will make a tight fit in the top of the cylinder-stud bolt holes; then either file, bore, or ream a hole out in the cylinder head so that it will take the over-size stud you are to use. For instance, if a 5/16″, use a ⅜″ tap and stud bolt. If a ⅜″, use a 7/16″ tap and stud bolt. If a ⅝″, use a ¾″ tap and stud bolt. The holes could be drilled out if you have no reamer. A straight reamer would be best.

To Remove a Tight Nut

Try heating it, if it cannot be budged with a wrench. Try pouring kerosene on the nut and bolt and let it stand for an hour or so. Drill holes in the nut and split it with a chisel if it will not come otherwise. This will save the threads of the bolt.

A Stripped Nut Will Not Grip

Usually the fine-thread nut is the one which causes this trouble. A method that may be adopted is to reline the nut uniformly with soft solder and then give it a start on the bolt, and, by working it down the thread, a little at a time, to cut a new thread inside the nut.

The soldering part of the operation is simple enough, the nut being fastened to a piece of iron wire, dipped in the killed spirits, and then held in the blow-lamp till hot enough to melt the solder. The same process reversed would apply equally well to a stripped bolt and nut used to cut a new thread on it.

Fig. 85A (next column). A simple method for inserting screws in inaccessible places.

Fig. 85B. Cut a slot in a cap-screw head with a hack saw and use a screwdriver to start capscrews in inaccessible places.

Fig. 85C. Showing the method for tightening a loose throttle-control lever. Remove the lever from the car, place it on the anvil portion of the vise, strike it a few sharp blow with a hammer, as indicated in the illustration.

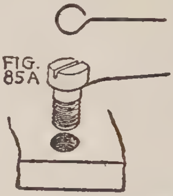

FIG. 85A

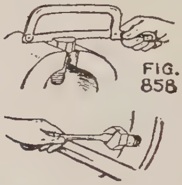

FIG. 85B

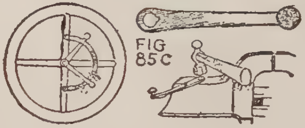

FIG 85C

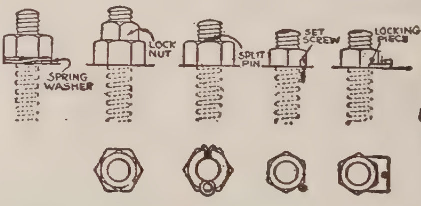
Methods of Locking Nuts and Studs

To prevent nuts from coming off, various locking devices are employed. The first one shown in Fig. 86 to the left is the well-known and most used lock washer. The next one is used a great deal also, and is operated by using two nuts. By holding the top one and backing off the lower one slightly, the nuts are securely locked. The next one is also used a great deal in connection with castellated nuts. The two other methods are used extensively by the Navy Department (absolutely sure, but expensive). The lower cuts show a plan view of the various locking devices directly above.

FIG. 86



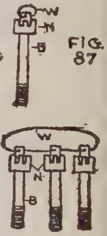


FIG. 87

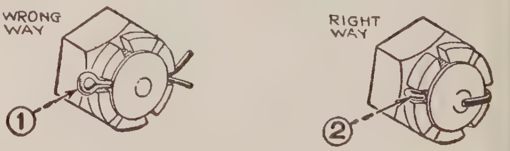
A stud locking method is shown in Fig. 87. It sometimes happens that after securely locking the nut on a stud, the stud unscrews itself at the other end, and is lost. When wired as shown in the lower cut, this is prevented.



Wrong and right way to secure a cotter pin: (1) Head of cotter not in slot of nut—turned wrong. Ends not split right—turned wrong. This combination will soon work loose and come out. (2) Head of cotter in right—pounded down firm—a snug fit in hole. End of cotter pounded back over end of bolt—other end pounded down. Cotter should be tight.

FILES

Kinds: There are many different kinds of files, but we will deal principally with those used for metal work and suitable for automobile repair shops.

Shapes of the files in general use are shown in Fig. 88.

Cutting surfaces are shown in the upper row of Fig. 89. The coarsest metal cutting file is the "**bastard-cut**"; the next is the "**second-cut**"; the next, "**smooth-cut**"; then, "**dead-smooth.**" Note that the finer the cut, the closer the teeth are together. **Coarse-cutting** files are used for **soft metal** or for removing a quantity of metal, and **finer** cut files are used for **finishing** or for **harder metals.**

Method of cutting teeth on a file: The teeth can be "double-cut" or "single-cut," but this does not interest the purchaser, as the manufacturer makes some of the files "single" and some "double" cut. But whichever way they are made, the point that determines the cutting surface of a file is as given in the paragraph above.

The flat file (1) (Fig. 88) tapers, but not to a fine point. Used for filing flat surfaces. A very popular file. Can be had in any of the grades of cutting surfaces as shown in the upper row of Fig. 89. Teeth are usually a "double-cut." This file comes in lengths from 3″ to 18″.

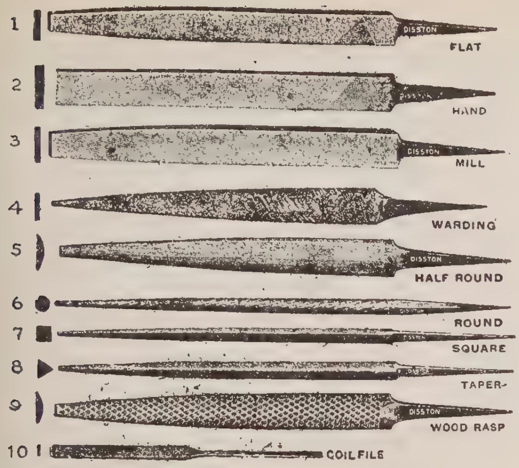


Fig. 88. Shapes of files in general use.

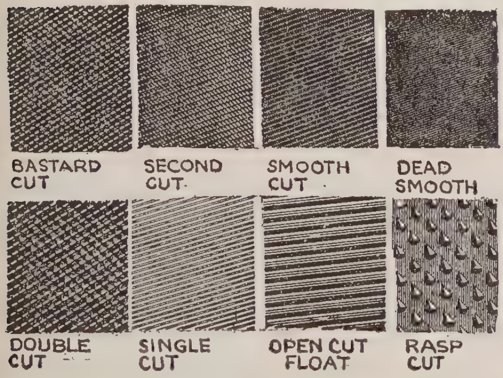

Fig. 89. The top row illustrates the different cutting grades of files that can be obtained; the closer the teeth are together, the finer the cut. The lower row illustrates different methods of cutting teeth on files.

The hand file (2) (Fig. 88) is also a flat file. Used very much for the same purposes as the "flat" file (1). Does not taper towards its end, but does taper in thickness. This file can also be had in different grades of cutting surfaces. The teeth are usually "double-cut." There is one point, however, where it differs. It has one or both edges plain (not cut at all), called "safe-edge." It would be suitable for beveling piston-ring grooves as shown in Fig. 90. Comes in lengths of 3″ to 16″.

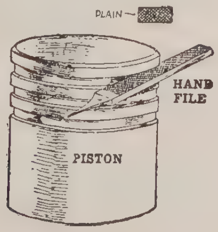

Fig. 90

Mill file (3): Is also a flat file. Used very much for the same purposes as the "flat" and "hand" file, but is of a cheaper make. Teeth are usually a "single-cut." Can be had in the different grades of cutting surfaces, but one point to remember about a "mill" file is that it is one grade finer cut than a "flat" or "hand" file. That is, if you call for a "mill" file with a "bastard-cut," it will be equal to a "hand" or "flat" file of a "second-cut." Lengths, 3″ to 18″.

Warding file (4): Is a flat file, but very thin, about half the thickness of other flat files of the same length. It tapers sharply to a point towards its end. Used for work where space is limited. Can be had in different grades of cut. Teeth are usually "double-cut." Lengths, 3″ to 10″.

Half-round file (5): Tapers. Can be had in different grades of cutting surfaces. Teeth usually "double-cut" on one side and "single-cut" on the convex or round side. Used for work curved in shape; the flat side is used for flat work. Lengths, 3″ to 18″.

Round file (6): Tapers. Used for enlarging round holes, etc. Is usually a "bastard-cut." A small round file is known as a "rat-tail" file. Lengths, 4″ to 18″.

Square file (7): Tapers. Usually a "bastard-cut." Teeth "double-cut." Used principally for enlarging apertures square in shape or rectangular. Lengths, 3″ to 18″.

A square "blunt" file is a square file which does not taper, but preserves its sectional shape from point to tang. It is used for finishing and enlarging mortises, key-ways, or splines. Usually "bastard-cut"; "double-cut." Lengths, 10″ to 20″.

Triangular files (8): Come in many different names as "three-square," "handsaw taper single-cut," "handsaw taper double-cut," "slim taper," and "extra slim taper."

The three-square file tapers and its teeth are usually "double-cut," with cutting surfaces mostly "bastard." Used for filing out square corners, filing taps, cutters, cutting steel tubing, notching round bars, etc. Lengths, 3″ to 18″.

The handsaw taper single-cut file tapers to a small point. Teeth "single-cut." Usually a "second-cut." Used for sharpening handsaws. The three-square file is not suitable for sharpening handsaws. Lengths, 3″ to 10″.

The handsaw taper double-cut file is another triangular file with teeth "double-cut," and a "second-cut" surface. Used for filing fine-tooth hand and metal workers' hack saws, which are harder than wood saws. Lengths, 3″ to 6″.

The slim taper: Teeth are "single-cut" with "second-cut" surface. It tapers and is triangular in shape but very light; in other respects like the "handsaw file." It has superseded the regular handsaw file as it has a greater sweep or stroke. Lengths, 3″ to 10″.

Extra slim taper: Lighter stock than the slim taper. Teeth usually "single-cut" with "second-cut" surface. Generally tapers, but occasionally is blunt. Lengths, 4″ to 8″.

Other triangular files are the "bandsaw file" for filing the teeth of a bandsaw; the "cantsaw file" for filing cross-cut saw teeth, and the "ginsaw file," which is a 4″, three-square, single-cut.

Wood rasp file (9): Is a very coarse-cut file. Note the "rasp-cut" in Fig. 89. Rasp files can be had with teeth shaped as shown, but in the different grades of fineness of cuts, as "coarse," "bastard," "second-cut," and "smooth." Can also be had in flat and half-round shapes. They are used for various purposes, as for wood cabinet work, wheelwright, carriage, and, to some extent, by plumbers and marbleworkers.

Coil file (10): A very fine, flat file, made especially for dressing down vibrator and screw points on ignition coils and platinum interrupter points on magnetos and timers.

Files to Use for Different Work

The larger the work, the larger the file. For flat surfaces, use the "hand," "flat," or "mill" file.

If the work is in a thin narrow space, use the warding file. If for interior work, curved or square, use the round, half-round, and square file.

For cast iron, use the "bastard-cut" to begin the work, and finish with a "second-cut." Cast iron is softer than steel.

For soft steel, use a "second-cut" to begin the work, and finish with a "smooth-cut." If a "mill" file is used, see "Mill file (3)."

For hard steel, use a "smooth-cut," finish with a "dead-smooth."

For brass or bronze, use a "bastard-cut," and finish with a "second" or "smooth-cut."

For babbitt, aluminum, lead and soft metals, use a "bastard-cut." A popular file used for soft metals is a "float" or "open-cut" file, which has wide, deep, open-cut teeth, which do not fill up as readily as those of a finer cut.

How to File

First, select the file suited for the work.

Second, the vise jaws should be about 42″ from the floor.

There are three general methods of using a file: "cross-filing," "draw-filing," and "revolving-filing."

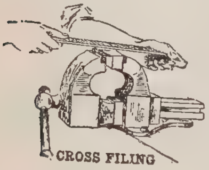

Fig. 90

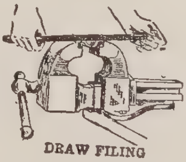

Fig. 91

Fig. 90. Cross-filing.
Fig. 91. Draw-filing.

Cross-filing: Fig. 90 represents the position of the file when used for filing flat surfaces. The file is grasped firmly but not tightly. The far end of the file may be grasped with the left hand, but not in such a way as to assist the left hand in drawing the file forward. The right hand will push it forward, and the left hand will regulate the pressure desired

If the pressure of the hand be equal through the stroke, it will be greatest on the corner nearest the workman at the commencement, and on the other corner at the end of the stroke—due to the leverage —and will tend to form a curved surface by imparting a slight rocking action to the file.

Therefore the pressure must be greatest on the left hand at the beginning of the stroke, and as the file crosses the work, must be gradually diminished on the left hand and at the same time increased on the right hand.

Notwithstanding this, it is impossible to file truly flat. If the work be examined with a straight edge, it will be found higher in the middle.

Draw-filing: To reduce this high part, recourse must be had to draw-filing (Fig. 91), which is the method used for filing bearing caps, which must be filed even or they will not fit up snug against the opposite member. The file is held at both ends and is operated over the work at right angles to the length of the file. In this position the cutting stroke can occur on the forward or the return stroke or both. An even pressure on each end of the file is necessary, and if this is effected, there will be little danger of filing one side more than the other, and the oscillation, which is certain in cross-filing, is mostly done away with in this method.

Revolving-filing: Is filing done on work in a lathe, chuck, or in some cases while in a drill press. Because of the work revolving at a greater rate of speed than the file moves in bench filing, the strokes are less frequent, but should continue through the length of the file, thereby bringing all the cutting edges into service. Hold the file in the same manner as in cross-filing in the vise. Do not exert as great a pressure as in cross-filing or draw-filing. Special "machine files" should be used where considerable of this work is done.

INSTRUCTION No. 65

MISCELLANEOUS REPAIRING: How to Solder; How to Braze; How to Case-Harden and Temper Steel, etc.; How to Straighten Metal Parts; Repairing and Adjusting Silent Chains; Gaskets; Radiator Repairing

EQUIPMENT FOR SOLDERING

The equipment required for soldering consists of a blow-pipe torch, soldering irons or coppers, and solder, acid or flux.

Blow-Pipe Torches[1]

There are many different methods of heating a soldering iron, the usual method being with the use of blow-pipe torches as illustrated below.

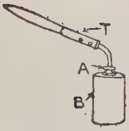

Fig. 1

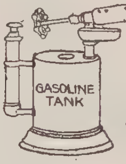

Fig. 2

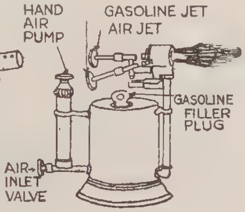

Fig. 3

Fig. 1. The "baby" blow-pipe torch does not require air to be pumped into the gasoline tank (B). It is intended for very light work.

Fig. 2. A single-jet blow-pipe torch.

Fig. 3. A double-jet blow-pipe torch.

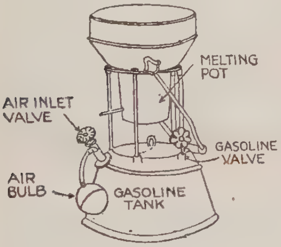

Fig. 4

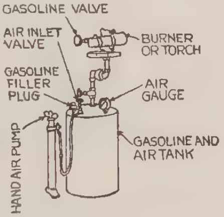

Fig. 5

Fig. 4. A gasoline torch or "fire pot," designed for melting solder and lead; used extensively by plumbers for wiping lead joints.

Fig. 5. A large-size gasoline blow-pipe torch designed for brazing, pre-heating, and general work. The principle of operation is similar to that explained in Fig. 12. With the torch shown in Fig. 5, about 75 lbs. of air is pumped into the gasoline and air tank by the hand air pump. The tank is usually of a 10-gallon capacity.

A Home-Made Gas Blow-Torch

Small soldering jobs, especially in cramped quarters, may be most readily done by means of a blow-torch. Such a torch may be made from pipe fittings in the manner illustrated (Fig 6). In brief, it comprises a piece of pipe, attached to the gas main by a length of rubber hose, with another piece of pipe, attached to the air line and welded to the gas nozzle, as shown. A spacer cross-brace is welded between the two pipes at the rear, making a torch a unit. A valve on the gas pipe renders regulation of the flame easy. Though this torch is somewhat small for brazing jobs, a heavier torch could readily be made for that purpose.

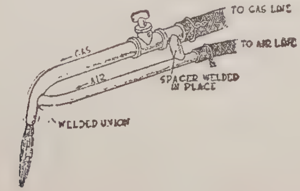

Fig. 6

Gas Torch and Soldering Iron

(A) copper soldering iron; (B) gas-burner tube; (C) gas burner; (D) gas tube to connect hose.

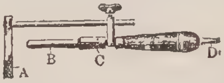

Fig. 7

The gas-heated soldering iron (Fig. 7) can be used with illuminating or acetylene gas by attaching it to a gas burner or to a Prest-O-Lite tank with a rubber tube. By removing the soldering iron, the burner can be used as a blow-pipe for brazing, and also for soldering aluminum. (For sale by automobile supply houses.)

Starretts Gas Heater

The heater (Fig. 8) will be found very useful in the machine shop, as it is convenient for tempering small tools, heating soldering irons, melting lead, babbitt, etc.; and as a forge for light work it will be found very valuable.

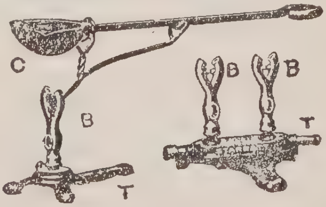

Fig. 8

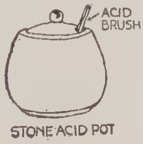
It consists of one, two, or three burners (B), with or without a tool holder, and is connected to the ordinary gas jet at (T). A ladle (C) 14″ long, holding 12 oz., can be had of the same company, L. E. Starrett, Athol, Mass.

Soldering Copper or Iron

A soldering copper or iron (Fig. 10) is a wedge-shaped block of copper, fitted in an iron fork with a wooden handle. Preparatory to its use, it is placed in a clear fire, or gas or blow-pipe torch burner until it is hot enough. The usual size used is No. 1 or No. 2 (1 lb. and 1½ lb. in weight, respectively).



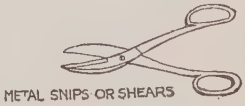


Fig. 9

Fig. 10 (above)

Fig. 11 (below)

If the copper is a new one, it must be tinned. When hot, file off the scale on both sides and ends for a quarter of an inch from the tip, so that the metal will be clean and bright. Dip the nose in the soldering fluid for a second, and then apply it to the stick of solder. A globule will melt off on to a piece of dry brick or tinplate which must be ready to receive it. Rub the nose of the copper in this solder, which will adhere to it as quicksilver does to zinc. The copper can then be used. Copper is used because copper readily absorbs heat and will retain it longer and give it off again rapidly.

---

[1] Imperial Brass Mfg. Co., Chicago, Ill., and Clayton & Lambert, Detroit, Mich., manufacture blow-pipe torches.

The soldering copper must not be allowed to get red hot, as the tin will be burned off and the tinning process must then be repeated. The reader should practice soldering at leisure.

How to Solder

In soldering two parts together, it is necessary that the contact surfaces be perfectly clean. A clean file, scraper, emery cloth, or a little acid is generally used in cleaning the surfaces. Sometimes, especially in old work, the emery cloth will not get a clean surface. A dark spot may be a depression; the file must then be used.

If the work to be cleaned is greasy, clean it first with hot water and soda.

After cleaning, the surface to be soldered should be warmed, and swabbed with prepared acid—that is, muriatic acid which has been prepared by dissolving in it as much zinc as it will hold.

The flux or acid generally used may be prepared in the following manner: To ¼ pint of muriatic acid add scraps of zinc in a pot (Fig. 9) until the acid ceases to bubble and a few small pieces of the metal remain. Let this stand for a day; then carefully pour off the clear liquid, or filter it through a piece of blotting paper. Add to this a teaspoonful of salammoniac, and when dissolved the solution is ready for use.

A solution of salammoniac and borax also makes a good flux for soldering copper and brass.

Wire solder, containing a flux, is generally used, thus saving the necessity of a separate flux or acid (obtainable from the Chicago Solder Co., 4203 Wrightwood Ave., Chicago, Ill.).

Soldering Pointers

The melting point of the soldering material must be lower than that of the article being soldered (see Index for melting points of different metals).

Hard soldering or brazing is a term used when the soldering mixture is composed largely of copper, brass, or silver. Use borax for flux. Hard soldering is best where the material will stand intense heat.

Soft soldering is the ordinary half-and-half (one-half lead and one-half tin). Plumbers' solder has 2 parts of lead to 1 of tin, and is therefore still softer than half-and-half, in order to fit it for working on lead pipe. See pages 738, 736 for solder for radiator repairing, known as "50-50" solder.

Sweating is a term used where the solder is applied to a surface to be soldered and the hot iron is then held on it until it "sweats" or runs in.

For electrical work use resin or a soldering paste, as acid sets up a resistance in the joint.

After an iron has been cleaned and heated and is then rubbed on a piece of "fluorite," the tin or solder will spread readily thereon.

How to Operate a Gasoline Torch—Single-Jet Type

Fill about two-thirds full of gasoline; the filler plug on this type of torch is at the bottom of the tank. The torch is turned up-side-down, the gasoline is poured in, and the plug is screwed up tight, making sure that it does not leak.

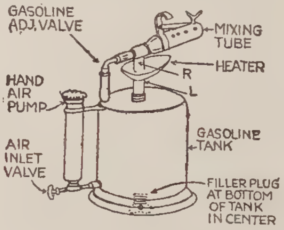

Fig. 12

Air is then pumped into the tank by the hand air-pump plunger, after first opening the air inlet valve (Fig. 12), and after making sure that the gasoline adjusting valve is closed.

Next hold the hand over the mixer tube, and slowly open the gasoline valve at which point gasoline will drip into the heater. Light this gasoline with both valves closed. This heats the pipe (**R**).

After the gasoline in the heater has burned up, the heat should be sufficient to vaporize the gasoline, causing air and gasoline to flow through the pipe (**L**) and (**R**) from the tank to the burner or mixer, when the gasoline valve is opened. A match is applied to this mixture, and the resulting flame should be blue in color; if it is yellow, the heating is not sufficient, and the operation must be repeated. It is advisable to protect the flame from wind while heating.

All torches work on the same principle. Some, however, have two valves (as shown in Fig. 3, page 719); this type is termed a "double-jet." They are also constructed with pots over the flame in which to melt lead; these are termed "fire pots" (Fig. 4).

For brazing, a similar principle is resorted to, except that a larger tank and burner and a separate air pump are used, as shown in Fig. 5.

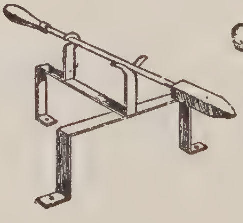

Fig. 13

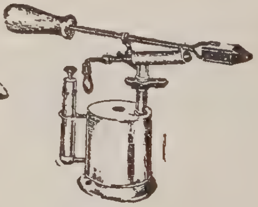

Fig. 14

Fig. 13. A soldering-iron stand which can easily be made, and is well worth the necessary time and labor.

Fig. 14. The usual method of placing a soldering iron on a blow-pipe torch to be heated.

Soldering Aluminum

There are various compounds on the market for soldering aluminum, but this operation depends more on the workman than on the solder, and unless considerable experience has been had, it is probably better to purchase solder than to attempt making it.

The chief difficulty in soldering aluminum is that the heat is dissipated so rapidly that it cools the soldering iron. Furthermore, aluminum oxidizes instantly upon exposure to the air. This extremely thin film effectually prevents a perfect union being made. If the parts are well heated and melted solder is kept melted by allowing the iron to stand on it, the surface can be scraped beneath the melted solder by the point of the soldering iron, thus preventing oxidation to a certain extent. In this way the metal can be tinned. When both parts to be brought together are well tinned, the parts can be united with some chance of success, nitrate of silver, resin, or zinc chloride being used as a flux.

A nickel soldering tool gives more satisfactory results than a copper one, as the latter alloys with the tin and soon becomes rough.

The parts to be united must be thoroughly cleaned. If the surface is of such a shape that it cannot be readily cleaned by scraping, it can be cleaned by dipping it into a solution of nitric acid in three times its bulk of hot water containing about 5 per cent of commercial hydro-fluoric acid. This causes a slight action on the surface of the metal, as shown by bubbles. Rinse the metal after removing from the acid bath and dry in hot sawdust; or thoroughly clean and allow it to stand two or three hours in a strong solution of hyposulphate of soda before being operated upon or cleaned in the acid bath described above.

Aluminum solder: The following formula, in the hands of a competent man, can be used to unite aluminum or aluminoid parts: tin, 10 parts; cadmium, 10 parts; zinc, 10 parts; lead, 1 part. It is best however, to purchase the solder ready made. Concerns making a specialty of aluminum and brazing solder are: Aluminum Brazing Solder Co., Widener Bldg., Philadelphia, Pa.; this concern claims that with the use of Peters aluminum and brazing solder crank cases, etc., can be successfully repaired. The Victory Aluminum Solder Co., 3334 Kedzie Ave., Chicago, Ill., is another manufacturer of this class of solder.

Soldering Cast Iron

To solder and tin cast iron, dissolve as much zinc as possible in one quart of common muriatic acid. Take a half-pint of warm water and dissolve in it 2 oz. of sal ammoniac. In a half-pint of warm water dissolve 2 oz. of chloride of tin. Then mix all thoroughly.

Where cracked cylinders, etc., are to be repaired, half-and-half solder is melted with some copper added. If this is used with the acid just described, excellent results will be obtained. A mixture of about 5 parts tin and 1 part copper is also recommended.

Another method of soldering cast iron: Clean the parts with a file until bright; also use muriatic acid. Wash the acid off with water. Then use a hot soldering iron and soldering acid (muriatic acid cut with zinc), so as to clean the pores of the iron where it is to be soldered. The work must be brought up to the heating point required to melt solder. When the work is thoroughly cleaned and heated in this manner, cool it with a solution of copper sulphate (copper sulphate dissolved in water). This will give a coppered surface. After coating, wash the surplus off; then use soldering acid, the solder and a hot soldering iron, and sweat or run the solder in. (*Sheet Metal.*)

Flux for Soldering Different Metals

Iron and steel: sal ammoniac or chloride of zinc.

Tinned iron: borax, sal ammoniac.

Zinc: chloride of zinc.

Copper and brass: rosin or chloride of zinc.

Lead: tallow or rosin.

Lead and tin: rosin and sweet oil.

Gasoline Feed-Line Repair

A broken gasoline feed line (taken as an example of soldering) may be quickly repaired by scraping the tube near the break, and winding it for 1 in. on each side with clean copper wire. The wire should then be heated, covered with soldering flux, and sweated together with solder. A solid sleeve is thus formed that makes the pipe stronger than originally.

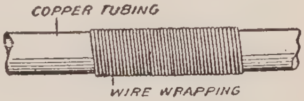

Fig. 15

Gasoline pipes sometimes get loose in the sockets of the unions. This is due to bad fitting, and shows that there is not sufficient elasticity in the pipe; it is too rigidly held. The screwing up of the union strains the pipe, and the vibration on the road causes the pipe to give way at its weakest point, namely, the soldered joint. If the pipe gets loose more than once, it shows that there is something wrong. A longer pipe should be put in, having a U-bend in it, or a complete circle, to give elasticity. The U-bend, or circle, should lie horizontally, with a drop towards the carburetor, otherwise there may be what is called an air-lock in the pipe, and the gasoline will not pass through.

If the carburetor float leaks (if of metal), it can be repaired with solder. Sometimes it is difficult to find the leak. For one method of locating it see Index under "Carburetor float repair."

Brazing

Brazing is infinitely stronger than soldering. It is by brazing that bicycle frames are built up. Bicycle makers use a gas blow-flame. This consists of two parallel pipes—one for gas and one for air. The air, which issues under pressure, causes a strong and very hot flame. The air pressure is produced by a small bellows worked by the foot. The work may be done with the torch shown in Fig. 5 (page 719).

The hard solder, as it is sometimes called, is a brass that melts at a low, red heat. It is generally bought in packets, and is in grains about the size of a pin's head. Brass wire is also used. After being wound around the part to be brazed, it melts and runs into the joint. The **flux** used for brazing is powdered borax.

Brazing a flange: If, for example, it is desired to braze a flange on to a pipe, the flange is placed on the pipe and the pipe is expanded by hammering till it is a tight fit. This is necessary, as it may shift its position in the act of brazing.

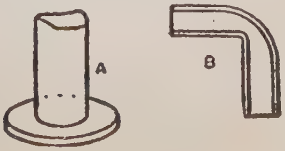

Fig. 16

The flange and pipe (A) (Fig. 16) are put in a clear fire in the forge. Then as it gets hot the spelter, with borax, is sprinkled round the joint, which melts and finds its way into the space between the pipe and the flange. If the reader has a gas or gasoline blowpipe, it will make the work easier, as the heat can be directed where required from above. When cool, the superfluous brass is filed off. In many cases it is impossible to keep the two pieces of metal in the correct places in the forge; therefore a pin or rivet must be put in, so that they cannot shift.

Wiping a Joint

Joining two pieces of lead pipe is termed "wiping a joint." The pipe is first cleaned and prepared, by spreading one pipe with an expander, as at (1) (Fig. 17), and pointing the other ends, which are slipped together, shown at (2). The solder is then melted in a ladle, as shown in (3), and poured around the joint. A pad about 3″ or 4″ square and about ¼″ thick, of canvas or velvet, is held in the hand under the pipe as shown (3), the surface being greased with tallow. The bottom layer may be an asbestos sheet, so that the molten metal will not burn through.

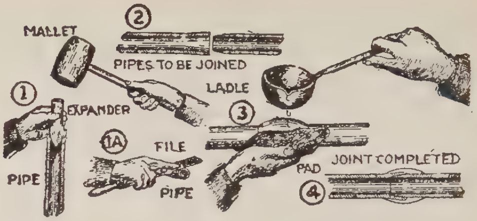

Fig. 17

As the melted solder is poured on the pad, it is wiped around the joint until it is heaped up all around it. The amount of metal used depends upon the size of the pipe. Rub the pipe on each side of the joint with a tallow candle to prevent the metal adhering to where it is not wanted.

Although copper or brass pipe may be joined without difficulty by the ordinary methods of soldering or brazing, the "wiping" method is about the only practical way to couple **lead pipe.**

MISCELLANEOUS[1]

How to anneal, to bend tubing, to use a metal saw, to make small springs and to repair a cracked cylinder, are explained in the pages following.

Annealing Tubing

The copper or brass tubing used for gasoline pipes, carburetors, etc., can be purchased either annealed or not annealed. When not annealed, it is stiff and hard. It is difficult to bend it when hard. The tubing can be softened by heating, as shown in Fig. 18 (called annealing). Iron rods and other metals of like nature can also be softened by annealing.

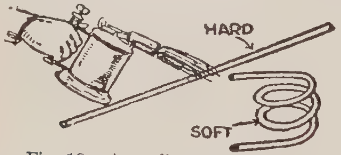

Fig. 18. Annealing copper tubing.

Bending Metal Tubing and Small Rods

The problem of bending metal tubing is one that comes up quite often in the motor vehicle repair and construction shop. Frequently when you undertake to bend some of the new kinds of metal tubing you are surprised to have it break, even though the usual precautions may have been taken to prevent a fracture of this nature. Fill the tube with fine sand packed tight, otherwise the walls are very liable to break, or they are liable to collapse.

First of all, it is best to **determine** the character of the **composition of the tubes.** Many tubes are made by different manufacturers and are finished nearly alike, and you cannot very well determine what procedure to follow when desiring bends or scrolls in them. But the file test will quickly make this clear; or even the point of a cold chisel will do to determine the nature of the metal. Then you can work accordingly.

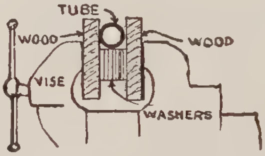

Fig. 19

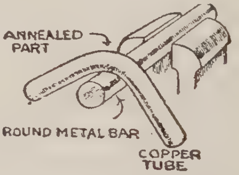

Fig. 20

Fig. 19. **Bending small tubing:** It is well to anneal the tubing first. Then procure several washers, and place side by side until the diameter of the tubing is obtained. Two wood blocks are placed one on each side of the washers and are clamped in the vise. The blocks serve as guides. The tubing is then bent by hand over this form.

Fig. 20. **Another plan** to secure a uniform bend of smaller tubing is to employ an outside mandril on the tube. This consists of a closely and tightly wound spiral of iron wire of about 14 gauge over the tube. This distributes the stresses in the operation of bending, and it can be unwound afterwards. Small-bore tubing can be bent by placing a piece of copper wire (a fairly good fit) inside, and withdrawing it afterwards. A piece of string solder well greased can be used and then melted out.

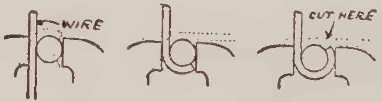

Fig. 21. To bend an "eye" in a small rod.

To bend wire or a small rod and yet leave it circular in form: Drill a hole in a flat piece of iron; fix this in a vise; heat the end of the rod, having previously marked the place where the bend is to be; insert the hot rod in the hole and bend down, using the hammer to insure a right-angle turn, not a curve. The hole must be larger than the rod or the hot end will not enter.

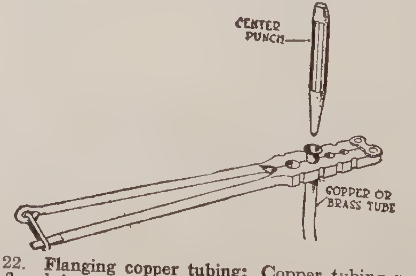

Fig. 22. **Flanging copper tubing:** Copper tubing may be readily flared for the attachment of unions by the use of a pair of lineman's splicing pliers. The end of the tube to be flanged is caught in the jaw of the pliers and a punch is used to press the end out to the extent required. Ordinarily some one of the grooves in the pliers will be found to fit almost any of the copper tubing commonly used. When this is not the case, the grooves may be readily enlarged by an emery wheel.

---

[1] *Automobile Repairshop Short Cuts:* A book containing over 1,500 time and labor-saving kinks, methods and devices, from more than 1,000 of the best garages, service stations, and repairshops in the U.S. Ideas that have been developed to save a good man's time, covering engine, clutch, gearset, running gear, and body repairs, managing and equipping the shop, etc. Collected and edited by *Motor World's* corps of experts. 256 pp., 9 x 12 Ins., 1,500 figs., cloth; price $3.50.

How to Use the Metal Saw

The fine-toothed blades should be used for iron and steel, and the **coarser** ones for brass and soft metals. For **cutting through a brass or steel tube** use a fine-toothed blade, as the teeth rip off the coarse ones. Before sawing, make a true circumferential line round the tube where the cut is desired; then, by turning the tube round a little between each cut, the latter will be true and square. The broken blades are useful at times for small repairs, as they are readily softened.

Another method for sawing tubing is shown in Fig. 23.

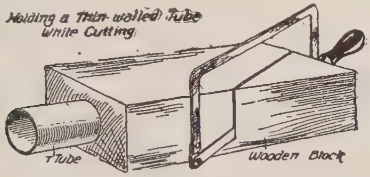

Fig. 23. Method of sawing through tubing. Consists of a wooden block with a drilled hole to receive the tube.

How to Make Small Springs

Spiral springs are now so readily obtained in a large variety that it is not often one is at a loss for a particular size of spring. The occasion may arise where a certain unusual size of spring is required. Figs. 24 and 25 illustrate two methods of winding small spiral springs.

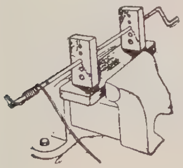

Fig. 24

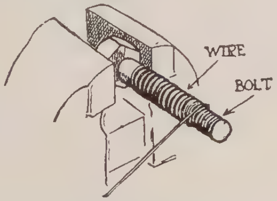

Fig. 25

Fig. 24. Springs of various sizes may be wound on the **spring winding outfit** illustrated. A cast-iron frame supports two uprights that act as bearings for the spring-winding spindle. These spindles are tool steel rod, having a diameter somewhat smaller than the inside diameter of the spring to be wound. One end is bent to form a crank and handle, the other being notched to receive the spring wire.

Fig. 25. How a spring is made by winding wire around a bolt.

Repairing a Cracked Cylinder[1]

Repairing a cracked cylinder: Welding is best, but if this is not convenient, repair with copper as directed below:

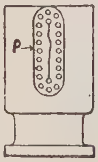

Fig. 26

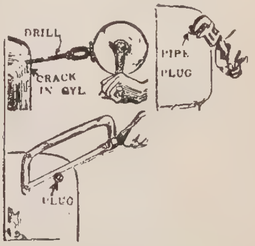

Fig. 27

A small hole should be drilled at each end of the crack, or a little beyond it (Fig. 26), for the crack may go farther than is visible to the eye. A quarter-inch hole should be drilled and tapped, and a screw inserted and screwed home, and the end filed off flush with the metal. Then a piece of stout sheet copper (**P**) (not less than 1/12″ thick) should be cut out, covering the crack extending about ¾″ all around. This must be bent to fit the cylinder and fixed down with a number of 3/16″ or ¼″ screws. Put a piece of canvas smeared with red lead, putty, or thick oil paint under the copper. The patch may leak a little at first, but will probably "take up" in a few days.

Plugging is another plan. A very small crack in a cylinder, probably caused by freezing of contained water, may be mended as follows. Drill a small hole in each end of the crack, and tap it for a small copper plug (Fig. 27). Scrape the surfaces near the crack until the metal is bright. Cover the crack with soft copper filings and melt them in with the blow-torch. Use a flux of rosin dissolved in alcohol, or simply drill and thread the hole, if not too large, and screw in a pipe-plug tap, and saw it off.

Rusting up a small leak in a cylinder: ¼ lb. of sal ammoniac to 1 quart of water, poured into the cylinder and left to stand for 48 hours has caused rust enough to form to close a small hole entirely. Be sure to wash out thoroughly. Another remedy is an "iron cement," secured at supply houses.

Cider or vinegar will cut rust out of cast-iron cylinder water jackets, if left standing for two or three days.

HEAT TREATMENT OF STEEL[2]

In ordinary shop practice this consists of the following: (1) the process of **annealing**; (2) the process of **hardening**; and, (3) the process of **tempering**.

Annealing Metal

Annealing or softening renders a metal in such a condition that it can be easily cut, machined, or bent. See Fig. 18, page 722, showing how tubing is annealed.

To anneal steel: Heat to a dull-red heat and then remove the metal from the heat and permit it to cool in the air.

Where the work is of great importance, an oven or crucible is used. A simple oven is shown in Fig. 28 and in Fig. 30, page 724.

A piece of gas pipe is used, large enough to admit the tool or metal to be heated. One end is closed and placed in the coals until the inside of the pipe has been heated to a bright red. Then the part to be heated is placed in the pipe and brought to the desired heat. Then, instead of cooling in the open air, the work is placed in a bed of non-heat-conducting material, such as charred bone, asbestos fiber, ashes, lime, fire clay, or sand. The metal should be left for a long period of time, well covered, until cool.

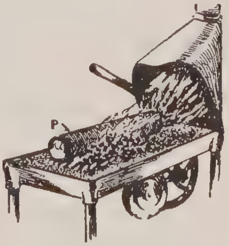

Fig. 28

Brass or copper is heated to a low red heat and quickly dropped into cold water.

---

[1] There is a spelter, called Peters Metallic Filler, which can be used in connection with an ordinary gasoline blow-pipe torch (or any heat up to 300° F.) for filling up cracked water jackets, cracked cast iron, steel, brass or bronze. This can be used instead of brazing and welding on cracks. Write Aluminum Solder Co., Widener Bldg., Philadelphia, Pa.

[2] A book dealing with the subjects of annealing, hardening, tempering, brazing, etc., can be secured of A. L. Dyke, Granite Bldg., St. Louis, Mo. Price $3.50.

Hardening

The process of hardening is accomplished by bringing the metal to the proper temperature, slowly and evenly, the same as for annealing, and then cooling more or less rapidly, depending on the grade of the steel being worked upon.

The degree of hardening is determined by the grade of steel, the temperature from which it is cooled, and the temperature and kind of cooling bath into which it is plunged for cooling.

Steel to be hardened is placed in the oven and permitted to come to a heat of about 650° or 700°. It then is placed in a heating bath of molten lead, fused cyanide of potassium, heated mercury, or some other preparation designed for the purpose. The degree of heat to which a piece of steel must be brought depends on the percentage of carbon contained within the steel. The more carbon, the lower the heat required to harden it.

It is essential that the cooling bath be of the same temperature during each process of cooling.

Ordinarily, steel is cooled in water, but many other liquids are used. If cooled in strong brine, the heat will be extracted very rapidly and the degree of hardness will be much greater. If cooled in mercury, a still greater degree of hardness is obtained.

If toughness is wanted without extreme hardness, the metal may be cooled in lard oil, fish-oil, or neats foot oil.

In hardening carbon steel, bring to a cherry-red heat, plunge into cold water (brine is best), and hold until hissing ceases; then remove and place in oil for complete cooling.

For hardening high-speed tool steel, see page 726.

When hardening brass, bronze, or copper, the work is accomplished by hammering or working while cold.

Tempering

Tempering differs from hardening, in that tempering is the process of making steel tough so that it will hold a cutting edge and not crack or check. Tempering makes the metal stronger and the grain finer. Tempering may be considered as a continuation of the hardening operation.

To temper, the metal or tool is heated slowly, to a cherry-red heat, then dipped into water (Fig. 29), to a depth of about ½″ or ¾″ above the point. When the piece has cooled to the point where the portion above the water has not lost its redness, remove it from the water and quickly rub the end with fine emery cloth.

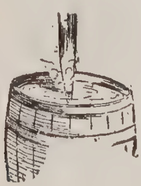

Fig. 29

While the heat from the uncooled portion of the metal gradually heats the point again, a change of color occurs at the polished point. When a **certain color** has been reached, the entire tool should be completely immersed in water and permitted to remain there until cold.

Colors for different work are as follows: Wood saws and springs: **dark blue, 600°**; cold chisels and screwdrivers: **dark blue or light purple, 600° or 520°**; punches, drills, and wood-working tools: **brown, 510°**; taps and reamers: ordinary **straw color, 450°**; lathe tools, planers, shapers, and slotter tools: **light straw color, 430°.** Colors darker than the dark blue, ranging through green and gray, signify that the piece has reached its ordinary temper, which means it is partially annealed.

After a **spring** has been properly hardened by dipping in fish-oil or lard, it may be held over the fire while still wet with the oil and permitted to catch fire. After the oil burns off the spring, it has been properly tempered. Self-hardening steel should never be placed in water.

Drills and small tools can be tempered quite well in a flame. Larger parts are better tempered on an iron plate on which has been placed a thick layer of fine sand and the flame allowed to play underneath. This insures the part being uniformly tempered.

Difficulty is often experienced in lathe work on **nickel-steel stock** through the failure of the tool to retain its cutting edge. To overcome this, heat the tool nearly to white heat and plunge it into kerosene oil. See also, page 725.

Case-Hardening

The process of hardening the surface of the steel, leaving the inside strong and tough, is termed "case-hardening." More carbon is added to the surface of the steel, which offers good wear-resisting qualities and has the effect of forming a very hard coat on the outside while leaving the inside practically unaffected. In other words, the outer surface only is hardened, as for instance, gear teeth or nuts which are hardened to only about 1/50″ deep (see page 725). (*Motor Age.*)

Example of Case-Hardening Steel

The outer surface of any piece of soft steel may be made hard by case-hardening. Its purpose is to increase the strength and wearing qualities of the steel. All machine work to be done on the steel should be done before the case-hardening, as grinding alone can be done afterward. (If any part of the piece must be left soft, this may be done by covering that part with asbestos paste or paper.)

The hardening compound: Mix 9½ parts of fine charcoal with 2½ parts of table salt. Place 2½ parts of kerosene oil in a dish, and put with it as much sawdust as is required to soak the kerosene up. Now mix the sawdust and oil with the charcoal and salt. This compound may be used many times.

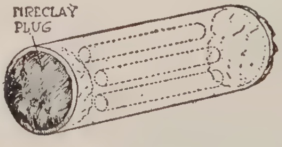

Fig. 30. Case-hardening steel. The pieces are packed in a pipe with the hardening compound—but they must not touch.

The crucible: Get a piece of iron pipe long and large enough to hold the pieces to be hardened (Fig. 30). Pack the pieces in this pipe with the hardening compound. Do not let one piece touch another, or touch the pipe side, but keep them well apart with the compound. Now close both ends of the tube with fire clay.

A large forge fire is necessary for heating the pipe, and the pipe should be heated to a bright-red heat. The length of time varies, depending on the size of the pieces and the depth of case desired.

Ordinarily two hours at bright-red heat will give 1/16″ case. This heat should be held as evenly as possible to give an even case and reduce warping effects.

To produce the maximum strength, two heat treatments are necessary after hardening. First heat each piece to a bright red and plunge in oil. Then again heat it to a dull red, and plunge. This will give a fine grain, both in the core and in the case.

Quick case-hardening: If a thin case is desired, this may be applied quickly by heating the piece to redness and sprinkling the part to be hardened with potassium cyanide. Keep the temperature constant for 4 or 5 minutes, then plunge the piece in water or oil. An exceedingly thin case will result that will increase the wearing qualities of the steel, better its appearance, and prevent rust.

To harden tools quickly: The tool should be heated to the correct temperature and then thrust into a potato, after which draw to the proper temper.

Another Method of Case-Hardening

It is possible **to case-harden small pinions** quite well by bringing them to a uniform bright-red heat and plunging them into finely-powdered yellow prussiate of potash, repeating the operation three or four times, and finally plunging into clean cold water while still at a red heat. The mild steel absorbs carbon from the potash to a depth of about 1/50″, and this surface hardens perfectly on the final cooling. Nuts so treated resist rough usage with the spanner much better than an ordinary soft-surface nut.

In treating parts of this class it is, however, important to remember that the threaded part should be filled up with clay so that it does not come in contact with the carbonizing material, otherwise it will be certain to be spoiled. Any roughness of the surface, such as on the teeth of pinions, can be smoothed off with emery cloth wrapped over a thin flat file. Parts made from tool or high-carbon steel are readily hardened by making them red-hot and plunging them into cold water. The correct heat is important, because if the parts be heated to a very bright red, they may be spoiled or decarbonized, and if heated to a white heat, they will certainly be decarbonized. On the other hand, if heated barely red, the parts will not harden.

Straightening Warped Pieces

Uneven heat and uneven cooling warps the steel. Case-hardened pieces cannot be straightened by pressure or by pounding, as this cracks the case.

To straighten a warped piece of case-hardened steel:

1. Find the high or "bowed" part. Mark this with a chalk line.
2. Heat the piece slightly—never near a red heat. (The amount of heat depends on the warp, and can be determined only by trial.)
3. Clamp the piece in a vise between the blocks, as shown in Fig. 31.
4. Direct a stream of water at the chalk line. This will contract the long side and make the piece straight.

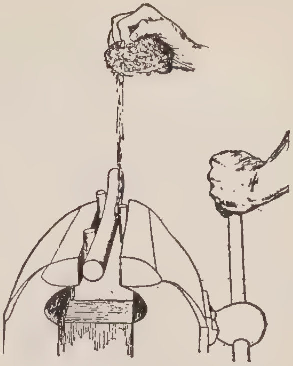

Fig. 31

How to Make Lathe Tools

High-speed steel should usually be heated until the tip of the tool starts to melt, and then plunged in oil, or buried in common salt until thoroughly cool.

High-carbon steel gives the best results when heated to dull red and plunged in oil.

Only **the tool point** proper should be heated to the plunging temperature, the heat being applied slowly at first, to be followed by the blast being turned on and the point heated to the required plunging temperature.

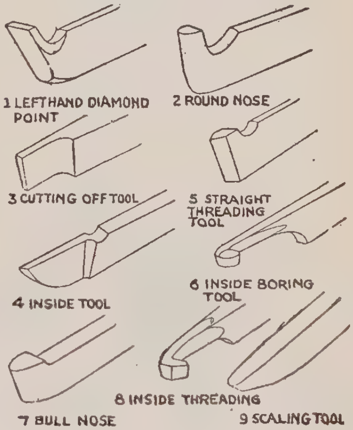

Fig. 32. There is a tool for doing each job most efficiently.

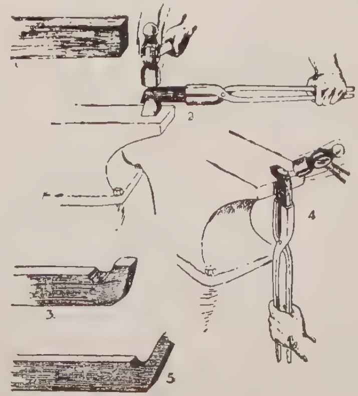

Fig. 33. Steps in making a lathe tool. The work should be done during one heat.

The tool should be plunged into the oil **when the heat is increasing,** and in the case of carbon steel at the instant the point reaches the plunging temperature—dull red, the fusing temperature in the case of high-speed steel. This is particularly necessary with high-carbon steels, as heating the steel white hot, allowing it to cool to dull red, and then plunging it in oil will make a poor tool.

High-speed steels, after hardening and grinding, are ready for use. Carbon-steel tools, however, must be tempered.

This may be done in two ways, the best being to plunge only the point of the tool in oil after heating to a dull red, thus leaving some heat in the heel of the tool.

When the point is black, remove the tool and rub the cutting edge with emery paper mounted on a stick. Watch the point closely, and as the heat is driven from the heel to the point, the color of the surface being polished will turn light straw, dark straw, and blue. When the point of the tool is straw color, plunge the whole tool in oil and cool it entirely.

The **other method of tempering** is to cool the tool after the first heating, polish the point, slowly heat it again until straw color, and then plunge it.

Almost any grinding wheel may be used for grinding the tool, but care must be taken not to draw the temper, or burn the tool. The tool should be held lightly against the wheel and frequently cooled in water. Grind the tools to the shape desired, following as closely as possible those illustrated Finish the cutting edges with an oil stone.

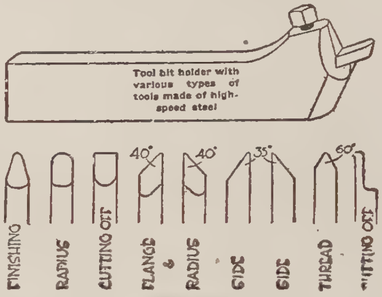

Fig. 34

Fig. 34 shows a tool bit-holder and a standard set of high-speed tools. These are excellent for repair-shop purposes, though expensive. The shapes illustrated will cover a great variety of work, and the tool should be changed to suit the work, rather than regrinding the tool each time. (*Motor World.*)

STRAIGHTENING BENT FRAMES, ETC.

Straightening a bent frame: To make the repair, the radiator is removed, a pan of charcoal is placed under the frame, and pieces of charcoal are heaped around the bend as shown; the frame is then heated up about the bent portion by playing upon the pile of charcoal with the flame of a blow-torch.

As the frame is brought to a cherry-red heat the device (**A**) (Fig. 35) is applied and used in connection with a wooden beam (**B**) which supports the jack.

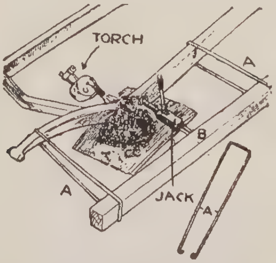

Fig. 35. Straightening a bent frame by heating.

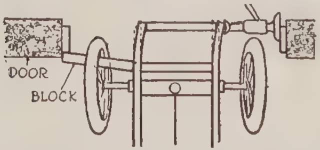

Fig. 36. Another method of straightening a bent frame.

The torch now is set aside, the charcoal removed, and while one man carefully operates the jack and slowly draws the bent member back to its proper shape, another assists the operation by tapping and shaping the heated section with a hammer.

This hammering is quite necessary and an important factor in bringing about a successful result as it assists the molecular action of the steel, and prevents the end of the frame from springing back out of line as the job cools off.

The entire straightening process must be done while the injured section is red hot, and the job must be completed before the red color is lost.

Bent frame horns may be pulled back into place by a chain, providing the force is applied in the proper place. The method of attaching the chain is shown in Fig. 37, and the force is applied by twisting the chain with a steel pinch bar. A jack placed against wooden blocks and with a chain sling over it, as shown, may be used to straighten the side members of the frame.

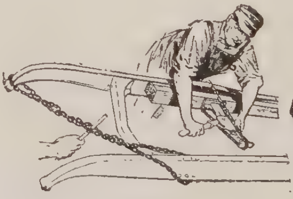

Fig. 37

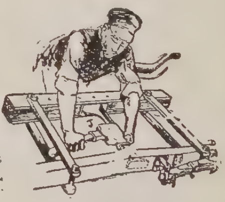

Fig. 38

Frames may be straightened without heating, and sometimes without even dismantling the car, by means of the simple device shown (Fig. 38). It consists of a wooden beam 4 in. x 6 in. x 5 ft., reinforced with iron ¼″ thick on each side. The beam forms the base of the device, to which are attached the steel arms which fasten to the frame. A powerful jack is used to apply the required pressure to bring the frame back to normal. A chain may be substituted for either of the arms.

Other methods of straightening bent frames are shown in Figs. 39 to 42. (From *Motor Age* and *Motor World.*)

Straightening dents in bumpers and similar articles can be done in minimum time with the device illustrated in Fig. 43.

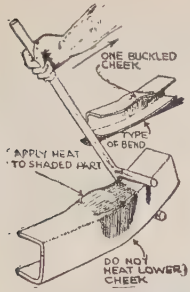

Fig. 39

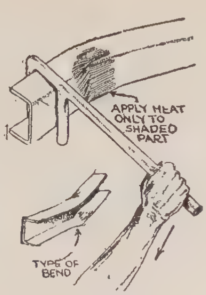

Fig. 40

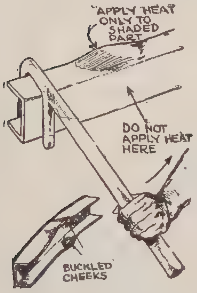

Fig. 41

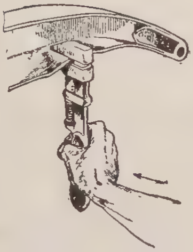

Fig. 42

Fig. 39. When one cheek and part of the face are buckled, only the bent parts should be heated.

Fig. 40. When the face is buckled very little heat should be applied to the cheeks.

Fig. 41. When both cheeks are buckled heat should not be applied to the face but to the shaded portion.

Fig. 42. Small crimps may be taken out with heat and a monkey wrench.

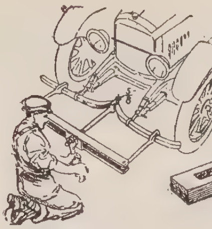

Fig. 43

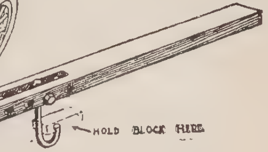

Fig. 44

It is not necessary to remove the bumper from the car. The central member, which does the pulling, may be slid from one end to the other as required, so that a dent in any part of the bumper may be removed.

A fender straightener, made of oak 3″ x 4″, is shown in Fig. 44.

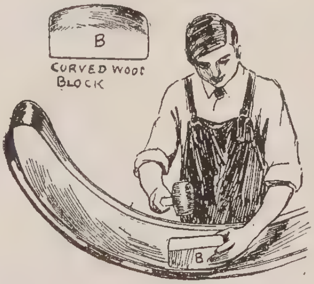

Fig. 45. Easy method of removing dents from fenders with the use of a shaped wood block.

TOOLS AND POINTERS ON STRAIGHTENING FENDERS, ETC.

With a small investment in tools, a little practice, and care in their use, a new department may be developed that will show a profit, and that will also feed other departments.

There is but one secret to sheet-metal straightening: to support all parts except that which is to be straightened, and to go slow, working the metal back to its original form by light blows.

To do this requires many special tools, some of them taken directly from the tinsmith trade; others can be developed on the job.

The Tools

1. **The blacksmith's fuller:** This is used as a hand anvil, either in conjunction with the light mallet, or the light hammer, particularly to remove small dents. The combination of flat surfaces with the rounded edge will cover a wide variety of work.
2. **Half-round file:** After all dents or indentations have been removed by use of the mallets, hammers, and hand anvils, this file is used to remove any small pits or hammer marks.
3. **Heavy wooden mallet:** Used in the preliminary straightening in order roughly to form the metal back to shape. The flat wooden surface does not dent the metal on flat or crowned surfaces.
4. **Light wooden mallet:** The most useful tool of all. After the metal has been pounded back to its original shape, the light mallet, in conjunction with some one of the hand anvils, is used to smooth up the work.

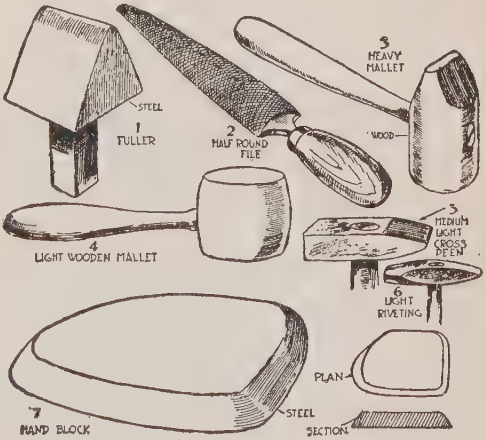

Fig. 46. Mallets, hammers, files, and special tools for straightening fenders, etc.

5. **Medium cross-peen hammer:** A tinsmith's hammer, used to smooth up the surface still further. Wooden mallets will not remove all of the smaller indentations. Hence this hammer must be used as it strikes the required concentrated blow over a limited area.
6. **Light riveting hammer:** Any minor indentation, not smoothed by No. 5 hammer, is taken out by the light riveting hammer. The cross-peen is used to finish corners, prior to filing.

7. **Hand block:** A steel block, roughly about 4″ square, and 1″ thick, with the corners rounded and beveled. The curves and beveled edges vary, so that some part of the block may be fitted to almost any part of the work. This and the light wooden mallet are the most used combination.

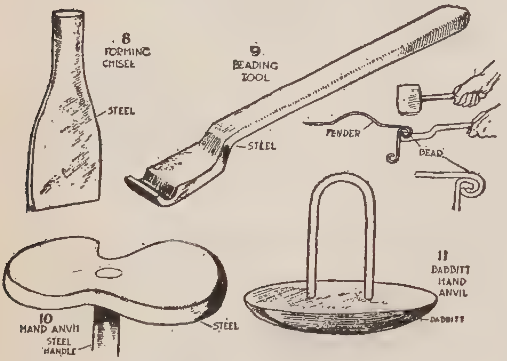

Fig. 47. Some unusual-shaped tools used in straightening fenders, etc.

8. **Forming chisel:** Made in an infinite variety of widths, shapes, and sizes. The one shown is used to form sharp corners, or edges. One with a half-round edge is used to reshape a groove. By grinding the edge to the desired form, the metal may be readily driven to that form.
9. **Beading tool:** The side strips on most fenders are held in place by rolled-in edges. When bent, these edges open. After straightening to the original form, the bead may be again closed by the aid of this tool, and a mallet or hammer.
10. **Hand anvil:** An irregular-shaped steel plate or block, mounted on a steel handle. The edges are beveled, and will fit almost any curved surface.
11. **Babbitt hand anvil:** Made in an infinite variety of forms by pouring melted babbitt into an unbent portion of the part to be straightened. When hard, the shape is that to which it is desired to form the bent portion. Make the handle as shown.

Reshaping Bent Metal

It is not usually advisable to attempt to straighten mudguards and lamps having broken surfaces.

The first step is to work it roughly back to its original shape with a heavy wooden mallet. Care must be taken not to break the surface or to draw it beyond the original shape.

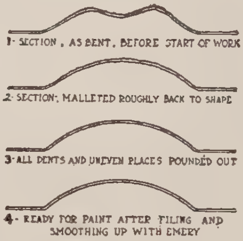
A hand anvil of some sort should always be used in conjunction with the hammer or mallet, to support the edges of the bent surface. Many light blows, rather than few heavy blows, should be applied, and the blows should be drawn, rather than applied dead on. The main thing is to go slow, to feel the dents with the hand anvil, and to direct the straightening blow to the point of the bend.

After the surface has been malleted to approximately the original shape, the smaller dents should be removed, using first the small mallet and then one of the metal hammers. This is slow work.

Filing

By passing the hand over the surface, many of the smaller dents may be felt and removed. Some, however, will still remain. These may be located by filing the surface down. The file will hit the high spots and pass over the low spots. Then the low spots may be pounded up to shape.

Finally it will be found that the file will touch all of the surface except the smallest indentations. Then file the whole surface down to a smooth surface and polish with emery paper.



1- SECTION, AS BENT, BEFORE START OF WORK
2- SECTION; MALLETED ROUGHLY BACK TO SHAPE
3- ALL DENTS AND UNEVEN PLACES POUNDED OUT
4- READY FOR PAINT AFTER FILING AND SMOOTHING UP WITH EMERY

Fig. 48. The four steps in removing a dent from a sheet of metal.

The four steps in this work are shown in Fig. 48, the section being that of a crowned mudguard. But whether the part to be straightened be mudguard, lamp or body, the principle involved is absolutely the same. (*Motor World.*)

Painting Fenders

Before applying the paint, the surface must be thoroughly cleaned with turpentine. This removes all grease that would otherwise prevent the paint from sticking. If the surface is that of a mudguard, the under side should also be cleaned and painted to prevent rusting.

For hurry-up jobs a quick-drying enamel or a black japan may be used to paint the repaired section, the latter, of course, being suitable only for use on black guards or parts. The japan, mixed in turpentine, will dry in about 15 minutes, and, after a few washes, cannot be detected from the rest of the finish.

Enameling Fenders, etc.

Enameling of fenders and of metal parts of bodies is a profitable business. Concerns who supply equipment for this class of work are: Despatch Mfg. Co., 104 N. Second St., Minneapolis, Minn.; Industrial Heating Mfg. Co., Cleveland, Ohio; National Rubber and Specialty Co., 4433 Chicker-ing Ave., Cincinnati, Ohio; Young Brass Co., 6500 Mack Ave., Detroit, Mich.

Painting Outfits

Painting outfits for automobile work can be secured of DeVilbiss Mfg. Co., Detroit, Mich., and Phillips Ave., Toledo, Ohio; Peasche Air Brush Co., 1219 W. Washington Blvd., Chicago, Ill.

Straightening Bodies

Upholstery must be removed or the body must be raised to get at both sides of the surface. Another difficulty is that two men are often required—one to hold the hand anvil and the other to use the mallet or hammer. The co-operation between the two must be perfect, or the anvil will not be back of the hammer blow and the surface will be bent still further. Body work is more difficult,

Dent in Gasoline Tank

A dent can be removed from a gasoline tank by plugging the vent, filling with water, and applying a 20-lb. air pressure. A lead or wood mallet is used by tapping gently around the outer edge of the dent (Fig. 49). (*Motor World.*)

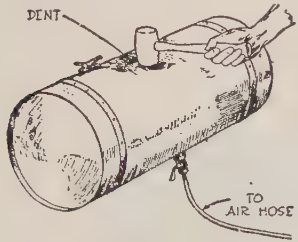


Fig. 49

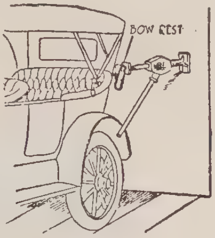

Fig. 50

Jack for Straightening Parts

An ordinary jack may frequently be used to advantage in straightening bent parts. For example (Fig. 50), one of the rests for the top bows was bent in a slight accident, and it was quickly straightened by backing the car up close to the garage wall, as shown, and using a jack.

To Stop Noises about the Car

When seeking to stop **rattling noises** about the car, attend first to the fenders, then to the brakes, hood fasteners, and lamps, and finally to doors and springs. As a rule the fenders, doors, and springs are the most troublesome source of noises on the average present-day machine.

FITTING EXHAUST MUFFLER CUT-OUTS, EXHAUST HORNS, AND SHOCK ABSORBERS

Fitting an exhaust "cut-out": Mufflers sometimes are not large enough, or are clogged up, and offer "back pressure" or resistance to the full passage of the exhaust. A "cut-out" is helpful in climbing hills and to assist in keeping the engine cool. The muffler cut-out is also a convenient method of ascertaining (by listening) whether all cylinders are firing regularly.

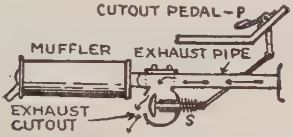

Fig. 51. Method of installing the exhaust cut-out.

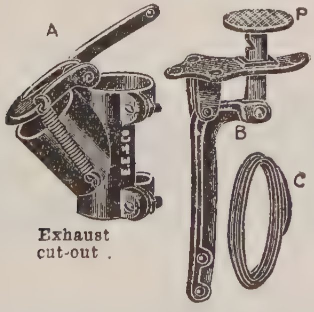

Fig. 52. Exhaust cut-out outfit. (A) exhaust cut-out; (B) foot pedal for operating; (C) flexible wire for connecting.

Note. When ordering an exhaust cut-out, measure the outside diameter of the exhaust pipe to which it is to be fitted, and specify this measurement. (See Index under "Sizes of exhaust pipes.")

Exhaust "cut-outs" are installed by cutting a hole in the exhaust pipe just ahead of the muffler (Fig. 51). Fittings, as shown in Fig. 52, ready to fit and with full instructions can be had from supply houses.

Attention to the cleaning of the muffler must not be neglected, for this is a point having a great effect upon efficiency. For open cars the writer considers a cut-out a necessity: not for roaring through towns or villages, but for the purpose of testing the firing and carburetion.

Although it is necessary to remove the muffler for a thorough cleaning, it is quite possible to effect a satisfactory temporary cleaning of the badly obstructed passages by tapping its sides all over lightly with a hammer or mallet. The result will be that much sooty accumulation will be knocked off and blown out through the tail pipe.

Fitting an exhaust whistle: The exhaust whistle (Fig. 53) is blown by the exhaust pressure; for instance, instead of the exhaust going out into the open air, as in the muffler cut-out (Fig. 51), it passes into the whistle.

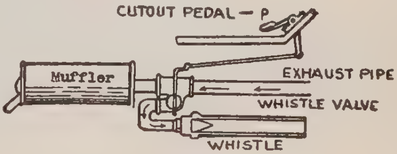

Fig. 53. Method of installing an exhaust whistle.

When fitted to an exhaust pipe, the exhaust is temporarily cut off from the muffler and thrown into the whistle by a special valve attached to the exhaust pipe. Multiple engines blow a whistle almost steadily, but single and double-cylinder engines blow in jerks or uneven blasts.

Attaching Shock Absorbers

Attaching Connecticut shock absorbers: Shock absorbers are necessary accessories. They prevent the rebound of springs after the spring action and thereby prevent springs being broken by the sudden up motion of the car, which is a common occurrence, in going over crossings, etc. If properly fitted, they are worth many times their cost. There are a number of different principles in use. The Connecticut friction type will be used as an example.

To fit: First fill the grooves inside the bushing in the end of each arm with graphite grease.

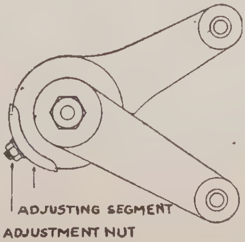

Fig. 54

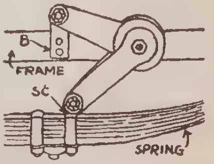

Fig. 55

In order to secure satisfactory results it is important that the angle of the arms be correctly adjusted, so that the cam which operates against the springs in the absorber will be in normal position when the car is loaded and standing still.

Care should be taken that the absorbers are so located that they will not strike the frame when the car is in motion. After the fittings have been attached, slip the absorbers on to the studs of the fittings by loosening up the adjustment nut, so that the arms can be pulled apart any desired distance.

Load the car with the full number of passengers that the car is designed to carry, and tighten up the adjustment nut. The lock washer should be on the stud and the nut tightened securely, so that there will be no danger of the adjusting segment slipping. See that the cotter pins are all in place in the end nuts.

After the absorbers are attached, no further adjustment or attention is required. (Manufacturers are Connecticut Shock Absorber Co., Meriden, Conn.)

REPAIRING AND ADJUSTING SILENT CHAINS

Silent chains are used to drive the cam shaft, generator, water pump, magneto, fan, etc., instead of gears.

The Morse silent chain, as used on many cars (see the next page), differs from other silent chains only in that the Morse employs two pins in the joint, one called the "seat pin" and the other the "rocker pin."

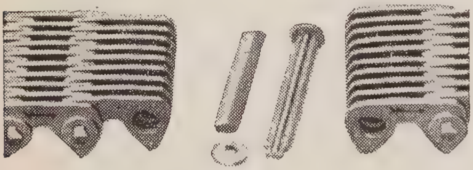

Fig. 56

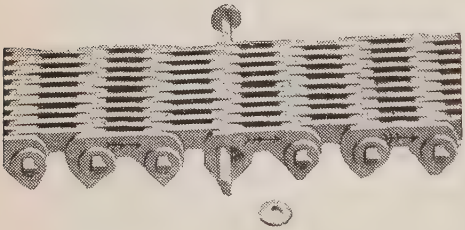

Fig. 57

To connect the ends of a Morse silent chain: Place the chain over the wheels to run in the direction indicated by arrows. On all automobile front-end drives the arrow side of the chain will be the near side, as shown in Figs. 56 and 57.

Bring the ends of the chain together and lap the link plates in regular order, as shown in Fig. 57; insert the "seat pin" (with washer riveted on one end) from the far side of the chain, taking care that the ribbed side of the pin points in the direction of rotation of the chain as shown in Fig. 57.

Insert the "rocker pin" from the near side of the chain as shown by Fig. 57, with the segmental, or pointed, side of the pin against the flat side of the "seat pin," and toward the direction of rotation of the chain. The relative positions of the two pins, when properly inserted, will be as shown by Fig. 63.

Place the washer on the end of the "seat pin" and, after backing up with a bar or wedge, rivet over the end with a few sharp blows of the hammer.

To shorten the chain one pitch by removing the "hunting link": All chains containing an odd number of links must include the thin-leafed section (HL) (Fig. 58). This row of leaves (collectively) is called the "hunting link."

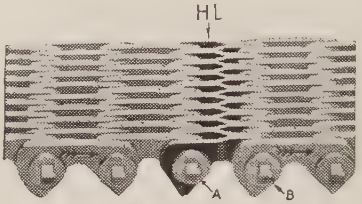

Fig. 58

To remove it, move the chain until the hunting link is on top of a wheel; then with a chisel in vertical position and the edge of the blade at right angles to the plane of the washer, strike sharply with a hammer until washers (**A**) and (**B**) are split sufficiently to make them fall off. This releases the pins in the two joints which can then be driven out, and the leaf-plates of the hunting link will fall away when the chain is lifted up.

The chain is thus reduced in length one pitch (one link), and all that is necessary to put it again in running order is to bring the ends together, mesh the link plates in regular order, and make proper connections as stated above. **The "pitch" of a silent chain** is the distance from center to center of the pins.

To shorten the chain one pitch, by removing four links and inserting three, one of which is the "hunting link": Arrange the chain with the arrow side as the near side, either flat (as shown) on some solid foundation, or on top of one of the wheels.

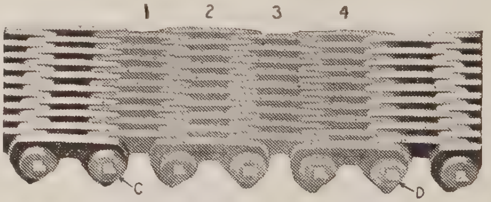

Fig. 59

Select a joint at the **head** of an arrow, and, with hammer and chisel, cut washer (**C**) (Fig. 59) until it falls off. Move to the right four links and cut washer (**D**), also at the **head** of an arrow, in the same manner.

Be careful that each severed washer is at the **head** of an arrow, otherwise the leaf-plates of the three-link section will not mesh in regular order with the chain.

Drive the pins from joints (**C**) and (**D**) and remove the links marked 1, 2, 3, and 4 in Fig. 59. Insert a three-link section in place of the removed section, making sure that the arrow on the new section points in the same direction as the arrows on the old chain. Bring the ends together, mesh the leaf-plates in regular order, and make connections.

Note. It is necessary to remove only four links and to insert the section of three links, as described above, where the chains are used with an even number of links and do not contain a hunting link (HL) (Fig. 58). If the chain contains a hunting link, it should always be shortened as described in the comments on Fig. 58.

Some of the engines on which the Morse "front-end" drive is used: Cadillac, Chalmers, Clyde, Colonial, Drexel, Erie, Ferro, Gray, Hackett, Haynes, Hupmobile, Jeffery, Jewett, King, Lozier, Scripps-Booth, Monitor, Maxwell, National, Nash, Olympian, Pullman, Packard, Winton, Princess, Stearns-Knight.

Silent Chain Adjustment[1]

Various methods are used for adjusting chain tension: For instance, if the chain drives the generator shaft, the generator can be moved in the slot holes to adjust the chain tension, as shown in Fig. 37 (page 75), or the shaft on which the sprocket is mounted can be rotated on an eccentric bearing (Fig. 36, page 74), or, if mounted in a separate case, shims can be installed under the case.

To adjust while running, tighten the chain until it becomes noisy; then slacken to the point where noise ceases. The chain should be as tight as possible without causing noise.

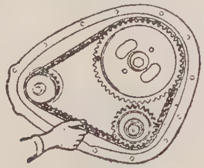

Fig. 60

To adjust where the cover is removed, as in Fig. 60, take hold of the chain and pull the long strand as far as it will go, to test the free movement. The total free movement will vary with the length between sprockets. If the length is from 5″ to 7″, the total free movement should be ⅜″ to ½″; if the length is from 8″ to 11″, the free movement should be from ½″ to ⅝″. If it becomes noisy remove 2, 4, or 6 links each; never an odd number.

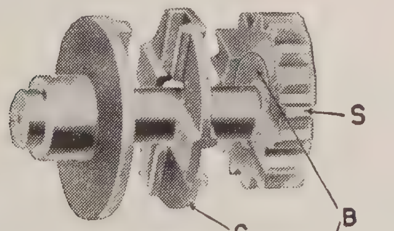

Fig. 61. Morse adjustable sprocket and vibration dampener for silent chains.

The Morse adjustable sprocket (Fig. 61) is designed for shafts, such as generator shafts, etc., when the shaft cannot be moved for adjustment. The sprocket (S) (Fig. 61) is mounted on a bearing which is eccentric to the shaft. By rotating the bearing, the sprocket is moved, thus adjusting the chain tension. The drive is through the sprocket to a plate-type universal joint (C) at the left end (Fig. 61), to the shaft. This joint also tends to relieve vibration of the chain, and is called a "vibration dampener." (Manufacturer, Morse Chain Co., Ithaca, N.Y.)

Chain alignment: When tightening a silent chain by movement of the generator, make sure that it is moved in perfect alignment, otherwise it will cause the chain and sprocket to wear rapidly. This is most important. If it is too tight, it will sing and also cause wear.

Example of Silent Chain Disassembling and Assembling (Cadillac models 53 and 55)

Detecting looseness: Looseness in the silent chains grows so gradually that it is scarcely to be noticed until the chains have become so loose that they jump the teeth of the gears. This, of course, destroys the timing. **The extent of the looseness may be felt** by grasping the generator shaft and rocking it back and forth. Any great looseness destroys the proper timing of the valves and necessitates a replacement of the chains.

Disassembling: After removing all parts so that access is gained to the chains, then turn the engine until one tooth of the cam-shaft-driven sprocket (A) (Fig. 64), which is marked with an arrow, is diametrically opposite the tooth with an (O). A tooth on the crank-shaft sprocket (B) has a similar arrow upon it, and the two teeth opposite each have an (O) mark. All should line up, as shown in Fig. 64.

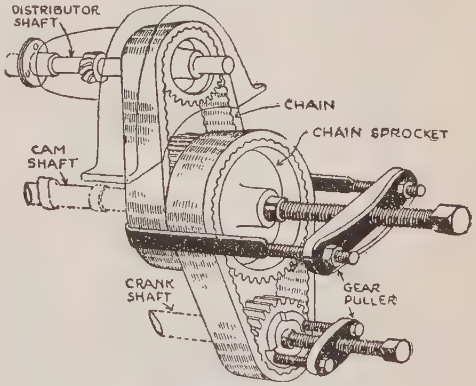

Fig. 62. Using special pullers, both gears and chains together with the distributor housing are removed at once. The generator universal must first be disconnected.

Apply the special gear puller, as shown in Fig. 62, to the crank-shaft gear; next apply the special cam-shaft gear puller, as also shown in Fig. 62.

Working both pullers together, remove both cam-shaft and crank-shaft gear, at the same time sliding the distributor housing and fan-drive chain forward. All will come off together. (The usual method is first to cut the riveted head of one of the seat pins on the driving chain, and to remove the seat pin and rocker pin. The driving chain is then removed. In refitting the new chains by this method, it is necessary to rivet the seat pins while on the gears and in the case. This is a difficult and tedious job. By the method outlined here, the chains are riveted on the bench easily, quickly, and with a certainty of the work being right.) Place the gears, chains, etc., on bench, removing cam-shaft driving chain.

---

[1] See pages 74 and 75 for remeshing timing gears when using silent chains. Chains have a tendency to wear in the pins, so much so that they will often have sufficient slack to strike the case covering it. A 17″ chain has been known to have $1\frac{1}{16}''$ slack after 8,000 miles running. In this case a new chain is necessary, or enough links must be removed to take up the slack.

The repair: Cut off the riveted head of one of the seat pins on the fan-shaft driving chain, and remove the seat pin and rocker pins. Remove the fan-shaft driving chain. Clean all parts with gasoline, and examine the gears for wear. If worn, the faces of the teeth will be ridged, showing the marks of the chain links, and must be replaced.

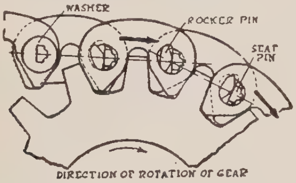

Fig. 63. In replacing the chains, make certain that the **arrows point in the direction of rotation,** and that the rocker and **seat pins are in the position shown.** Otherwise the chain will quickly ruin itself.

Place a new fan-shaft chain over the fan-shaft gear with the arrows on the outside links pointing in the direction in which the chain is to run (Fig. 63).

Rivet a small washer to one end of a seat pin in a vise. Bring the ends of the chain together. Insert a rocker pin; then drive the seat pin with its washer into place. Be certain that the rocker pin and seat pin are in the position shown in Fig. 63. Head over the end of the seat pin. Rivet up the new cam-shaft driving chain in the same manner.

Assembling: Place the cam-shaft gear on the fan chain, with the mark (O) in the lowest position. Place the cam-shaft chain on the gear, with the arrows pointing in the direction of rotation. Place the crank-shaft gear into the cam-shaft chain with the marks as shown in Fig. 64. Now slide the whole assembly into place on the engine, driving the gears home with a brass bushing and machinist's hammer. Replace the nut and washer on the crank-shaft end; and then replace the parts which are disassembled.

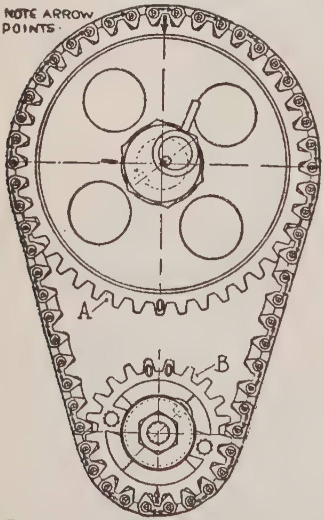

Fig. 64. The marks on the cam-shaft gear (**A**) should line up with those on the crank-shaft gear (**B**) before the gears are removed, and should be replaced in exactly the same position.

The valve timing: The valve timing was automatically cared for in replacing the cam-shaft driving chain as directed, providing the valve tappets have the proper clearance. The exhaust tappet should have .003″ clearance, the intake .002″; the exhaust should close and the inlet open on dead center. The inlet should never open at a point more than 1″ past dead center on the flywheel.

Ignition timing: Open the compression relief cocks, crank the engine until No. 1 cylinder (the one nearest the radiator, on the right-hand side when facing the engine from the front) is on the firing center. The pointer above the flywheel will then be exactly over the mark 1-5 on the flywheel, and both valves of No. 1 cylinder will be closed.

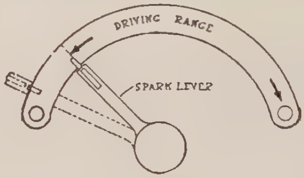

Fig. 65. Position of the spark lever, when timing the ignition. The end of the lever on the quadrant should line up with the point of the arrow, as illustrated.

With the timer open, as shown in Fig. **6A**, page 215, loosen lock screw (**A**) slightly. Then set the spark lever as shown in Fig. 65.

Connect the test lamp into the primary circuit, as shown in Fig. 65**A**. When the breakers are closed, the light will be lighted, if the ignition switch be closed.

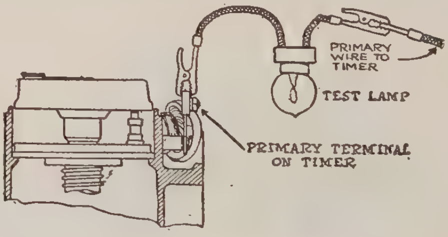

Fig. 65**A**. By placing a test light in the primary circuit, the exact instant that the spark occurs can be determined, as the light then goes out.

Replace the distributor rotor, and turn by hand until the distributor brush is under the terminal marked No. 1 on the distributing cover. Turn on the ignition switch. The light should light. Turn the rotor very slowly, in the direction in which it is driven by the engine, until the lamp goes out. Remove the rotor; tighten screw (**A**) of Fig. **6A**, page 215.

Replace the rotor and retard the spark. Then move the spark lever slowly back toward the point of the arrow, as shown in Fig. 65. When the point of the arrow is reached, the light should go out. If it does not, reset the rotor and cam, as directed.

GASKETS

Gaskets are used on the engine and transmission and other parts of the car, the **purpose** being to make tight joints. Thin gaskets are preferable to thick ones, and should always be used on all joints that come together square. Metal to metal joints are best, but it is next to impossible to make both flanges meet absolutely square. It is for this reason that some sort of flexible material is interposed to make up for the inequalities in material and workmanship.

There are several kinds of gaskets: Paper, asbestos, asbestos wire-lined, copper, copper-asbestos lined, cork, and felt, and in some instances, lead can be used.

For engine cylinder heads (if of the detachable type), the type of gasket almost universally used is the soft copper gasket, either lined with asbestos on each side, or copper on each side with asbestos inside, usually the latter.

When taking off the cylinder head for removing carbon, etc., the old gasket can be used again, but many repairmen find it advisable and economical in the long run to take no chances and to fit a new gasket.

When using a gasket of this type the use of **shellac is not recommended.** It has a tendency to set after the engine has run a short time, which interferes with the final tightening.

When applying a new gasket, in order to insure compression in all cylinders, the cylinder head should be drawn down firmly on the gasket and block with an even pressure at all points before the later operations of tightening are attempted.

The Victor Mfg. Co. states that while grease and shellac are used in applying gaskets, experience dictates that the best practice is to see that the face of the head and cylinder block, as well as the gasket itself, are **thoroughly clean,** and then to apply the gasket without grease or shellac. With the Victor gasket, soft copper is used, which works into the uneven parts.

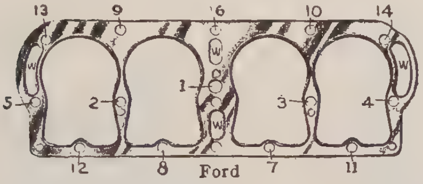

Fig. 66. **When putting on a new gasket, the bolts should be tightened in the order indicated above;** that is, tighten 1, then 2, 3, and so on to insure against lessening of compression and against leakage of water into the cylinders. This illustration also shows the shape of a typical copper asbestos-lined cylinder-head gasket used on cylinders with detachable heads.

The stud or bolt holes are numbers 1 to 14. The holes in the gasket provided for water circulation from the cylinder head to the cylinder water jacket are the other holes (W). Sometimes, when gaskets do not fit properly, the water works its way into the cylinder, thus causing water in the crank case, as well as a loss of compression.

Fig. 66 shows the **order in which cylinder-head stud bolts should be tightened.** The same general principle applies to all "fours," "sixes," "eights," and "twelves." A socket wrench is the best tool to use.

After the first operation of drawing down the nuts, they should be gone over in the same order a second and third time until they are as tight as it is safe to make them without stripping the threads.

The final tightening should be done after the engine has run a few hours, when, it will be noted, about a full turn can be taken on all nuts.

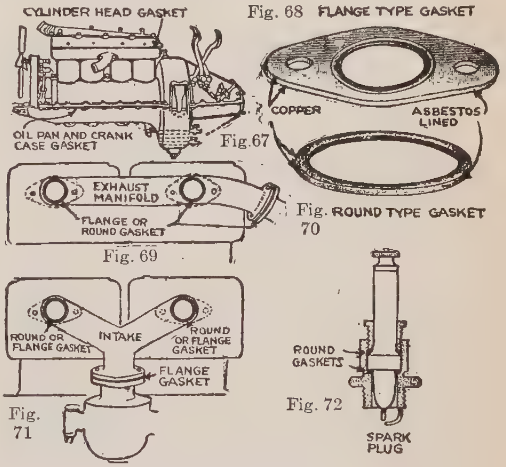
A type of gasket used extensively is the Victor gasket, made of pure copper and asbestos. When properly installed, they will not leak or blow out. See Fig. 66, showing a typical example of this type of gasket, and Fig. 67 showing how it is placed between the cylinder head and the cylinder block of the engine. Gaskets of this type can be secured in sets or singly for different engines.

Where old gaskets are used over again, the important point is to see that the surfaces are **clean,** and that the gasket is not damaged.

If there is a water leak or compression leak, a new gasket should be fitted after cleaning all surfaces thoroughly. If a new one is not available, then put shellac on each side of the gasket and apply before it dries, but be sure to scrape and clean the surfaces carefully before applying, otherwise a leak will occur. Alcohol is used to clean surfaces which were previously coated with shellac. Bear in mind that if there are any rough surfaces the gasket will leak.

Asbestos gaskets for cylinder heads of marine, stationary, and such types of engines are often used. The copper and asbestos gaskets are preferable, however. The following explanation will serve to make this clearer.

Asbestos gaskets of this type can be purchased ready to apply, or cut from sheet stock. They are made of closely woven, long-fiber asbestos yarn and brass wire closely woven and impregnated with a heat and water-resisting compound. The red compound on one side sticks to the flange when a joint is broken. The graphite on the other side allows the joint to be easily taken apart. Sold in rolls or in gaskets cut to order. This is also used in many places, such as the water plate, but it is more commonly used where there is a great deal of heat. If sheet asbestos (not wire-woven) is used, it ought first to be soaked in linseed oil.



Figs. 67 to 72. Showing the different places where the round and flanged type of gasket can be used.

Copper (also brass) asbestos-lined gaskets, termed the "flange" type (Fig. 68) are used extensively for placing between the intake manifold and cylinder (Fig. 71), and also between the carburetor and the intake manifold; between the cylinder and the exhaust manifold; between the exhaust manifold and the exhaust pipe (Fig. 69).

The round type of copper asbestos-filled gasket (Fig. 70) is used in spark plugs (Fig. 72). The Victor Mfg. Co., 5750 Roosevelt Road, Chicago, supplies gaskets of this type. When ordering, the inside diameter is given, or else name the make of car and where the gasket is to be used.

Paper gaskets are often used in many places on the engine, but cork gaskets are preferable. Some of the places where paper can be used are between the cylinder and crank case (not between the cylinder head and cylinder); on the oil and water pumps; on the generator and starter motor; on the carburetor (lead, cork, and leather gaskets are also sometimes used here); on the transmission gear-case cover. The housing cover over the differential is sometimes fitted with a gasket, but more generally it is simply given a coat of shellac. The hub flanges of wheels, clutch members, valve-case covers, etc., also require paper gaskets.

When using paper gaskets, select a heavy wrapping paper and cut it to size, or order direct of the manufacturer.

A gasket paper which is oil and water-proof is made by the Weber Supply and Specialty Co., 127 N. Dearborn St., Chicago, Ill.

Many repairmen make a practice of coating the gasket with grease in order to hold it in place while fitting the parts together.

To remove paper on the running-boards of new cars: A new car usually has brown paper over the running board and floor boards, to protect them in transit. A good way to remove this neatly is to fasten a safety-razor blade in a small block of wood and trim close. No ragged edges will then be in evidence.

Cork gaskets are not suitable for cylinder heads, as they would burn or blow out under the extreme heat and pressure to which they are subjected in this particular spot. The cork gasket is used extensively for the same purposes mentioned in connection with paper gaskets, such as for oil, water, and gasoline connections. They are particularly adaptable for pressed-steel parts because of their flexibility, which enables them to fill up all the rough spots and unevenesses in such parts. Their main applications are between the oil pan and the crank case; on the oil-pan bottoms; on the valve-plate covers; in the water-manifold connections; in the timing-gear case; on hand-hole covers on the transmissions, clutch and differential housing, and hub flanges of wheels, and for all similar purposes.

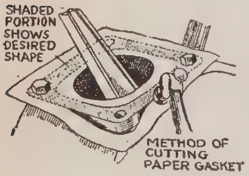
Felt gaskets are seldom used.

Cutting Gaskets

Perhaps one of the first things at bench work that a young repairman is taught on entering a shop is that of cutting gaskets.

The gasket between the base of the cylinders and the crank case and the cover of the gear box are usually made of paper (or of cork, which is obtained already cut. Paper gaskets are also obtainable from the manufacturer, already cut).

If care is not exercised in removing a cylinder from the crank case, or other parts, the paper gasket may easily be damaged by part of it adhering to the cylinder and another part to the crank case. Should the gasket be ruined by any chance, a new one can easily be made in a few minutes.



SHADED PORTION SHOWS DESIRED SHAPE
METHOD OF CUTTING PAPER GASKET

Fig. 73

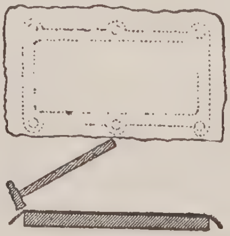


Fig. 74

Fig. 73. Cutting a **gasket for the lower part of the cylinder,** where it fits to the crank case.

Fig. 74. Cutting a gasket for the transmission cover.

Cutting gaskets: A sheet of fairly heavy wrapping paper should be obtained and a hole made just large enough to accommodate the piston. The paper is then rested on the crank case or cylinder (Fig. 73), and with the aid of a ball peen hammer tapped all around the edges. It is, however, best first to mark the holes for the holding-down bolts, and to insert the latter to hold the paper in position.

When making the corners and also the holes for the bolts it is best to use the peen or round end of the hammer.

It is not necessary to strike the paper a hard blow, a series of slight taps only being required. With these, it will be found that the gasket will have a nice clean cut edge, and will conform exactly to the desired shape.

It does not matter much how complicated the shape of the gasket may be, for if these suggestions are followed, making a new one will be fairly simple.

The hardest part of the whole procedure is to keep the paper in place on the crank case, but if the holes for the holding-down bolts are first made and the bolts are then inserted, as shown in the illustration, no difficulty should be experienced.

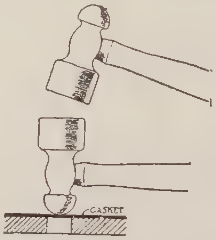

Fig. 75

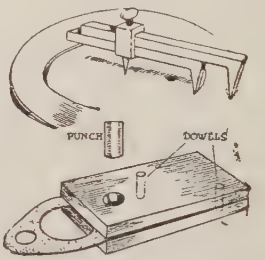

Fig. 76 (upper)
Fig. 77 (lower)

Fig. 75. When cutting gaskets from metal and asbestos packing, felt, and other materials, it is sometimes difficult to **cut bolt holes,** especially those close to an edge, without damaging the material. A way out of the difficulty is to use two round-headed hammers, placing the round head of one over the hole and striking it with the other.

Ball bearings of various sizes are also useful in cutting small holes, such as for studs, in gaskets. After the gasket is cut to shape by hammering around the edge of the gasket flange, a ball bearing is put over the hole and hammered until the hole is cut in the gasket. This method produces sharply defined edges. In cutting paper gaskets it is advisable to grease the paper first, so that it will stick to the surface.

Fig. 76. **A device for cutting circular gaskets** may be made out of two pieces of steel shaped as shown and fitted with a clamp which forms the center. The two cutting members are adjustable, so that practically any size of gasket may be cut.

Fig. 77. It is difficult to cut holes in gaskets and not have ragged edges. When there are a great **many holes of a given size to be made, it is advisable to construct a die** consisting of two plates of metal doweled together and with a hole or series of holes through which the dies may be pushed. The gasket material is slipped between the plates, and then the die is forced through with a hammer.

Another method is to file a chiseled edge on short sections of different sized iron pipes, which can be used as punch cutters.

Cutting gaskets for gear box or transmission cover: The same principle applies here (see Fig. 74). Be careful in tapping to see that the edges are not broken. Sometimes it is possible to press the paper by hand and to make indentation enough from which to cut the gasket.

Other gaskets, such as mobolene and asbestos gaskets, are made in a similar manner, but are usually marked off by pressure of hand or finger, when placed over the part to be fitted, and then cut out with a sharp knife. Asbestos gaskets for cylinder heads are sometimes made when nothing else can be had. The asbestos is soaked in linseed oil before applying.

Packing for Water Pumps and Lubricators

Packing for water pumps and lubricators: For packing the water-pump shaft, etc., nothing has been found better than asbestos string plentifully smeared with a mixture of heavy oil and graphite. Candle wicking can also be used if asbestos string is not handy.

Shellac

Shellac is an excellent preparation to insure a good tight joint, and ought to be used on only one side of a gasket. Shellac dries up; but a good way to handle it is to have a wooden stopper which can be used for applying the shellac as well as serving as a stopper.

When a workman wishes to spread a coat of shellac upon a gear-case cover, or a gasket, he has but to invert the bottle with the stopper in place, then remove the stopper and roll the large end over the surface to be smeared, and a coat of shellac is left in its wake.

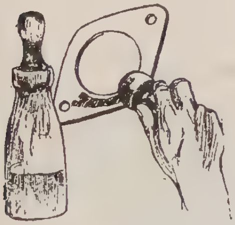

Fig. 78

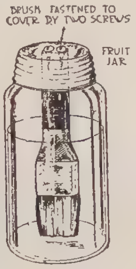

BRUSH FASTENED TO COVER BY TWO SCREWS
FRUIT JAR

Fig. 79

Figs. 78 and 79. Methods of keeping shellac on hand for ready use.

How to mix shellac: Secure an open-mouth bottle; fill nearly full of flake shellac, and pour in alcohol, and let it dissolve. This will make a very thick solution. To make it thinner, put in less flakes of shellac. The flakes can be secured at any drug store.

Using shellac: In replacing detachable cylinder-heads, only the smallest possible amount of shellac should be used, and this should be quite thin. If the shellac is heavy and any considerable quantity is used, it will squeeze out into globules and the first explosion will blow these into the valve ports, where they will start an accumulation of carbon.

Note. When using shellac on a gasket, use it on but one side. The gasket can then be used over and over again. Otherwise it will be necessary to make a new one each time it is removed. Common grease is used by many to hold a gasket in place until the part is placed in position and drawn up.

Berry Bros., Detroit, Mich., manufacture shellac, and also a substitute called **"gasket cement,"** which is made from grasstree gum. It is stated that this is as satisfactory as shellac.

Shellac with copper gaskets: Where copper gaskets are used, it is best to clean all surfaces thoroughly and to use a new gasket and draw it tight. After running the engine for a day or so, draw the gasket up. If the surface is not clean, the gasket will leak.

If a new gasket is not obtainable and the old gasket is used over again, and if shellac was used, then clean the shellac from the surface and also clean the old gasket with alcohol. Shellac can then be used on both sides, as there will probably be some rough surfaces still left. Do not get shellac in the valves or cylinder.

Shellac with paper gaskets: Use shellac on one side only, that is, coat one of the metal surfaces and then put the gasket over it, and bolt down the other metal side before it dries. This leaves one side of the gasket dry, and before bolting down the metal surfaces, a light coating of oil or grease can be given to the other metal surface. This will facilitate the easy removal of the gasket without ruining it.

Paper gaskets are not always shellacked, for if one proves to be damaged, then the shellac and the paper gasket itself will have to be removed by scraping and by the use of alcohol before another can be applied.

Many mechanics simply put **a light coat of grease** over both sides which hold the gaskets in place, while fitting the metal surfaces.

If there are studs to hold the gaskets, while the parts are being put in place, it is best not to use grease or shellac.

RADIATOR REPAIRING

Radiators are divided into two classes: **tubular radiators** with straight vertical tubes with crimped fins, as in Fig. 14, page 147, and with vertical tubes with horizontal fins, as in Fig. 15, page 147. The **cellular type** comprises both the tubular type, resembling the genuine cellular, as in Fig. 18, page 147, and the cellular type, as in Fig. 19, page 148.

Equipment

The equipment necessary for repairing tubular radiators, as well as those of the cellular type, consists of the following:

1. **A table,** as shown at (1) (Fig. 81) for assembling or disassembling, or a **work bench** as shown in Fig. 80. The latter is designed for Ford radiators. This work bench (Fig. 80) includes a table, dimensions of which are given on the illustration, covered with tin, and with racks for turning radiators upside down or otherwise.
2. **A test tank,** as shown in (2) Fig. 81, or in Fig. 80. Air pressure is necessary, but not over 8 or 9 lbs.
3. **A compressor** (12) (Fig. 81) should be provided for the air pressure, and a hot-water tank can be used for an air receptacle with a gauge (8) on the tank to indicate pressure. This air tank can be used for testing radiators, as explained on pages 736, 737. It can also be used for the air supply to the torch (Fig. 80), in connection with gas.

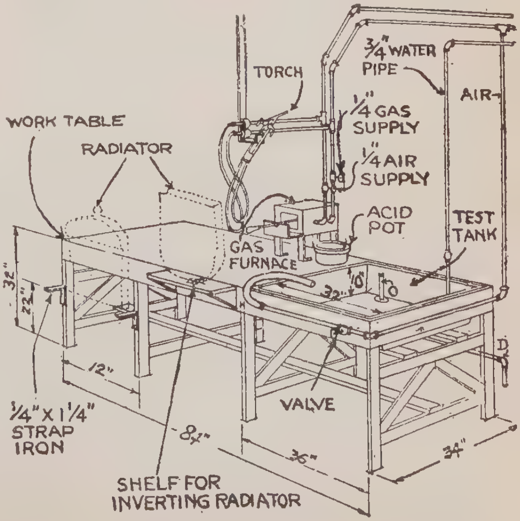

Fig. 80 Radiator repair outfit.

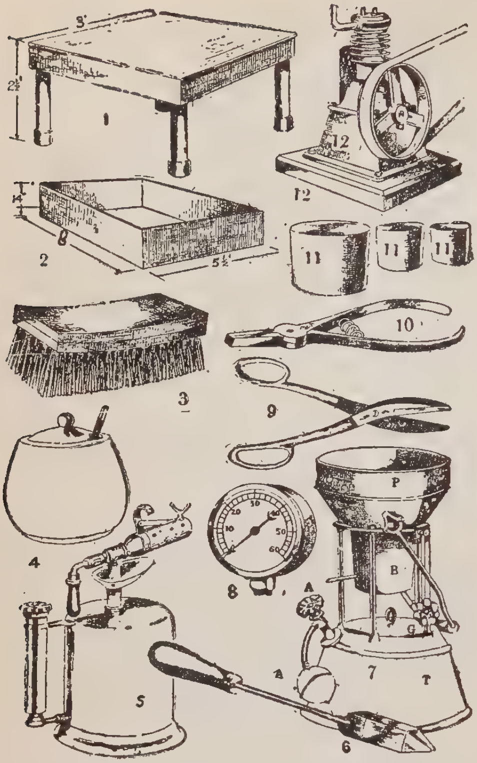

Fig. 81. Radiator repair tools and devices.

4. **A gasoline fire-pot torch** (7) (Fig. 81) or a gas furnace (Fig. 80) must be provided for heating the soldering irons.
5. **Two soldering irons** (6) (Fig. 81) heavy enough to convey sufficient heat to the work. The iron should taper to a flat point as in Fig. 82. Long-pointed irons for core work are also necessary.
6. **Acid** (4) (Fig. 81) must be kept in a stone pot. It is made of commercial muriatic acid cut with zinc, that is, zinc is placed in the acid and left in it until boiling stops. It is used for cleaning parts before soldering, and as a flux for soldering.
7. **A blow-pipe torch** (5) (Fig. 81) must be used, but should be of a type which will give a concentrated or flooding flame. It is used for soldering, loosening, or removing sections.
8. **A combined gas and air-type torch** (Fig. 80) is necessary. This torch should throw a fine needle-point flame (see page 751). With such a torch and with wire solder, inside core leaks, honeycomb radiators, and hard-to-get-at places can be reached, but a torch of this kind must be kept in motion, otherwise part will be burned.
9. **Wire brushes** (3) for cleaning off rust. See also page 740 for small scrapers.
10. **Metal snips,** or shears (9).
11. **Weaver pliers** (10) for straightening core material, also rods for running through bent tubes.
12. **Rubber plugs** (11), ½" to 4" diameter in ¼" sizes for closing openings in radiators when testing with air. See also pages 737, 740.

Soldering Pointers

Solder: Use "50-50" solder. It can be secured in wire or bar form. See also pages 738, 720.

The soldering iron should be well tinned. When iron becomes so dirty that it cannot be cleaned on sal-ammoniac it should be filed and re-tinned.

To tin an iron, heat it, dip it into the acid, and rub it on a piece of sal-ammoniac, at the same time holding a bar of solder on the iron and thus coat its surface with the solder. Or, if a pot of molten solder is at hand, dip the iron into it. Never permit the iron to become red hot.

To clean old fittings hard to solder, heat the part light red and plunge it into raw muriatic acid.

Sweating: When extra strength is desired, seams are "sweated." Sweating is accomplished by first putting the soldering iron (Fig. 82) on the seam to be sweated so as thoroughly to heat the metal. The solder is then flowed on to and between the pieces of metal to be united. The iron is again laid on the seam, in order to make sure that the solder flows in as deeply as possible. The iron must be **very hot.**

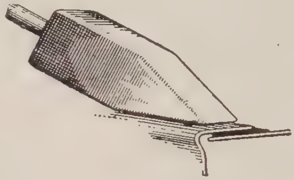

Fig. 82. Sweating a seam.

Torch for radiator work: Although the soldering iron, which is drawn to a very fine point, is used extensively for soldering radiators in close places, the torch can also be used, especially for reaching the inner part of cells of a cellular radiator. The torch must throw a very fine **needle-point** flame.

The type R-1 torch, not illustrated, of the Imperial make, is suitable for this work. It operates from city or coal gas. See also page 751.

The Wasburn Burner Corpn., Kokomo, Ind., also manufactures a torch designed especially for radiator repair work, producing a fine needle-point flame.

A gasoline gas generator, manufactured by F. L. Curfman, Maryville, Mo., is a very satisfactory method of generating gas for a torch for radiator repair work where gas is not obtainable, and the price is very reasonable ($12.50).

A gas torch, No. 70, to operate from this gasoline gas generator throws a needle-point flame and sells for $3.00. Supplied by F. L. Curfman.

Testing Radiator for Leaks

After the removal of the radiator from the car, the first thing to do is to test it. The inlet, outlet, and filler cap must be plugged, so that air pressure may be applied to the overflow pipe. Then if the radiator be put under water, the bubbles will show where the leaks are.

When removing a radiator, the hose and flange are left on, as shown in Fig. 83. If the radiator is to be repaired, then the lower hose is removed.

The openings in the radiator are then stopped up by means of expanding rubber plugs, or by an arrangement as shown in Fig. 84. (Similar plugs can be secured of F. L. Curfman.) One plug is inserted in the intake, another in the water return, and another in the filler opening.

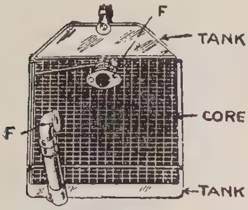

Fig. 83

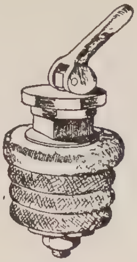

Fig. 84

The air pressure is applied to the radiator through the overflow pipe, by slipping the rubber hose from the air line over the overflow tube. The radiator is then immersed in a tank full of water (Fig. 85), and the **leaks determined by the bubbles.** The leaky parts are then marked.

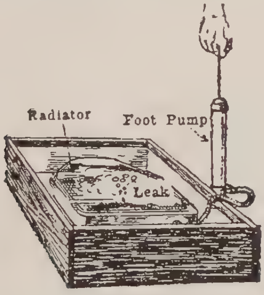

Fig. 85. Testing a radiator submerged in water with air pressure.

Another method for closing up a radiator for testing is to solder a piece of tin in the filler opening and to put a rubber plug in the bottom outlet and bolt a rubber gasket at (F) (Fig. 83). Then place the air-pressure hose on the overflow pipe.

Another plan is to remove the radiator from the car and plug up all but one opening; then run the tube of a tire pump through a **cork** and place the cork in this last opening.

Note. **A radiator should never be subjected to a pressure greater than 2 to 4 lbs.** New units will withstand from 8 to 15 lbs., but that is seldom necessary.

The next procedure is to determine if the radiator is a tubular or cellular type, by studying page 147.

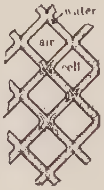
Removing Core of Radiator for Repairs

The core of a radiator consists of all the tubes or cells through which the water flows from the upper tank to the lower tank (see Fig. 83). The core is connected to the upper tank and the lower tank by projecting it into the tanks and then soldering it.

The core can be a tubular or cellular type, as shown in Figs. 86 and 87.

In the cellular type (Fig. 86), the water flows **around** the cells and air circulates **through** the cells, whereas **in the tubular type** of core, the water flows **through** the tubes (Fig. 89), and air circulates around the tubes.

When a **radiator core is damaged badly,** the core must be removed. Place the radiator on the repair bench, face down, and unsolder the lugs which hold the shell to the body. Then with a torch and a pry bar (Fig. 87), unsolder the core from the bottom tank; next unsolder the core from the top tank, starting at the lower flange or header. The core can then be removed. Do not hold the flame in one place too long.



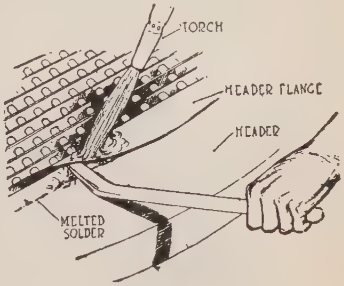


Fig. 86 Fig. 87

Fig. 86. Cellular type of radiator core.

Fig. 87. Tubular type of radiator core.

Repairing Radiator Tubes

To straighten damaged radiator tubes when the core is removed, use a long steel bar (Fig. 88). This will also clean the tubes and all tubes should be subjected to this process.

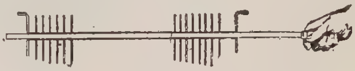

Fig. 88

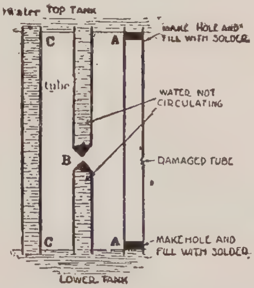
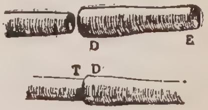
When only one or two tubes are damaged,[1] the tube can be cut out of service altogether; for instance, see (**A**) (Fig. 89). Make holes at the extreme top and bottom of the tube and as close to the header as possible, using a prick punch. Flow solder into the holes liberally, and let it set until hard. See (**A**) (Fig. 89).





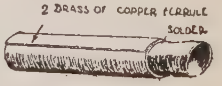


Fig. 89

Fig. 90 (upper)

Fig. 91 (below)

Sometimes **tubes are cut out of service** by cutting the tube and pinching it, and soldering as shown at (**B**). This, however, is not good practice, as the water will collect and freeze in winter.

To splice a tube (see Fig. 90): Cut out the damaged part of the tube. Select another piece of the same diameter as the piece removed, but slightly longer. Spread one end by reaming with a punch or any tapered tool, and make the other end smaller by making a few cuts in it lengthwise, and then compress the end. Fit the large end (**D**) over the end of the tube being repaired, and the other end over the other part of the tube, and solder.

---

[1] It is not necessary to remove the core or to tear down the radiator for slight repairs. Simply force the fins to one side and straighten them after the repair. Before making a repair, it is, of course, necessary to test, in order to find out where the leak is. This should then be soldered without removing the core, if it is only a slight leak.

Another method (see Fig. 91) is to wrap a piece of light brass or copper around the injured part of the tube, so that the edges of the patch just meet or fail to do so by a slight margin, and then to solder it.

There are many methods of repairing radiators: A method for repairing a leaky tube is shown in Fig. 92.

The radiator is placed on a bench, and the leaky part of the tubes is heated with a blow-torch. When quite hot—a little hotter than boiling—muriatic acid soldering solution is poured through the fins, all over the leaky tubes, to clean their surfaces. The cleaning process is very important.

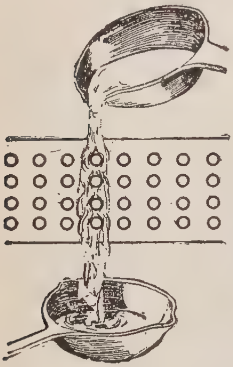

Fig. 92

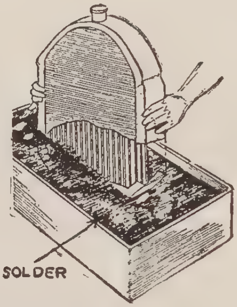

Fig. 93

Fig. 92. Illustrating how solder is poured over the leaky radiator tubes.

Fig. 93. Illustrating dipping a radiator in a solder bath.

A ladleful of solder is then melted. The radiator is bolstered up from the bench on blocks, and the melted solder is poured through the fins, over the leaky tubes. Note the method of catching the excess solder.

Then the radiator is turned over and the solder is poured in from the other side in exactly the same manner.

A little more acid is then added and a torch is applied to melt the solder and sweat it into all the leaks, closing them permanently.

What is known commercially as "50-50" solder is adapted to this work.
